Since we use a K -length block of data, this method is called a *block-adaptive* approach. Thus the algorithm adapts the weights block-by-block.

Define the matrix $\bar{X}_K(k)$ as the k th block of \bar{x} column vectors ranging over K data snapshots. (Note the switch in use of k from Eq. 25-21 to the use of k representing block number in the following equations. k still represents an iteration step.) Thus

$$\bar{X}_K(k) = \begin{bmatrix} x_1(1+kK) & x_1(2+kK) & \cdots & x_1(K+kK) \\ x_2(1+kK) & x_2(2+kK) & & \vdots \\ \vdots & & \ddots & \\ x_M(1+kK) & \cdots & & x_M(K+kK) \end{bmatrix} \quad (25-22)$$

where

k = block number

K = block length

Thus the estimate of the array covariance matrix is given by

$$\hat{R}_{xx}(k) = \frac{1}{K} \bar{X}_K(k) \bar{X}_K^H(k) \quad (25-23)$$

In addition, the desired signal vector can be defined by

$$\bar{d}(k) = [d(1+kK) \quad d(2+kK) \quad \cdots \quad d(K+kK)] \quad (25-24)$$

Thus the estimate of the covariance vector is given by

$$\hat{r}(k) = \frac{1}{K} \bar{d}^*(k) \bar{X}_K(k) \quad (25-25)$$

The SMI weights can then be calculated for the k th block of length K as

$$\begin{aligned} \bar{w}_{\text{SMI}}(k) &= \bar{R}_{xx}^{-1}(k) \bar{r}(k) \\ &= [\bar{X}_K(k) \bar{X}_K^H(k)]^{-1} \bar{d}^*(k) \bar{X}_K(k) \end{aligned} \quad (25-26)$$

As an example of the SMI technique, again we use an $M = 8$ element array with uniform spacing $\lambda/2$. Allow the desired signal to arrive at the angle $\theta_0 = 30^\circ$ and an interferer to arrive at $\theta_1 = -60^\circ$. Let the block length be $K = 30$. Assume the noise variance is $\sigma_n^2 = .01$.

The optimum Wiener weights are found, and the resulting array pattern is seen in Figure 25-7. The SMI pattern is similar to the LMS pattern and was generated with no iterations, albeit at the cost of collecting K data samples.

The SMI algorithm, although faster than the LMS algorithm, has several drawbacks. The covariance matrix may be ill conditioned, resulting in errors or singularities when inverted. In addition, for large arrays, there is the challenge of inverting large matrices. To invert the covariance matrix of size $M \times M$ requires $M^3/2 + M^2$ complex multiplications.²¹ The SMI update frequency will necessarily depend on signal frequencies and on channel fading conditions.

Recursive Least Squares

Even though the SMI method is faster than the LMS algorithm, the computational burden and potential singularities can cause problems. However, we can recursively calculate the required covariance matrix and the required covariance vector in a method called recursive least squares (RLS). Recall that in Eqs. 25-23 and 25-25 estimates of the covariance matrix and vector were taken as the sum of the terms divided by the block length K . When we calculate the weights in Eq. 25-26, the division by K is cancelled. Thus we can simplify the expressions for the covariance matrix and the covariance vector:

$$\hat{R}_{xx}(k) = \sum_{i=1}^k \bar{x}(i)\bar{x}^H(i) \quad (25-27)$$

$$\bar{r}(k) = \sum_{i=1}^k d^*(i)\bar{x}(i) \quad (25-28)$$

FIGURE 25-7 Weighted SMI array pattern

where

k = block length and last time sample k

$\hat{R}_{xx}(k)$, $\hat{r}(k)$ = covariance estimates ending at time sample k

Both of the preceding summations use rectangular windows, and thus they equally consider all previous time samples. Since the signal sources can change or slowly move with time, we might want to deemphasize the earliest data samples and emphasize the most recent ones. This can be accomplished by modifying Eqs. 25-27 and 25-28 such that we forget the earliest time samples. This is called a *weighted estimate*. Thus

$$\hat{R}_{xx}(k) = \sum_{i=1}^k \alpha^{k-i} \bar{x}(i) \bar{x}^H(i) \quad (25-29)$$

$$\hat{r}(k) = \sum_{i=1}^k \alpha^{k-i} d^*(i) \bar{x}(i) \quad (25-30)$$

where

α = “forgetting” factor

The “forgetting” factor is also sometimes referred to as the exponential weighting factor.³⁴ α is a positive constant such that $0 \leq \alpha \leq 1$. When $\alpha = 1$ we restore the ordinary least squares algorithm. $\alpha = 1$ also indicates infinite memory. Let us break up the summation in Eqs. 25-29 and 25-30 into two terms: the summation for values up to $i = k - 1$ and the last term for $i = k$.

$$\begin{aligned} \hat{R}_{xx}(k) &= \alpha \sum_{i=1}^{k-1} \alpha^{k-1-i} \bar{x}(i) \bar{x}^H(i) + \bar{x}(k) \bar{x}^H(k) \\ &= \alpha \hat{R}_{xx}(k-1) + \bar{x}(k) \bar{x}^H(k) \end{aligned} \quad (25-31)$$

$$\begin{aligned} \hat{r}(k) &= \alpha \sum_{i=1}^{k-1} \alpha^{k-1-i} d^*(i) \bar{x}(i) + d^*(k) \bar{x}(k) \\ &= \alpha \hat{r}(k-1) + d^*(k) \bar{x}(k) \end{aligned} \quad (25-32)$$

Thus future values for the array covariance estimate and the vector covariance estimate can be found using previous values. The advantage of the recursion approach is that you need not calculate the covariance for an entire block of length k . Rather, each update only requires the current time sample and the previous covariance matrix.

Not only can we recursively calculate the most recent covariance estimates, we can also use Eq. 25-31 to derive a recursion relationship for the inverse of the covariance matrix. The next steps follow the derivation in Haykin.³⁴ We can invoke the Sherman Morrison-Woodbury (SMW) theorem³⁵ to find the inverse of Eq. 25-31. The SMW theorem states

$$(\bar{A} + \bar{z} \bar{z}^H)^{-1} = \bar{A}^{-1} - \frac{\bar{A}^{-1} \bar{z} \bar{z}^H \bar{A}^{-1}}{1 + \bar{z}^H \bar{A}^{-1} \bar{z}} \quad (25-33)$$

Applying Eq. 25-33 to Eq. 25-31, we have the following recursion formula:

$$\hat{R}_{xx}^{-1}(k) = \alpha^{-1} \hat{R}_{xx}^{-1}(k-1) - \frac{\alpha^{-2} \hat{R}_{xx}^{-1}(k-1) \bar{x}(k) \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1)}{1 + \alpha^{-1} \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1) \bar{x}(k)} \quad (25-34)$$

We can simplify Eq. 25-34 by defining the gain vector $\bar{g}(k)$

$$\bar{g}(k) = \frac{\alpha^{-1} \hat{R}_{xx}^{-1}(k-1) \bar{x}(k)}{1 + \alpha^{-1} \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1) \bar{x}(k)} \quad (25-35)$$

that transforms Eq. 25-34 into

$$\hat{R}_{xx}^{-1}(k) = \alpha^{-1} \hat{R}_{xx}^{-1}(k-1) - \alpha^{-1} \bar{g}(k) \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1) \quad (25-36)$$

Equation 25-36 is known as the Riccati equation for the RLS method. We can manipulate Eq. 25-35 to yield

$$\bar{g}(k) = \left[\alpha^{-1} \hat{R}_{xx}^{-1}(k-1) - \alpha^{-1} \bar{g}(k) \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1) \right] \bar{x}(k) \quad (25-37)$$

It is clear that the term inside the brackets of Eq. 25-37 is equal to Eq. 25-36. Thus

$$\bar{g}(k) = \hat{R}_{xx}^{-1}(k) \bar{x}(k) \quad (25-38)$$

Now we can derive a recursion relationship to update the weight vectors. The optimum Wiener solution is repeated next in terms of the iteration number k , and we can substitute Eq. 25-32 yielding

$$\begin{aligned} \bar{w}(k) &= \hat{R}_{xx}^{-1}(k) \hat{r}(k) \\ &= \alpha \hat{R}_{xx}^{-1}(k) \hat{r}(k-1) + \hat{R}_{xx}^{-1}(k) \bar{x}(k) d^*(k) \end{aligned} \quad (25-39)$$

We may now substitute Eq. 25-36 into the first covariance matrix inverse seen in Eq. 25-39:

$$\begin{aligned} \bar{w}(k) &= \hat{R}_{xx}^{-1}(k-1) \hat{r}(k-1) - \bar{g}(k) \bar{x}^H(k) \hat{R}_{xx}^{-1}(k-1) \hat{r}(k-1) + \hat{R}_{xx}^{-1}(k) \bar{x}(k) d^*(k) \\ &= \bar{w}(k-1) - \bar{g}(k) \bar{x}^H(k) \bar{w}(k-1) + \hat{R}_{xx}^{-1}(k) \bar{x}(k) d^*(k) \end{aligned} \quad (25-40)$$

Finally we may substitute Eq. 25-38 into Eq. 25-40 to yield

$$\begin{aligned} \bar{w}(k) &= \bar{w}(k-1) - \bar{g}(k) \bar{x}^H(k) \bar{w}(k-1) + \bar{g}(k) d^*(k) \\ &= \bar{w}(k-1) + \bar{g}(k) [d^*(k) - \bar{x}^H(k) \bar{w}(k-1)] \end{aligned} \quad (25-41)$$

Note that Eq. 25-41 is identical in form to Eq. 25-16.

FIGURE 25-8 RLS array pattern

As an example of the RLS method, again let the array be an $M = 8$ element array with uniform spacing $\lambda/2$ with a desired signal arriving at the angle $\theta_0 = 30^\circ$ and interfering signal at $\theta_1 = -60^\circ$. As before, the noise variance is $\sigma_n^2 = .01$. Starting with initial array weights of zero and a forgetting factor $\alpha = .9$, Figure 25-8 shows the resulting RLS beam pattern.

The advantage of the RLS algorithm over SMI is that it is no longer necessary to invert a large covariance matrix. The recursive equations allow for easy updates of the inverse of the covariance matrix. The RLS algorithm also converges much more quickly than the LMS algorithm.

Conjugate Gradient Method

The problem with the steepest descent method is the sensitivity of the convergence rates to the eigenvalue spread of the covariance matrix. Greater spreads result in slower convergences. The convergence rate can be accelerated by use of the conjugate gradient method (CGM). The goal of CGM is to iteratively search for the optimum solution by choosing conjugate (perpendicular) paths for each new iteration. “Conjugacy” in this context is intended to mean “orthogonality.” The method of CGM produces orthogonal search directions resulting in the fastest convergence. Figure 25-9 depicts a top view of a two-dimensional performance surface where the conjugate steps show convergence toward the optimum solution. Note that the path taken at iteration $k + 1$ is perpendicular to the path taken at the previous iteration k .

The CGM method has its roots in the desire to solve a system of linear equations. One of the earliest references to CGM is found in a 1952 journal article by Hestenes and Stiefel.³⁶ Additionally, early work was performed by Fletcher and Powell³⁷ in 1963 and Fletcher and Reeves³⁸ in 1964. The CGM has also been called the *accelerated gradient* approach (AG) by Monzingo and Miller.²⁰ The CGM method was modified for use in predicting array weights by Choi et al.^{39,40} A survey of this method has been written by Godara,³³ and a

FIGURE 25-9 Convergence using conjugate directions

concise summary of the method can be found in Sadiku.⁴¹ The following summary is taken from the previous two references.

CGM is an iterative method whose goal is to minimize the quadratic cost function

$$C(\bar{w}) = \frac{1}{2} \bar{w}^H \bar{A} \bar{w} - \bar{d}^H \bar{w} \quad (25-42)$$

where

$$\bar{A} = \begin{bmatrix} x_1(1) & x_2(1) & \cdots & x_M(1) \\ x_1(2) & x_2(2) & \cdots & x_M(2) \\ \vdots & \vdots & \ddots & \vdots \\ x_1(K) & x_2(K) & \cdots & x_M(K) \end{bmatrix} \quad K \times M \text{ matrix of array snapshots}$$

K = number of snapshots

M = number of array elements

\bar{w} = unknown weight vector

$\bar{d} = [d(1) \ d(2) \ \dots \ d(K)]^T$ = desired signal vector of K snapshots

We may take the gradient of the cost function and set it to zero in order to find the minimum. It can be shown that

$$\nabla_{\bar{w}} C(\bar{w}) = \bar{A} \bar{w} - \bar{d} \quad (25-43)$$

We may employ the method of steepest descent in order to iterate toward the minimum of Eq. 25-43. We wish to slide to the bottom of the quadratic cost function by choosing an optimal route that requires the least number of iterations. Let us start with an initial guess for the weights $\bar{w}(1)$ and find the residual $\bar{r}(1)$. The first residual value after the first guess is given as

$$\bar{r}(1) = -\nabla_{\bar{w}} C(\bar{w}(1)) = \bar{d} - \bar{A}\bar{w}(1) \quad (25-44)$$

We can next choose a direction vector \bar{D} that gives us the new conjugate direction to iterate toward the optimum weight. Thus

$$\bar{D}(1) = \bar{A}^H \bar{r}(1) \quad (25-45)$$

The general weight update equation is given by

$$\bar{w}(n+1) = \bar{w}(n) - \mu(n) \bar{D}(n) \quad (25-46)$$

where the step size is determined by

$$\mu(n) = \frac{\bar{r}^H(n) \bar{A} \bar{A}^H \bar{r}(n)}{\bar{D}^H(n) \bar{A} \bar{A}^H \bar{D}(n)} \quad (25-47)$$

We may now update the residual and the direction vector. We can premultiply Eq. 25-46 by $-\bar{A}$ and add \bar{d} to derive the updates for the residuals:

$$\bar{r}(n+1) = \bar{r}(n) + \mu(n) \bar{A} \bar{D}(n) \quad (25-48)$$

The direction vector update is given by

$$\bar{D}(n+1) = \bar{A}^H \bar{r}(n+1) - \alpha(n) \bar{D}(n) \quad (25-49)$$

We can use a linear search to determine $\alpha(n)$, which minimizes $C(\bar{w}(n))$. Thus

$$\alpha(n) = \frac{\bar{r}^H(n+1) \bar{A} \bar{A}^H \bar{r}(n+1)}{\bar{r}^H(n) \bar{A} \bar{A}^H \bar{r}(n)} \quad (25-50)$$

The GCM procedure is to find the residual, the corresponding array weights, and to update until convergence is satisfied. It can be shown that the true solution can be found in no more than K iterations. This condition is known as *quadratic convergence*.

For the $M = 8$ element array with elements uniformly spaced $\lambda/2$, let us find the array weights under the following conditions: The arriving signal appears at 45° ; one interfering signal arrives at -30° and a second interfering signal arrives at 0° . The noise has a variance of $\sigma_n^2 = .001$, and we use a data block size $K = 20$. The plot of the norm of the residual is shown in Figure 25-10. It can be seen that the residual drops to very small levels after 14 iterations. The resulting antenna pattern is shown in Figure 25-11. Note that two nulls are placed at the two angles of arrival of the interference.

FIGURE 25-10 Norm of the residuals for each iteration

Constant Modulus

Many adaptive beamforming algorithms are based upon minimizing the error between a reference signal and the array output. The reference signal is typically a known sequence used to “train” the adaptive array or a desired signal based upon an a priori knowledge of

FIGURE 25-11 Array pattern using CGM

the arriving signals. In the case where a reference signal is not available, you must resort to an assortment of optimization techniques that are “blind” to the exact content of the incoming signals.

Many wireless communication and radar signals are frequency or phase modulated signals. Some examples of phase and frequency modulated signals are FM, PSK, FSK, QAM, and polyphase. Therefore the amplitude of the signal should ideally be a constant. Thus the signal is said to have a constant magnitude or *modulus*. However, in fading channels where multipath exists, the received signal is the composite of many delayed and attenuated replicas. Thus the propagation channel may introduce an amplitude variation on the signal magnitude. Frequency selective channels by definition destroy the constant modulus property of the signal. If we know that the arriving signals of interest should have a constant modulus, we can devise algorithms that restore or “equalize” the amplitude of the original signal.

Dominique Godard²³ was the first to capitalize on the constant modulus (CM) property in order to create a family of blind equalization algorithms used in two-dimensional data communication systems. Specifically, Godard’s algorithm is suited for phase modulating waveforms, using a cost function called a *dispersion* function of order p to determine optimum array element weights. The Godard cost function is given by

$$C(k) = E \left[\left(|y(k)|^p - R_p \right)^q \right] \quad (25-51)$$

where

$p, q = \text{positive integers}$

Godard showed that the gradient of the cost function is zero when R_p is defined by

$$R_p = \frac{E[|s(k)|^{2p}]}{E[|s(k)|^p]} \quad (25-52)$$

where

$s(k) = \text{zero-memory estimate of the array output } y(k)$

The resulting error signal is given by

$$e(k) = y(k) |y(k)|^{p-2} (R_p - |y(k)|^p) \quad (25-53)$$

This error signal can replace the traditional error signal in the LMS algorithm to yield

$$\bar{w}(k+1) = \bar{w}(k) + \mu e^*(k) \bar{x}(k) \quad (25-54)$$

The $p = 1, q = 2$ case reduces the cost function to the form

$$C(k) = E \left[\left(|y(k)| - R_1 \right)^2 \right] \quad (25-55)$$

where

$$R_1 = \frac{E[|s(k)|^2]}{E[|s(k)|]} \quad (25-56)$$

If we scale the array output estimate $s(k)$ to unity, we can write the error signal in Eq. 25-53 as

$$e(k) = \left(y(k) - \frac{y(k)}{|y(k)|} \right) \quad (25-57)$$

Thus the weight vector in the $p = 1$ case becomes

$$\bar{w}(k+1) = \bar{w}(k) + \mu \left(1 - \frac{1}{|y(k)|} \right) y^*(k) \bar{x}(k) \quad (25-58)$$

The $p = q = 2$ case reduces the cost function to the form

$$C(k) = E \left[\left(|y(k)|^2 - R_2 \right)^2 \right] \quad (25-59)$$

where

$$R_2 = \frac{E \left[|s(k)|^4 \right]}{E \left[|s(k)|^2 \right]} \quad (25-60)$$

If we scale the array output estimate $s(k)$ to unity, we can write the error signal in Eq. 25-53 as

$$e(k) = y(k) \left(1 - |y(k)|^2 \right) \quad (25-61)$$

Thus the weight vector, in the $p = 2$ case, becomes

$$\bar{w}(k+1) = \bar{w}(k) + \mu \left(1 - |y(k)|^2 \right) y^*(k) \bar{x}(k) \quad (25-62)$$

The cases where $p = 1$ or 2 are referred to as constant modulus algorithms (CMAs). The $p = 1$ case has been proven to converge much more rapidly than the $p = 2$ case.⁴² A similar algorithm was developed by Treichler and Agee⁴³ and is identical to the Godard case for $p = 2$.

Least Squares Constant Modulus

One severe disadvantage of the Godard CMA algorithm is the slow convergence time. The slow convergence limits the usefulness of the algorithm in dynamic environments where the signal must be captured quickly. This also limits the usefulness of CMA when propagation channel conditions are rapidly changing. The previous CMA method is based upon the method of steepest descent by taking the gradient of the cost function. A faster algorithm was developed by Agee²⁴ using the method of nonlinear least-squares. The least-squares method is also known as the Gauss method based upon the work of Gauss in 1795.⁴⁴ This method is referred to as the LS-CMA algorithm⁴⁵ and is also known as an autoregressive estimator based on a least squares minimization.⁴⁶

The following derivation is taken directly from Agee²⁴ and Rong.⁴⁵ In the method of least squares, one defines a cost function that is the weighted sum of error squares or the total error energy. The energies are the energies of a finite sample set K . The cost function is defined by

$$C(\bar{w}) = \sum_{k=1}^K |\phi_k(\bar{w})|^2 = \|\bar{\Phi}(\bar{w})\|_2^2 \quad (25-63)$$

where

$$\begin{aligned} \phi_k(\bar{w}) &= \text{error at } k\text{th data sample} \\ \bar{\Phi}(\bar{w}) &= [\phi_1(\bar{w}) \quad \phi_1(\bar{w}) \quad \cdots \quad \phi_K(\bar{w})]^T \\ K &= \text{number of data samples in one block} \end{aligned}$$

Eq. 25-63 has a partial Taylor-series expansion with a sum-of-squares form given as

$$C(\bar{w} + \bar{\Delta}) \approx \|\bar{\Phi}(\bar{w}) + \bar{J}^H(\bar{w})\bar{\Delta}\|_2^2 \quad (25-64)$$

where the complex Jacobian of $\bar{\Phi}(\bar{w})$ is defined as

$$\bar{J}(\bar{w}) = [\nabla\phi_1(\bar{w}) \quad \nabla\phi_2(\bar{w}) \quad \cdots \quad \nabla\phi_K(\bar{w})] \quad (25-65)$$

and

$\bar{\Delta}$ = offset, which updates weights

We wish to find the offset $\bar{\Delta}$ that minimizes the sum-of-squared errors. Taking the gradient of Eq. 25-64 and setting it equal to zero, we find the optimum offset vector to be

$$\bar{\Delta} = -[\bar{J}(\bar{w})\bar{J}^H(\bar{w})]^{-1}\bar{J}(\bar{w})\bar{\Phi}(\bar{w}) \quad (25-66)$$

The new updated weight vector is then given by

$$\bar{w}(n+1) = \bar{w}(n) - [\bar{J}(\bar{w}(n))\bar{J}^H(\bar{w}(n))]^{-1}\bar{J}(\bar{w}(n))\bar{\Phi}(\bar{w}(n)) \quad (25-67)$$

The new weight vector is the previous weight vector adjusted by the offset $\bar{\Delta}$. The number n is the iteration number not to be confused with the time sample k .

Let us now apply the least squares method to the constant modulus algorithm using the “1-2” cost function:⁸

$$C(\bar{w}) = \sum_{k=1}^K |\phi_k(\bar{w})|^2 = \sum_{k=1}^K \|y(k) - 1\|^2 \quad (25-68)$$

where

$$y(k) = \bar{w}^H \bar{x}(k) = \text{array output at time } k$$

We may write ϕ_k as a vector such that

$$\bar{\phi}(\bar{w}) = \begin{bmatrix} |y(1)| - 1 \\ |y(2)| - 1 \\ \vdots \\ |y(K)| - 1 \end{bmatrix} \quad (25-69)$$

We may now define the Jacobian of the error vector $\bar{\phi}(\bar{w})$ as

$$\begin{aligned} \bar{J}(\bar{w}) &= [\nabla(\phi_1(\bar{w})) \quad \nabla(\phi_2(\bar{w})) \quad \cdots \quad \nabla(\phi_K(\bar{w}))] \\ &= \begin{bmatrix} \bar{x}(1) \frac{y^*(1)}{|y(1)|} & \bar{x}(2) \frac{y^*(2)}{|y(2)|} & \cdots & \bar{x}(K) \frac{y^*(K)}{|y(K)|} \end{bmatrix} \\ &= \bar{X} \bar{Y}_{CM} \end{aligned} \quad (25-70)$$

where

$$\bar{X} = [\bar{x}(1) \quad \bar{x}(2) \quad \cdots \quad \bar{x}(K)] \quad (25-71)$$

and

$$\bar{Y}_{CM} = \begin{bmatrix} \frac{y^*(1)}{|y(1)|} & 0 & \cdots & 0 \\ 0 & \frac{y^*(2)}{|y(2)|} & & 0 \\ \vdots & & \ddots & \vdots \\ 0 & 0 & \cdots & \frac{y^*(K)}{|y(K)|} \end{bmatrix} \quad (25-72)$$

Multiplying the Jacobian times its Hermitian transpose we get

$$\bar{J}(\bar{w}) \bar{J}^H(\bar{w}) = \bar{X} \bar{Y}_{CM} \bar{Y}_{CM}^H \bar{X}^H = \bar{X} \bar{X}^H \quad (25-73)$$

The product of the Jacobian times the energy matrix is given by

$$\bar{J}(\bar{w}) \bar{\Phi}(\bar{w}) = \bar{X} \bar{Y}_{CM} \begin{bmatrix} |y(1)| - 1 \\ |y(2)| - 1 \\ \vdots \\ |y(K)| - 1 \end{bmatrix} = \bar{X} \begin{bmatrix} y^*(1) - \frac{y^*(1)}{|y(1)|} \\ y^*(2) - \frac{y^*(2)}{|y(2)|} \\ \vdots \\ y^*(K) - \frac{y^*(K)}{|y(K)|} \end{bmatrix} = \bar{X}(\bar{y} - \bar{r})^* \quad (25-74)$$

where

$$\bar{y} = [y(1) \quad y(2) \quad \cdots \quad y(K)]^T \quad (25-75)$$

and

$$\bar{r} = \begin{bmatrix} \frac{y(1)}{|y(1)|} & \frac{y(2)}{|y(2)|} & \cdots & \frac{y(K)}{|y(K)|} \end{bmatrix}^T = L(\bar{y}) \quad (25-76)$$

In this form, note that $L(\bar{y})$ is a hard-limiter acting on \bar{y} . Substituting Eqs. 25-70 and 25-72 into Eq. 25-67 we get

$$\begin{aligned} \bar{w}(n+1) &= \bar{w}(n) - [\bar{X}\bar{X}^H]^{-1} \bar{X}(\bar{y}(n) - \bar{r}(n))^* \\ &= \bar{w}(n) - [\bar{X}\bar{X}^H]^{-1} \bar{X}\bar{X}^H \bar{w}(n) + [\bar{X}\bar{X}^H]^{-1} \bar{X}\bar{r}^*(n) \\ &= [\bar{X}\bar{X}^H]^{-1} \bar{X}\bar{r}^*(n) \end{aligned} \quad (25-77)$$

where

$$\bar{r}^*(n) = \begin{bmatrix} \frac{\bar{w}^H(n)\bar{x}(1)}{|\bar{w}^H(n)\bar{x}(1)|} & \frac{\bar{w}^H(n)\bar{x}(2)}{|\bar{w}^H(n)\bar{x}(2)|} & \cdots & \frac{\bar{w}^H(n)\bar{x}(K)}{|\bar{w}^H(n)\bar{x}(K)|} \end{bmatrix}^H \quad (25-78)$$

While only one block of data is used to implement the LS-CMA, the algorithm iterates through n values until convergence. Initial weights $\bar{w}(1)$ are chosen, the complex-limited output data vector $\bar{r}^*(1)$ is calculated, the next weight $\bar{w}(2)$ is calculated, and the iteration continues until satisfactory convergence is achieved. This is called the *static* LS-CMA algorithm because only one static block of length K is used for the iteration process. The LS-CMA algorithm bears a striking resemblance to the sample matrix inversion (SMI) algorithm in Eq. 25-26.

The chief advantage of the static LS-CMA is that it can converge up to two orders of magnitude faster than the conventional CMA algorithm. The static LS-CMA algorithm computes the weights simply based upon a fixed block of sampled data. To maintain up-to-date adaptation in a dynamic signal environment, it is better to update the data blocks per each iteration. Thus a dynamic LS-CMA algorithm is more appropriate. The dynamic LS-CMA is a modification of the previous static version. Let us define a dynamic block of data as the array output before applying weights. For the n th iteration, the n th block of length K is given as

$$\bar{X}(n) = [\bar{x}(1+nK) \quad \bar{x}(2+nK) \quad \cdots \quad \bar{x}(K+nK)] \quad (25-79)$$

The weighted array output for the n th iteration is now defined as

$$\bar{y}(n) = [y(1+nK) \quad y(2+nK) \quad \cdots \quad y(K+nK)]^T = [\bar{w}^H(n)\bar{X}(n)]^T \quad (25-80)$$

The complex limited output data vector is given as

$$\bar{r}(n) = \begin{bmatrix} \frac{y(1+nK)}{|y(1+nK)|} & \frac{y(2+nK)}{|y(2+nK)|} & \dots & \frac{y(K+nK)}{|y(K+nK)|} \end{bmatrix}^T \quad (25-81)$$

Replacing Eq. 25-77 with the dynamic version, we have

$$\bar{w}(n+1) = [\bar{X}(n)\bar{X}^H(n)]^{-1} \bar{X}(n)\bar{r}^*(n) \quad (25-82)$$

where

$$\bar{r}^*(n) = \begin{bmatrix} \frac{\bar{w}^H(n)\bar{x}(1+nK)}{|\bar{w}^H(n)\bar{x}(1+nK)|} & \frac{\bar{w}^H(n)\bar{x}(2+nK)}{|\bar{w}^H(n)\bar{x}(2+nK)|} & \dots & \frac{\bar{w}^H(n)\bar{x}(K+nK)}{|\bar{w}^H(n)\bar{x}(K+nK)|} \end{bmatrix}^H \quad (25-83)$$

We can further simplify Eq. 25-83 by defining the array covariance matrix and the covariance vector as

$$\hat{R}_{xx}(n) = \frac{\bar{X}(n)\bar{X}^H(n)}{K} \quad (25-84)$$

and

$$\hat{p}_{xr}(n) = \frac{\bar{X}(n)\bar{r}^*(n)}{K} \quad (25-85)$$

The dynamic LS-CMA is now defined as

$$\bar{w}(n+1) = \hat{R}_{xx}^{-1}(n)\hat{p}_{xr}(n) \quad (25-86)$$

As an example of the LS-CMA algorithm, let us define a constant modulus signal as a 32-chip binary sequence. Allow this signal to arrive at the receiver via a direct path and two additional indirect paths. Assume that the indirect multipaths are delayed a half-chip width and a full-chip width, respectively. Further, allow the first multipath term to be attenuated by 30 percent and the second path to be attenuated by 10 percent. The signal and multipath geometry is defined such that the direct path arrives at 45° to the array, the second path arrives at -30° , while the third path arrives at 0° . The SNR is 20 dB. Let us choose a block length of 24 data samples covering six chips. Allow the block to update for every iteration n . As in previous examples, we use an $M = 8$ element array with elements uniformly spaced at $\lambda/2$. Figure 25-12 shows the composite arriving signals before and after the application of the dynamic LS-CMA. Figure 25-13 shows the resulting array pattern.

26.1 GENERAL DISCUSSION

The plane of polarization, or simply the polarization, of a radio wave is defined by the direction in which the electric field vector is aligned during the passage of at least one full cycle. In the general case, both the magnitude and the orientation of the electric field vector will vary during each cycle, and the electric field vector will map out an ellipse in the plane normal to the direction of propagation at the point of observation. In this general case (see Figure 26-1a), the polarization of the wave is said to be elliptical. The minor-to-major-axis ratio of the ellipse is called the *ellipticity* and will be expressed in this chapter in decibels. (Although the axis ratio is less than unity, when expressing ellipticity in decibels, the minus sign is frequently omitted for convenience. The term *axial ratio* is also in common use. It is the reciprocal of ellipticity.) The direction in which the major axis lies is called the *polarization orientation* and in this chapter will be measured from the vertical (see Figure 26-2).

The two special cases of ellipticity of particular interest are (1) an ellipticity of ∞ dB (minor-to-major-axis ratio zero), which is *linear polarization*, and (2) an ellipticity of 0 dB (minor-to-major-axis ratio unity), which is *circular polarization*. A linearly polarized wave is therefore defined as a transverse electromagnetic wave whose electric field vector (at a point in a homogeneous isotropic medium) at all times lies along a fixed line. A circularly polarized wave is similarly defined as a transverse electromagnetic wave for which the electric and/or magnetic field vector at a point describes a circle. In attempting to produce a linearly polarized wave, elliptical polarization is thought of as imperfect linear polarization, while in attempting to produce a circularly polarized wave, elliptical polarization is thought of as imperfect circular polarization.

Confusion occasionally results in the use of mental pictures similar to Figure 26-1 and Figure 26-2 when you overlook the fact that although the electric vector makes one complete revolution (see Figure 26-2) per cycle, it does not rotate at a uniform rate except in the special case of a circularly polarized wave. In this special case, rotation occurs at the rate of ω rad/s.

Figure 26-1c shows a circularly polarized wave having a right-hand sense. It is also possible, of course, to have left-hand circularly polarized waves. The definition of right-hand circular polarization as standardized¹ by the Institute of Electrical and Electronics Engineers and as used in this chapter is as follows: for an observer looking in the direction of propagation, the rotation of the electric field vector in a stationary transverse plane is clockwise for right-hand polarization. Similarly, the rotation is counterclockwise for left-hand polarization.

FIGURE 26-1 Diagrammatic illustration of waves of various polarization: (a) Elliptical polarization; (b) Linear polarization; (c) Circular polarization (right-hand)

FIGURE 26-2 Polarization ellipse

One simple way of determining experimentally the sense of rotation of a circularly polarized wave is to make use of two helical beam antennas of opposite sense. A right-hand helical antenna transmits or receives right-hand polarization, while a left-hand helical antenna transmits or receives left-hand polarization. If a circularly polarized wave is received first on a right-hand helical antenna and then on a left-hand helical antenna, the antenna that receives the greater amount of signal will have a sense that corresponds to the sense of the received wave. In the case of an elliptically polarized wave, the sense will be taken to be the same as that of the predominant circular component.

It is important to note that not all workers in the field use the same definition of polarization sense, and confusion may arise as a result of the ambiguity in its definition. The work of different authors should be compared with this precaution in mind.

Wave Polarization State Synthesis

Any wave of arbitrary polarization can be synthesized from two waves orthogonally polarized to each other. For example, a circularly polarized wave will be produced by the coexistence of a vertically and a horizontally polarized wave, each having the same amplitude and with a 90° phase difference between them. If they have other than the same amplitude and/or other than a 90° relationship, the resulting wave will be elliptically polarized. If, for example, the amplitude of the vertically polarized wave is zero, the resulting wave is linearly polarized and has a horizontal orientation. Further, if the two waves have equal amplitude but 0° phase difference, the resulting wave is linearly polarized with 45° orientation. There are two possible combinations of vertically and horizontally polarized waves that can produce a wave of some specific ellipticity. One of the combinations will produce a predominantly left-hand wave, and the other combination will produce a predominantly right-hand wave. Figures 26-3 and 26-4 show the two cases. Separate illustrations are provided to emphasize the need for care in specifying the coordinate system in this work and the need for consistency in adhering to the selected coordinate system while performing and interpreting any theoretical or experimental work.

It is often of interest to know only the ratio of the magnitudes of the vertically and horizontally polarized waves forming an elliptically polarized wave and the phase angle

$$E_V = \frac{1}{2} [E_{\text{MAJOR}} (1 + e^{j2\beta}) + E_{\text{MINOR}} (1 - e^{j2\beta})]$$

$$E_H = \frac{e^{j\pi/2}}{2} [E_{\text{MAJOR}} (1 - e^{j2\beta}) + E_{\text{MINOR}} (1 + e^{j2\beta})]$$

FIGURE 26-3 Linear-component synthesis of an elliptically polarized wave having a predominantly left-hand sense

between them. Such information can be obtained graphically with the aid of Figure 26-5. In this chart, the phase angle shown is the relative phase of the vertical element when the relative phase of the horizontal element is zero.

Example Given an ellipticity of 3.0 dB and an orientation of $\beta = 37^\circ$, find the ratio of the magnitudes of the vertically and horizontally polarized waves and the phase angle between them. Draw a line from the center of the chart to the periphery at the 37° point. Lay off a distance from the chart center to the $V/H = 3.0$ -dB line measured on the horizontal diameter. Read $V/H = 0.8$ dB and a phase angle of 71° for predominantly right-hand sense or 289° for predominantly left-hand sense.

It is also possible to synthesize any elliptically polarized wave from two circularly polarized waves having opposite senses. For example, a linearly polarized wave will be produced by the coexistence of a right-hand and left-hand circularly polarized wave of the same amplitude. The orientation of the resulting linearly polarized wave will be determined by the phase difference between the two circularly polarized waves. Figure 26-6 provides the formulas for calculating the values.

Characteristics of Wave Polarization

Any discussion of wave polarization typically begins with a brief description including a few of the unique physical characteristics associated with electromagnetic wave propagation and wave interaction with the surrounding environment. It is important to note that while a complete description of wave polarization can require significant mathematical development, the resulting observable wave behavior can be expressed by several accessible characteristics.

$$E_V = \frac{1}{2} [E_{\text{MAJOR}} (1 + e^{j2\beta}) - E_{\text{MINOR}} (1 - e^{j2\beta})]$$

$$E_H = \frac{e^{j\pi/2}}{2} [E_{\text{MAJOR}} (1 - e^{j2\beta}) - E_{\text{MINOR}} (1 + e^{j2\beta})]$$

FIGURE 26-4 Linear-component synthesis of an elliptically polarized wave having a predominantly right-hand sense

FIGURE 26-5 Polarization chart

TABLE 26-1 Two Sample Applications of Circularly Polarized Antennas and Some Typical Characteristics

	Response to Linear Polarization of Arbitrary Orientation	Precipitation-clutter Suppression in Radar Service (values based on search radar)
Ideal ellipticity*	0 dB	0 dB
Satisfactory ellipticity*	-3 dB	-0.5 dB
Unsatisfactory ellipticity*	-10 dB	-1.5 dB
Azimuth beamwidth	Omnidirectional	1-5°
Elevation beamwidth	20°	20°
Bandwidth	Greater than 50 percent	5-15 percent
Standing-wave ratio	5	1.15
Power rating	Milliwatt level	>100kW, <10MW

*Over all or almost all of the radiation pattern

Polarization Quality Although there is reasonably general agreement on the preceding definitions, the use of the words *circular polarization* does not always have quite the same meaning to different workers in the field. The difference lies in the permissible departure (for the application at hand) from precise polarization circularity before the circularly polarized antenna becomes unsatisfactory. The application of a circularly polarized antenna often falls into one of two categories. The first category is the use of a circularly polarized antenna to provide response to a linearly polarized wave of arbitrary orientation. The second category is the use of a circularly polarized antenna for suppression of precipitation clutter in radar service.² Table 26-1 shows typical characteristics for each of the applications.

Orthogonal circularly polarized antenna pairs are also in use for frequency-reuse applications with communications satellites.³ Channel isolation in excess of 20 dB is readily attainable. Stutzman and Overstreet⁴ describe a practical polarization-ellipticity field measurement technique. Further discussion is in Section 26.2.

Orthogonality For any arbitrarily polarized antenna, there can be another antenna polarized so that it will not respond to the wave emanating from the first antenna. The polarizations of the two antennas are said to be orthogonal. Using the convention of Figure 26-6, two polarization ellipses will be orthogonal if they satisfy the relation

$$-E_{R1} E_{R2} = E_{L1} E_{L2} \quad (26-1)$$

Figure 26-5 can be used to determine the orthogonal-polarization ellipse to a given ellipse by performing an inversion through the center of the chart and reading the phase-shift scale associated with the opposite predominant sense.

Reflection When a vertically polarized wave is reflected from a smooth surface, there is no change in its character.* When a horizontally polarized wave is reflected from a smooth

*Strictly speaking, this statement is correct only if the smooth surface is the interface between a normal propagation medium and one having an impedance of infinity. However, we are here interested only in the relative difference between the vertical and horizontal cases, so the detail will be overlooked.

surface, there is a 180° phase shift because of the coordinate system reversal in space when you look in the reversed direction of propagation. When a circularly polarized wave is reflected from a smooth surface, its horizontal component is altered by 180° ; hence the sense of its polarization is reversed. For an elliptically polarized wave, reflection is equivalent to altering the differential phase shift (e.g., the phase difference between the horizontally and vertically polarized linear components) by 180° . The new polarization ellipse may be determined with the aid of Figure 26-5 by inverting the original (before reflection) ellipticity across the horizontal diameter and reading the phase-shift scale corresponding to the opposite predominant sense.

Circularly polarized antennas are unique in being entirely unable to “see” their own images in any symmetrical reflecting surface, since the reflected wave has its sense reversed and is, therefore, orthogonal to the polarization of the antenna from which it originated.

Polarization Transmission Efficiency Within a communication link consisting of a transmitting antenna and a receiving antenna, it is useful to define a factor to quantify how well the receiving antenna extracts energy from the transmitting antenna with respect to the transmitted wave polarization. Polarization transmission efficiency or simply *polarization efficiency*, p , is the ratio of power accepted by a receiving antenna of a given polarization to the power accepted from the same transmitted wave passing an antenna whose polarization has been adjusted to match the incoming wave polarization. In order that a receiving antenna may extract the maximum amount of energy from the passing radio wave, it must have a polarization identical to that of the passing wave. For example, a vertically polarized receiving antenna should normally be used to receive a signal from a vertically polarized transmitting antenna assuming no polarization distortion in the transmission path. Similarly, a right-hand circularly polarized antenna should be used for the reception of waves from a right-hand circularly polarized transmitting antenna. In general, maximum transmission will result between two elliptically polarized antennas when:

1. Their axis ratios $E_{\text{minor}}/E_{\text{major}}$ are the same.
2. Their predominant senses are the same.
3. Their ellipse orientations are translated by a minus sign; that is, $\beta_{\text{trans}} = -\beta_{\text{rec}}$.

Condition 3 will result in a parallel-ellipse major axis in space and implies that only in three special cases will identical antennas at each end of the circuit with the same orientation yield maximum transmission. These three cases are

1. $\beta = 0^\circ$ or 180°
2. $\beta = \pm 90^\circ$
3. $E_{\text{minor}}/E_{\text{major}} = 1$, so that β has no significance

Identical antennas can always be made to yield maximum transmission, however, if they are rotated to cause the major axes of their waves to be parallel in space.

When two arbitrarily polarized antennas are used, the polarization efficiency from the receiving-antenna terminals will be

$$p = \frac{|(E_{R1}E_{R2} + E_{L1}E_{L2})|^2}{(|\mathbf{E}_{R1}|^2 + |\mathbf{E}_{R2}|^2)(|\mathbf{E}_{R2}|^2 + |\mathbf{E}_{L2}|^2)} \quad (26-2)$$

All four variables in Eq. 26-2 are vector quantities. Similar expressions in terms of linear components, or axial ratios, may be found in Sichak and Milazzo⁵ and Hatkin.⁶

TABLE 26-2 Polarization Transmission Efficiency with Various Polarizations at the Transmitting and Receiving Antennas

Antenna 1	Antenna 2	p
Vertical, e.g.: $E_R = 1$ $E_L = 1e^{j0} \quad \beta = 0$	Vertical, e.g.: $E_R = 1$ $E_L = 1e^{j0} \quad \beta = 0$	1
Vertical, e.g.: $E_R = 1$ $E_L = 1e^{j0} \quad \beta = 0$	Horizontal, e.g.: $E_R = 1$ $E_L = 1e^{j\pi} \quad \beta = 90^\circ$	0
Vertical, e.g.: $E_R = 1$ $E_L = 1e^{j0} \quad \beta = 0$	Circular (right), e.g.: $E_R = 1$ $E_L = 0$	$\frac{1}{2}$
Circular (right), e.g.: $E_R = 1$ $E_L = 0$	Circular (left), e.g.: $E_R = 0$ $E_L = 1$	0
Circular (left), e.g.: $E_R = 0$ $E_L = 1$	Circular (left), e.g.: $E_R = 0$ $E_L = 1$	1

The values of E_R and E_L may be obtained with the aid of Figure 26-6. Table 26-2 shows some typical combinations of interest.

Polarization efficiency is frequently expressed in dB and referred to as *polarization loss* or *polarization mismatch factor*. Polarization loss is given by

$$L_p = -10 \log(p) \quad (26-3)$$

Figure 26-7 shows a graphical means developed by Ludwig to display the maximum and minimum values of loss due to mismatched polarization between two antennas of arbitrary polarization. As an example of the use of the graph, if a predominantly right-hand polarized (RCP) transmitting antenna has an axial ratio of 8 dB and a predominantly left-hand polarized (LCP) receiving antenna has an axial ratio of 4 dB, draw two straight lines that intersect at the point P shown on the graph. This point is near the minimum-loss curve of 4 dB and the maximum-loss curve of 16 dB, and therefore the loss will vary (approximately) between 4 and 16 dB as one or the other antenna is rotated about its axis.* Further use of the graph to determine true gain with respect to a perfectly polarized antenna is described in Ludwig.⁷

Depolarization and Anisotropic Media

The polarization efficiency between two like polarized antennas in a communication link can be reduced through wave depolarization. *Depolarization* is the deviation of the wave polarization from its intended state. Normally, the polarization state of a wave traveling through isotropic media remains constant along the direction of propagation. Many common media types including air are considered to be nominally isotropic. However, a wave

* Portions of this paragraph and Figure 23-7 are reprinted with permission from the publishers of *Microwave Journal*.

Offset reflectors, which essentially eliminate aperture blockage, in particular have received a considerable amount of attention. Methods of computing the interbeam isolation and thus the frequency-reuse performance have been developed.¹⁴ For a symmetrical paraboloid, it has been shown that a physically circular feed with equal E - and H -plane amplitude and phase patterns will produce no cross-polarization;¹⁵ however, in an offset configuration, cross-polarization will be present because of the asymmetry. Chu and Turrin¹² have computed the maximum cross-polarization as a function of the offset angle θ_c and half of the reflector subtended angle θ_0 for linear polarization with a circular symmetric feed providing a 10-dB taper at the aperture edges. Their results, presented in Figures 26-8 and 26-9, show that the amount of cross-polarization decreases with increasing f/D and increases with increasing offset angle. In addition, they have shown that if the feed is perfectly circularly polarized, no cross-polarized energy will be found in the far-field pattern, although the position of the beam will be displaced from the axial direction because of a phase shift across the aperture. Figure 26-10 presents their results as a function of θ_0 and θ_c as a parameter.

FIGURE 26-9 Maximum cross-polarization of linearly polarized excitation (after T. S. Chu and R. H. Turrin¹² © IEEE 1973)

FIGURE 26-8 Cross-polarization and beam displacement versus f/D ratio ($\theta_0 = \theta_c$) (after T. S. Chu and R. H. Turrin¹² © IEEE 1973)

The reduction of cross-polarized energy in offset configurations can be accomplished by careful feed design. The complex focal fields for an incoming plane wave can be calculated and a feed horn designed to match the focal plane by using multimode or hybrid

FIGURE 26-10 Beam displacement of circularly polarized excitation (no circular cross-polarization) (T. S. Chu and R. H. Turrin¹² © IEEE 1973)

modes (see Chapter 14). Alternatively, a polarizing grid can be used in front of the feed horn to reduce the cross-polarization.¹⁶ In general, the grid will not consist of parallel wires but will be aligned to match the polarization of the primary field incident on the reflector surface. Additional details on the subject of frequency reuse are found in Chapters 15, 44, 45, and 54.

Radar Precipitation-Clutter Suppression

Precipitation clutter is the name given to the radar echo from such targets as rain, snow, etc. It is not unusual for a radar to be rendered useless because precipitation clutter is sufficiently strong and extensive to hide the presence of a desired target (such as an aircraft). Because raindrops are substantially spherical (or at least much more so than an aircraft), they qualify as symmetrical reflectors. As mentioned in Section 26.1, a circularly polarized antenna is unable to see its own image in a symmetrical reflector. Therefore, if the radar antenna is circularly polarized, the echo from a symmetrical target such as a spherical raindrop will be circularly polarized with the wrong sense to be accepted by the antenna and will not be received. The echo from a composite target such as an aircraft will have scrambled polarization and will usually contain a polarization component to which the circularly polarized radar antenna can respond.

In other words, if the radar antenna is perfectly circularly polarized and the clutter is caused by spherical raindrops, the clutter cancellation will be perfect, enabling the presence of an otherwise-hidden composite target to be detected. When the radar antenna is elliptically polarized, the cancellation of an echo from symmetrical targets will not be complete; also, if the antenna is circularly polarized and the target is not symmetrical, cancellation will not be complete.

Cancellation ratio (CR) is defined as the ratio of radar power received from a symmetrical target when using a precipitation-clutter-suppression technique to the power received from the same target when not using the suppression technique. Cancellation ratio is not the same as cross-polarization ratio. Figure 26-11 shows cancellation ratio as a function of the polarization ellipticity of the antenna illuminating the symmetrical target.

Cancellation ratio, expressed in decibels, is related to the antenna polarization ellipticity by

$$CR_{dB} = 20 \log \left[\frac{1 - E^2}{1 + E^2} \right] \quad (26-4)$$

Note that the polarization ellipticity E is the ratio of minor to major axis (field quantities) and that the bracketed fraction is a voltage ratio.

Table 26-4 shows the extent of cancellation of various targets when the antenna is perfectly circularly polarized.

The use of circular polarization results in some reduction in the radar power received from an aircraft target also. The reduction can vary over wide limits, depending on aircraft type, aspect ratio, wavelength, etc., and by its nature it can only be described statistically. However, reduction values well under 10 dB are often observed. Additionally, dense precipitation usually does not completely surround a radar at all ranges, but tends to occur in patches. The net improvement in apparent

FIGURE 26-11 Cancellation ratio as a function of polarization ellipticity

TABLE 26-4 Cancellation of Various Targets for Circular Polarization

Target	Return Using Circular Polarization Relative to Return Using Linear Polarization
Sphere	Complete cancellation
Disk facing radar	Complete cancellation
Large sheet facing radar	Complete cancellation
Wire grating facing radar (wires parallel to linear polarization for that case)	6-dB cancellation
Double-bounce corner reflector	Zero cancellation
Triple-bounce corner reflector	Complete cancellation

signal-to-noise ratio (that is, the desired aircraft-target signal to precipitation-clutter noise) obtained by using circular polarization for precipitation-clutter suppression is worthwhile, with net improvement in the 10- to 20-dB area being readily achievable.

26.3 ANTENNA POLARIZATION AND POLARIZATION SYNTHESIS

Circular polarization can be achieved by a combination of electric and magnetic antennas provided that the fields produced by these antennas are equal in magnitude and in time-phase quadrature. A simple case of this combination is a horizontal loop and a vertical dipole.¹⁷ The time-phase-quadrature relationship is a fundamental relationship between the fields of a loop and a dipole when their currents are in phase. If the loop and dipole are oriented as in Figure 26-12, the fields in the plane of the loop are given by

$$E_L = jCJ_1(ka)e^{j(\omega t - kr)} \tag{26-5}$$

$$E_D = C_1e^{j(\omega t - kr)} \tag{26-6}$$

where

- C and C_1 = constants
- $k = 2\pi/\lambda$
- λ = free-space wavelength
- a = radius of loop
- r = distance from center of loop
- J_1 = Bessel function of the first order

provided that the currents in the loop and dipole are in phase. Thus, if

$$CJ_1(ka) = C_1 \tag{26-7}$$

the resulting field of the combination will be circularly polarized. Equation 26-7 will be true if the loop diameter is less than about 0.6 wavelength and the dipole length is less than a half wavelength. In this particular combination it should be noted that the resulting radiation

FIGURE 26-12 Horizontal loop and vertical dipole

FIGURE 26-13 Slotted-cylinder circularly polarized antenna

pattern is circularly polarized at all points since the individual pattern of the loop and dipole are essentially the same. However, in practice this is difficult to obtain, except over narrow bandwidths, because of the different impedance characteristics of the loop and dipole.

A second combination is shown in Figure 26-13, consisting of two vertical half-wavelength-long cylinders in which vertical slots are cut.¹⁷ Feeding the two vertical cylinders will give a vertically polarized omnidirectional pattern in the plane normal to the axis of the cylinders, while feeding the two slots will give a horizontally polarized pattern in the same plane. If the power to both feeding arrangements is adjusted to be equal and the phase adjusted by controlling the length of the feedlines so that the two are in time-phase quadrature, the resulting pattern will be circularly polarized.

A combination of a slot and a dipole has been developed for a more directional antenna, e.g., as an element for a phased array.¹⁸ The configuration, which is shown schematically in Figure 26-14, uses a waveguide as the slot and a printed dipole as the complementary element. Since the waveguide and dipole radiation patterns track over a wide range of angles, this combined element can be used to generate any arbitrary polarization by controlling the complex excitations of the individual elements. Some overall degradation in the polarization performance will result from the difference in phase centers between the two individual elements.

The normal radiation (broadside) mode of a helix can also be considered as a combination of electric and magnetic antennas (dipoles and loops) producing circular polarization. This type of antenna has been discussed in Chapter 13.

A pair of crossed slots in the broad wall of a rectangular waveguide in which the field configurations in the waveguide are such that one slot is in time-phase quadrature with the other can also be considered as a combination of electric and magnetic antennas producing circular polarization. The combination will be discussed in greater detail shortly.

Two or more similar antennas when properly oriented in either time phase or space phase or a combination of body may be used to give a circularly polarized radiation field. A simple case is a pair of crossed half-wavelength dipoles. In Figure 26-15 circular polarization is obtained by having the equal currents in the dipoles in phase quadrature.

FIGURE 26-14 Slot-dipole element

FIGURE 26-15 Crossed dipoles—current in phase quadrature

FIGURE 26-16 Crossed dipoles—current in phase— $\lambda/4$ separation

FIGURE 26-17 Deviation of circularity as a function of off-axis angle for a pair of crossed dipoles

Radiation is right-circularly polarized in one direction and left-circularly polarized in the opposite direction. If the pair of crossed dipoles is fed in phase and separated in space by a quarter wavelength as shown in Figure 26-16, circular polarization is again produced; however, the sense is the same in both directions. In both combinations the resulting field is circularly polarized only on axis. The deviation in circularity as a function of the off-axis angle is plotted in Figure 26-17.

Another case of a simple combination of similar antennas to produce circular polarization is a pair of narrow slots at right angles and located at the proper point in the broad wall of a rectangular waveguide.¹⁹ This may be explained by noting that the equations for the transverse and longitudinal magnetic fields of the dominant (TE_{10}) mode in a rectangular waveguide (see Figure 26-18) are

$$H_x = H_0 \sqrt{1 - \left(\frac{\lambda}{2a}\right)^2} \sin \frac{\pi x}{a} \quad (26-8)$$

$$H_z = -jH_0 \frac{\lambda}{2a} \cos \frac{\pi x}{a} \quad (26-9)$$

FIGURE 26-18 Field configuration, TE_{10} mode

FIGURE 26-19 Position of crossed slots for circular polarization versus wavelength

FIGURE 26-20 Theoretical axial ratio for $x = a/4$

From these two equations it may be seen that the fields are in phase quadrature and there are two values of x at which $|H_x| = |H_y|$. The values of x are given by

$$x = \frac{a}{\pi} \cot^{-1} \left[\pm \sqrt{\left(\frac{2a}{\lambda} \right)^2 - 1} \right] \quad (26-10)$$

Two crossed slots at either of these points will then radiate circularly polarized energy. Figure 26-19 is a plot of x versus λ over the wavelength range between the cutoff of the TE_{10} and TE_{20} modes. The orientation of the slots is arbitrary, and they may be made resonant and thus radiate a large amount of power (see Chapter 8). The theoretical axial ratio for $x = a/4$ is shown in Figure 26-20, which gives circular polarization at a frequency for which $\lambda = 2a/\sqrt{2}$.

26.4 DUAL-MODE HORN RADIATORS

A conventional waveguide horn may be used for the radiation and beaming of circularly polarized waves provided that it is fed with waveguide capable of propagating vertically and horizontally polarized waves simultaneously. The horn may be either symmetrical or asymmetrical, that is, square (round) or rectangular (elliptical). Figure 26-21 illustrates two types.

FIGURE 26-21 Examples of symmetrical and asymmetrical dual-mode horns

Symmetrical Case

A circularly polarized field will be obtained on the peak of the radiation pattern when the horn is fed through the square waveguide with equal-amplitude vertically and horizontally polarized modes arranged to be in quadrature. The radiated field will not, in general, be circularly polarized at other points on the radiation pattern because the vertically and horizontally polarized radiation patterns will have different beamwidths.

There are several methods useful in compensating for the two different beamwidths. Figure 26-22 shows two methods applied to the *azimuth plane* only of the horn. In actual practice, it is necessary to apply one of these methods (usually method *B*) to the elevation plane as well as to the azimuth plane.

When designing a circularly polarized horn for some specific radiation-pattern width, the standard design methods (such as those in Chapter 6 and Rhodes²⁰) are applicable, bearing in mind, of course, that an *E*-plane dimension for one polarization is an *H*-plane dimension for the other and also bearing in mind the effects of any compensating scheme.

When the horn is designed along conventional pyramidal or sectoral lines, phase tracking for the vertically and horizontally polarized fields is usually not a problem; that is, the radiation centers of phase for the two polarizations are sufficiently close so that differential phase-shift variations over the radiation pattern usually do not exceed about 10 to 15° within the tenth-power points on the beam.

Horns are sometimes constructed with a wide flange around the aperture for mechanical reasons. On small horns especially, the flange width should be no larger than necessary to avoid degradation of phase tracking.

Simple conical horns have beamwidths more alike for the two principal polarizations than do pyramidal horns. Controlled excitation of TM_{11} modes can further refine beamwidth matching. However, such structures are not as conveniently connected to square or rectangular waveguide as pyramidal horns.²¹

Corrugated conical horns offer excellent radiation-pattern amplitude and phase tracking for the two principal polarizations over bandwidths of half an octave³ or more.

Measurements reported in the literature²² show that cross-polarization components suppressed 30 dB or more from 8 to 11 GHz over all angles within approximately $\pm 45^\circ$ of boresight. The conical-horn geometry is shown in Figure 26-23. These structures tend to be larger for a given beamwidth than those of Figure 26-22 and may limit the closeness of adjacent secondary-beam pointing when they are used as juxtaposed feeds. Figure 26-24 shows the relationship between polarization ellipticity and cross-polarization component.

FIGURE 26-22 Two methods of compensating dual-mode horns for improved circularity

FIGURE 26-23 Section through conical corrugated horn—9-GHz nominal design frequency

FIGURE 26-24 Relationship between polarization ellipticity or axial ratio and cross-polarization component

Asymmetrical Case

The preceding discussion is also applicable to asymmetrical horns, except that circularly polarized fields on the peak of the radiation pattern will not be obtained unless allowance is made for the difference in phase velocity of the vertically and horizontally polarized waves within the asymmetrical-horn flare. The differential phase shift may attain quite large values. For example, a measured differential phase shift of about 220° has been observed at 2800 MHz in a horn having a flare length of about 14 in (356 mm), a width of 2.84 in (72.1 mm), and a height of 7.8 in (198 mm).

The magnitude of differential phase shift can be computed to an accuracy of perhaps 10 percent by evaluating the integral

$$\text{Differential phase shift} = \int_0^L [\beta(\ell) - \beta(\ell)] d\ell \quad (26-11)$$

$V_{\text{pol}} \quad H_{\text{pol}}$

in which L is the flared length of the horn and $\beta(\ell)$ is based simply on the appropriate width of the flare and the operating wavelength. Figure 26-25 shows the information in detail. Note that the differential phase shift may vary fairly rapidly with frequency. In the example mentioned earlier, the differential phase shift increased by about 15° for every 100-MHz decrease in frequency between 2900 and 2700 MHz.

Methods of Obtaining Quadrature

Quadrature phase relationship between two orthogonally polarized modes in round or square waveguide may be achieved by any of the following techniques:

1. Rectangular or elliptical cross section
2. Ridge guide
3. Dielectric slab
4. Multiple-lumped-element loading
5. Turnstile junction

FIGURE 26-25 Method of determining differential phase shift in a sectoral horn

The choice of method must be based on the application, keeping such things in mind as ease of design, bandwidth, power-handling capacity, ease of adjustment, and ease of fabrication. Table 26-3 shows the trend of these characteristics in order.

The first three methods listed in the table are based on causing the phase velocity of the vertically and horizontally polarized modes to differ within the same section of waveguide. This section of waveguide will then be of different phase length for the two polarizations. Selection of the appropriate length to furnish the requisite differential phase shift is the last step in the design process.

For example, a rectangular section of waveguide carrying TE_{01} and TE_{10} modes and having internal dimensions a and b will produce differential phase shift at the rate of

$$\frac{2\pi}{\lambda} \left[\sqrt{1 - \left(\frac{\lambda}{2a}\right)^2} - \sqrt{1 - \left(\frac{\lambda}{2b}\right)^2} \right] \quad \text{rad/unit length} \quad (26-12)$$

TABLE 26-3 Preference Trends for Methods for Obtaining Phase Quadrature

Method	Ease of Design	Bandwidth	Power-handling Capacity	Ease of Adjustment	Ease of Fabrication (small quantity)
Rectangular or elliptical cross-section guide	1	5	1	5	4
Ridge guide	4	3	2	2	3
Dielectric slab	5	2	5	3	1
Multiple-lumped-element loading	2	1	3	1	2
Turnstile junction	3	4	4	4	5

FIGURE 26-26 Differential phase shift in a partially loaded square waveguide

The values for a , b , and λ must be in the same units, of course. If such a section is to be connected to a square waveguide, it will be necessary to employ a suitable intermediate transformer section. Quarter-wavelength sections having an impedance equal to the geometric mean of the input and output impedances are satisfactory. Note that the differential phase shift (which can be computed with the aid of the preceding formula) of the transformer will contribute to the total.

Ridge waveguide can be handled in the same manner as the preceding rectangular guide. In the ridge case, however, the quantities $2a$ and $2b$ in the preceding expression should be replaced with λ_{CUTOFF} for TE_{01} and λ_{CUTOFF} for TE_{10} , respectively.

Dielectric-slab loading in a square waveguide will also produce a difference in phase velocity for the two modes of interest. Figure 26-26 provides details for a typical dielectric loaded waveguide. Just as earlier, it is necessary to provide means for obtaining an impedance match at each end of the phasing section. It is not sufficient as a rule to have the phasing section as a whole appear matched; it is important to have each end matched separately. If this precaution is not observed, it will be very difficult to predict total phase shift as well as the change in phase shift with a change in geometry. Consequently, adjustment or tailoring is difficult. Power-handling capacity will be somewhat lower in the loaded waveguide than in the unloaded case.

Lumped-element loading in a square waveguide has also been used successfully. The use of probe pairs is particularly convenient. Pair doublets and pair triplets are the most common, with the latter providing greater bandwidth and greater power-handling capacity for a given differential phase shift. Figure 26-27 shows design data for the doublet and triplet cases. The length of the probe necessary for a given value of susceptance is shown in Figure 26-28.

Circularly polarized waves can be generated directly in a waveguide junction

FIGURE 26-27 Probe phase-shifter design

FIGURE 26-28 Susceptance as a function of probe penetration

known as a *turnstile junction* (not to be confused with a turnstile antenna). The general geometry is illustrated in Figure 26-29.

Dual-Mode Generation

The generation of two orthogonally polarized modes in a section of square or round waveguide can be accomplished in several ways, of which the two most common are

1. Coaxial cable probes at right angles
2. Conventional rectangular waveguide inclined at 45°

The second case is particularly convenient because the ratio of magnitudes of the vertically and horizontally polarized waves can be altered merely by altering the inclination of the rectangular guide.

In generating and guiding dual modes in square or round guide, care should be employed to keep the geometry symmetrical about each of the two principal longitudinal planes. Any asymmetry will tend to excite the TM_{11} or TE_{11} modes. For square or round guide, these two modes will usually not be very far from cutoff. For example, in square guide, with dimensions a high and a wide, cutoff for the TE_{01} and TE_{10} modes occurs at $\lambda = 2a$. The cutoff for TM_{11} and TE_{11} modes occurs at $\lambda = 2\sqrt{2}a$, or only about 41 percent above cutoff for the dominant modes.

In all the discussion earlier concerning phase shift, it has been assumed that there is an impedance match for each of the generated dual modes. The existence of mismatch may produce an unexpected alteration in the phase shift. For example, if there is a perfect match

FIGURE 26-29 Turnstile junction

FIGURE 26-30 Possible phase variation with standing-wave ratio

for both the vertically and the horizontally polarized modes and the differential phase shift noted, the appearance of a mismatch in one of the modes may produce a change in differential phase shift, as shown in Figure 26-30. If the same magnitude of mismatch appears in both modes, the change may be as large as twice that of Figure 26-30.

26.5 MICROSTRIP PATCH RADIATORS

Circular polarization can be produced by microstrip patch antennas in a variety of manners. The methods for producing CP in a patch antenna are often described as either single or dual feed types. Dual feed patches are normally fed at two points on the antenna with equal amplitude and 90° out of phase using either a hybrid power divider or a quarter-wave offset feed.²³ Dual feed methods have the advantage of being conceptually easier to design even though they require external components. The single feed method must excite two orthogonal modes with one feed and without the use of external hybrids. This is accomplished by carefully choosing the radiating patch geometry such that orthogonal degenerate modes are properly excited to produce circular polarization. These *degenerate* modes have equal or nearly equal amplitudes and radiate in directions orthogonal to each other.

Figure 26-31 shows three common methods of creating circular polarization in a square or nearly square patch with a single feed. The antenna in Figure 26-31a is an asymmetric or nearly square patch²⁴ that has one edge length slightly greater than the other, $\Delta/a \ll 1$. Feeding the antenna at either point 1 or 3 will excite the mode normal to that particular edge,

FIGURE 26-31 Single feed microstrip patches for circular polarization. Dashed lines represent single feed locations capable of producing circular polarization.

and the antenna will behave as a linearly polarized microstrip patch antenna. However, if the antenna is fed from either point 2 or 4, or along either patch bisecting diagonal, two orthogonal modes will be excited and circular polarization will be created. It is possible to produce either right- or left-hand sense circular polarization depending on the selection of feed location. The position of the feed along the diagonal also has a significant impact on the input impedance seen by the patch.

The antenna in Figure 26-31*b* is a corner-truncated square patch. Two opposing corners are trimmed a small amount, Δ , where $\Delta/a \sim 0.1$. This antenna creates circular polarization in a manner similar to the nearly square patch of Figure 26-31*a* by creating two orthogonally degenerate modes from the slight perturbation in antenna geometry due to the truncated corners.²⁵ In this case, however, the antenna must be fed from point 1 or 3, or from a point along either of the antenna center lines. Both right- and left-hand sense circular polarization may be established with this geometry depending on which feedpoint is chosen. If the antenna is fed along the diagonals, only linear polarization will be produced. The antenna in Figure 26-31*c* is a slotted patch, and it also produces circular polarization by creating a small perturbation in the geometric symmetry. This antenna has a diagonal slot cut in the radiating patch that is angled at 45° from the patch edge. The length and width of the slot are design dependent. Like the truncated square patch, the slotted patch must be fed from either point 1 or 3, or from either of the lines that are diagonal to the patch geometry perturbation to produce circular polarization along. Additional details on the subject of microstrip patch antennas can be found in Chapter 7.

26.6 TRANSMISSION- AND REFLECTION-TYPE POLARIZERS

A transmission polarizer is an anisotropic propagation medium whose anisotropy is adjusted to achieve time (i.e., phase) quadrature for two waves whose (linear) polarization vectors are mutually orthogonal. Such polarizers operate independently of the nature of the source of the waves, are often relatively bulky and awkward to adjust, can be very inexpensive to manufacture, and can have very high power-handling capability.

The simplest type of polarizer is a parallel-metal-plate structure (see Figure 26-32). In this structure, the incident linearly polarized energy is inclined 45° to the metal-plate edges, so that there are two equal field components, one parallel to the plates and one perpendicular to the plates. The component perpendicular to the plates passes through the structure relatively undisturbed, while the component parallel to the plates experiences a phase shift relative to free-space propagation. If the spacing and length of the plates are adjusted so that the field parallel to the plates advances $\lambda/4$ with respect to the field perpendicular to the plates, the two fields at the exit of the plates result in a circularly polarized wave. This structure is commonly referred to as a *quarter-wave plate*.

Any anisotropic dielectric can be used as a transmission-type polarizer, provided only that

FIGURE 26-32 Parallel-plate polarizer

FIGURE 26-33 Parallel-dielectric-plate polarizer

positioning and properties result in two equal-amplitude, quadrature-phased linearly polarized waves at the exit port.

There are several ways to produce such anisotropy: (1) parallel metal plates,^{26,27} (2) parallel dielectric plates²⁸ (see Figure 26-33), and (3) a lattice structure composed of strips or rods.^{29,30} The first two methods are the heaviest, while the last two are the least frequency-sensitive. An unfortunate complication in design and adjustment of the simplest configurations is caused by imperfect impedance matching at the entrance and exit ports; in general, it is different for the two principal polarizations. Unwanted amplitude and phase effects result, including the result of a nonunity standing-wave ratio (SWR) inside the polarizer.

A variation of the Method 3 just mentioned is the meander-line polarizer.³¹⁻³⁴ Figure 26-34a shows a typical meandering configuration of a thin metal conductor supported on a dielectric sheet. In general, a greater number of layers of such sheets yields greater bandwidths, just as in multiple discontinuities used for broadband transmission-line transformers.

FIGURE 26-34 Typical meander-line dimensions and radome applications: (a) Typical nominal dimensions of conductors on a layer (not to scale); (b) Four-layer polarizer-radome on a horn, illustrating orientation angle of typical conductors (not to scale)

Kotlarenko³¹ reports bandwidths of 1.7 to 1 for axial ratios of less than 3 dB for incidence angles ranging over 30° when using a six-layer design. A five-layer design used at normal incidence yielded axial ratios under 3 dB for bandwidth exceeding an octave.

Epis³⁴ reports axial ratios under 3 dB over bandwidths of 1.75 to 1 by using a four-layer meander-line structure as a horn radome and a bandwidth exceeding 2.5 to 1 with axial ratios below 1.8 dB with six layers.

Reflection-type polarizers are essentially half-length transmission-type polarizers mounted on a conducting sheet. The simplest type of reflection-type polarizer is a series of closely spaced metal vanes, one-eighth wavelength high, on a conducting sheet. The incident energy is polarized at 45° to the vanes, so that the component parallel to the vanes is reflected by edges of the vanes and the component perpendicular to the vanes is reflected by the conducting sheet, thus delaying it 90° with respect to the parallel component and producing circular polarization. In general, any of the anisotropic propagating systems described earlier may be halved longitudinally and, with proper design, mounted above a conducting sheet to form a reflection polarizer.

Circular polarization may also be obtained via reflection from a conventional lossless dielectric when the dielectric constant ϵ exceeds 5.8 and the incidence angle θ satisfies the condition $\sin^2 \theta = 2/(\epsilon + 1)$.³⁵

26.7 POLARIZATION MEASUREMENTS

The measurement of circularly polarized antennas or antennas of unknown polarization is generally similar to that of other antenna types, except that it is often necessary to measure the state of polarization (degree of polarization ellipticity, or axial ratio) as well as the other more customary parameters. Several methods are commonly used to measure the additional parameters required to characterize antenna polarization. These methods include the radiation pattern methods, polarization pattern methods, amplitude-phase methods, and multiple component methods.³⁶

The radiation pattern method is convenient and is generally performed using either a single linearly polarized probe antenna or two orthogonally polarized antennas. In the single antenna variation, the probe antenna is arranged to rotate about its boresight axis at an angular velocity, ω_p , as the unknown test antenna is rotated through its desired pattern cut at an angular velocity, ω_θ . Provided that the rotational velocity of the probe is much quicker than the rotational velocity of the test antenna ($\omega_p \gg \omega_\theta$), the resulting pattern will give the ellipticity magnitude as a function of the pattern angle. This method, however, will not give the right-hand or left-hand sense, which must be separately determined.

Attention is called here to the unusual degree of sensitivity of polarization measurement to small distorting influences of secondary paths in a measuring setup. Figure 26-35 illustrates the conditions.

FIGURE 26-35 Influence of the reflected wave on the measurement of a circularly polarized wave

27.1 INTRODUCTION

Following the experimental validation of James Maxwell's electromagnetic theory in 1884 by Heinrich Hertz, the first real technological application using electromagnetic waves in transmitting information signals was carried out by Guglielmo Marconi at the beginning of the 20th century.¹ Marconi realized from the beginning of his work that the use of vertical metallic towers as antennas enables the radiation of low-frequency (LF) waves in the region of 50–100-kilohertz (kHz) and also provides efficient propagation by the ground wave propagation mechanism, although the exact computation of the field in this mode went through much testing, starting from the pioneering work of Sommerfeld and lasting into the 1940s with the work of Norton.² During this early period of radio communications, it was also realized that vertical mounted antennas could support long-distance ionosphere communication links of single or multiple hops. Because of this, in the early period of radio communication systems the broadcasting and point-to-point links mostly used vertical monopole antennas constructed by using vertical metallic towers and utilizing the low- (30–300-kHz) and medium- (300–3000-kHz) frequency bands. Despite the growing use of higher frequencies—starting in the 1930s with the high (3–30 MHz) and later very high (30–300 MHz), ultra high (300–3000 MHz), and microwave (>3 GHz) frequencies—the importance of low and medium frequencies has not diminished, because they offer unique properties such as very stable propagation conditions and the ability to penetrate the sea and earth.

A fundamental difficulty in achieving efficient radiation at low frequencies is the necessity of having antenna dimensions comparable to radiation wavelength (λ) in the air. Restricting the antenna geometry to a vertical monopole of height h , the radiation efficiency drops with the ratio $(h/\lambda)^2$ as the wavelength increases. Maximum efficiency is obtained if the antenna height is $h = \lambda/4$, also providing that a good match to a low-impedance transmission line (50- Ω) is achieved. For medium frequencies (MF) at 600 kHz at the radiation wavelength $\lambda = 500$ m, maximum efficiency is achieved if $h = 125$ m, which doesn't pose a serious construction problem. However, at the low edge of low frequencies with a corresponding height of much more than 500 m, you have to restrict the antenna height to less than 400 m. The basic environmental condition restricting the antenna height is the wind load. In particular, wind loads exhibiting no homogeneity along the vertical axis could pose serious challenges to the mechanical stability of the mast. Earthquake-induced forces are not significant.

Although the possible radiation mechanism at low frequencies is not restricted only to a vertical monopole, as will be discussed later in Section 27.5, vertical monopole antennas predominately are used in constructing very-low- (10–30-kHz) and low-frequency (30–300-kHz) radiation systems.

Another unique property of low-frequency antennas is related to the insignificance of the receiving antenna's dimensions. This is because at low frequencies atmospheric noise exceeds the receiver internal noise, and therefore the receiver output signal-to-noise power ratio is independent of antenna efficiency and size.

27.2 FUNDAMENTALS OF VERTICAL MONOPOLE ANTENNA RADIATION PROPERTIES

The radiation properties of a vertical monopole antenna, shown in Figure 27-1 and having height h , are easily computed by using the image theory, assuming the earth surface is a perfect conductor. For an earth medium with good conductivity $\sigma > 0.01$ S/m (Siemens/meter),

FIGURE 27-1 Vertical monopole antenna geometry

in practical terms, the ground surface can be assumed to have perfect conductivity. Usually wire grids (see “VLF and LF Antennas” in Section 27.3) are used to achieve good conductivity in the vicinity of the antenna. Therefore, to understand the fundamental radiation properties of low-frequency vertical monopole antennas, the earth surface could be assumed to be a perfect conductor. Then, based on fundamental concepts of antenna theory, the total electric current distribution on the vertical antenna tower is almost equal to a sinusoidal function as

$$I(z) \approx I_0 \sin(k_0(h-z)) / \sin(k_0 h) \quad (27-1)$$

where z is the distance measured from the base of the monopole, I_0 is the base current, and $k_0 = 2\pi/\lambda$ is the free space propagation constant. At very low frequencies (VLF), $h \ll \lambda$, Eq. 27-1 reduces to a linear relationship, $I(z) \approx I_0 k_0 (h-z)/h$. The antenna characteristics are defined in terms of its radiation resistance

$$R_r = 160\pi^2 (h_e/\lambda)^2 \quad (27-2)$$

where h_e is the equivalent antenna height computed by the equation

$$h_e = \frac{1}{I_0} \int_0^h dz I(z) \quad (27-3)$$

The antenna radiation efficiency is computed as the ratio of the radiated power to total power fed to the antenna:

$$\eta = \frac{R_r}{R_r + R_l} \quad (27-4)$$

where R_l is the total loss antenna resistance representing the non-radiated power consumed by the antenna structure and the ground medium in the vicinity of the monopole.

The radiation pattern that is identical to a Hertzian dipole is defined in terms of radiated power density (W/m^2) in free space:

$$P(\theta) = P(\pi/2) \sin^2(\theta) \quad (27-5)$$

where the radiation power density at the horizontal plane is

$$P(\pi/2) = \frac{22.75k_0^2 h_e^2 I_0^2}{r^2}$$

where $r \gg \lambda$ is the distance of field measurement point and θ is the angle between the vertical axis and the position vector.

From the early period of radio engineering (1910–1920), it was understood that the efficiency of a monopole antenna can be increased significantly by making the antenna current as constant as possible along the vertical axis. This is achieved by loading the antenna top with various conductor structures, as shown in Figure 27-2. Usually, a symmetric radial network of wire conductors as shown in Figure 27-2c is used. The loading increases the equivalent antenna height and therefore the radiation efficiency.

Top-loading increases the equivalent antenna height, h_e , and thus the radiation resistance and radiation efficiency. The antenna loading is accounted for by the existing capacitance, C_0 , between the top-loading and ground. The equivalent antenna height, h_e , can be computed by using Eq. 27-3 and the current distribution:

$$I(z) \approx I_0 \sin(k_0(h + s - z)) / \sin(k_0(h + s)) \quad (27-6)$$

where s is the slant length of the top-loading wires.

In modeling the low-frequency antenna, the equivalent circuit shown in Figure 27-3 is used for the input impedance of the monopole.

Based on the equivalent circuit, the input impedance of the antenna can be computed as follows:

$$Z_{in} = R_T(\omega) + j\omega L - 1/j\omega C = R_T(\omega) + jX_T(\omega) \quad (27-7)$$

where $R_T = R_r + R_l$ is the total antenna base resistance, L is the antenna mast inductance, and $C = C_a + C_0$ is the total (mast plus the top-loading wires) antenna capacitance. The reactance (imaginary) part of the impedance can be written in terms of the antenna resonance frequency

$$\omega_0 = 1/\sqrt{LC} \quad (27-8)$$

as follows:

$$X_T(\omega) = \omega L(1 - (\omega_0/\omega)^2) \quad (27-9)$$

FIGURE 27-2 Three types of top-loading monopole antennas: (a) inverted L, (b) T top-loading, and (c) radial wire top-loading

FIGURE 27-3 Monopole antenna equivalent circuit: L = antenna inductance, C_0 = top-loading capacitance, C_α = antenna mast capacitance, R_r = radiation resistance, R_l = total loss resistance, and ΔC = antenna feedpoint leak capacitance

Usually at VLF (3–30 kHz) the operation frequency is much less than the resonance frequency.

A critical parameter, especially at frequencies less than 100 kHz, is the antenna bandwidth determining the available communication channel capacity or the maximum data bit rate of transmission.³ The intrinsic 3-dB antenna bandwidth is computed³ using the definition of the quality (Q) parameter of the equivalent circuit of Figure 27-3:

$$BW_0 = f/Q = 1.102458 \times 10^{-7} Ch_e^2 f^4 \quad (27-10)$$

where $f = \omega/(2\pi)$ is the operation frequency. The overall bandwidth of the system is determined taking into account the antenna losses and is

$$BW_l = BW_0 / \eta \quad (27-11)$$

Above 150 kHz the antenna bandwidth restriction is limited, and traditionally, monopole antennas are used to broadcast double-side amplitude modulation signals.

The most common broadcast antenna type used in the frequency region of VLF, LF, and MF is the vertical monopole. However, in theory other types of antenna, especially vertical loop antennas, have been suggested to cope with the difficulty of constructing very tall masts needed at the low edge of the spectrum. This topic is analyzed in Section 27.4.

27.3 PRACTICAL LOW- AND MEDIUM-ANTENNA STRUCTURES: DESIGN AND CONSTRUCTION BASICS

Design and construction of low-frequency antennas poses formidable civil engineering tasks primarily having to do with the erection of the metallic tower structures, which could be as high as 400 m. Concerning the electromagnetic properties of the antenna, issues to be addressed are

- The conductivity properties of the ground environment where the antenna is to be installed and, in case of poor conductivity ($<10^{-2} \text{ S/m}$), mounting the antenna inside the earth grid of wires
- Metallic mast, supporting steel ropes, and top-loading wires as well as high-voltage insulators to be used in connecting structures of different voltages and the antenna base insulator
- Antenna matching unit to achieve tuning of the antenna capacitive impedance to low-impedance (50- Ω) power amplifier output

Next, these issues are addressed for VLF, LF, and MF antennas.

VLF and LF Antennas

The most common antenna structure used at the 16-200-kHz band is the base-insulated top-loaded antenna already shown in Figure 27-2c. Alternative structures, as shown in Figure 27-2a and b, have also been used in the past, such as *T*- and inverted-*L*-shaped antennas. A spiral top-loading structure also has been proposed to achieve relatively small size, low feed voltage, and even to reduce the tuning circuit inductor size.⁴ Increased capacitance for VLF umbrella radial-wire top-loading antennas using multiple-wire rib construction also has been analyzed.⁵ The use of this type of top-loading wiring provides an approximately 20 percent increase of capacitance without any serious change of effective height of the monopole antenna. Other types of structure such as “Tratic” and “Trideco” antennas, shown in Figure 27-4, have been used in transmitting high power levels. The capability of lowering top-load wires without appreciably losing efficiency is an important property of this type of multiwire antenna.

The most commonly used structure is the base-fed monopole antenna using an umbrella type top-loading structure. Figure 27-5 shows various parts of this type of antenna. A site-assembled triangular tower of up to 600 m is used to construct the monopole. A highly critical component is the base ceramic insulation, which should provide sufficient high-voltage strength. In practical terms the base voltage is limited to 250 kilovolts (kV), thus restricting the highest power to be transmitted by each monopole antenna. The top-loading consists of 16–24 steel wires of 1–1.5-inch diameter connected directly to the tower’s top point, and then the active wires are discontinued by an insulator and continue with supporting guy wires, which are anchored to the ground through a second insulator to reduce the induction of loop currents due to capacitive coupling to supporting guy wires. The angle between the tower axis and active top-load wires should be larger than 50–60° to reduce the self-shielding phenomenon of the top-load wires. In addition to top-loading insulated guy wires, the tower should be supported by guy wires to the ground with a 120° angle separation at two or three levels along the tower height to provide sufficient resistance to wind load. For the supporting wire, guy insulators should be placed both at the tower and the ground anchoring point. Assuming the monopole height is h , the space to be allocated for the antenna installation should have a diameter of at least $3.5h$.

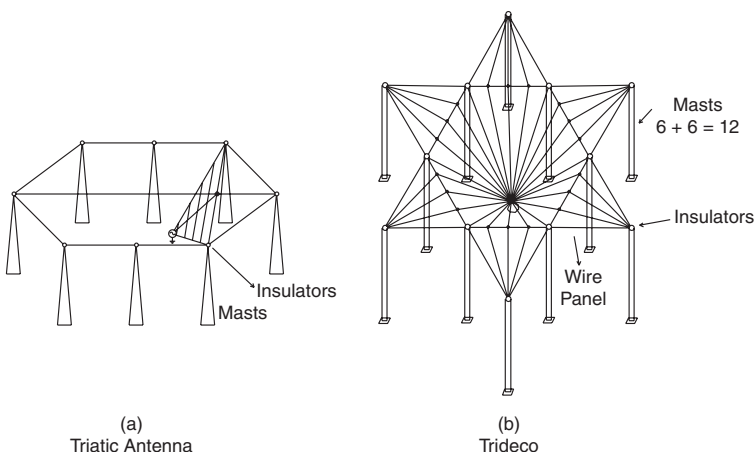

FIGURE 27-4 Tratic and Trideco VLF antennas

FIGURE 27-5 Umbrella-type top-loading VLF antenna: (a) LF antenna mast, (b) LF antenna supporting guys, (c) LF antenna base insulator-feeding point, and (d) LF top-loading

In Figure 27-6 the variation of top-load capacitance with the number of wires is shown for an antenna of $h = 250$ m height and top radial wires geometry shown before and depicted also in Figure 27-6. The computation was carried out by a method of moments (see Section 27.4).

Conductors Used in VLF-LF Antennas

The choice of conductor wires and structural cables is a critical issue. Top-loading conductors should have as low resistance as possible, taking into account the skin effects to guarantee low radio frequency (RF) losses. Furthermore, active wires should have adequate tensile strength and minimum weight. The conductor diameter and total conductor area

FIGURE 27-6 Variation of top-loading capacitance for an umbrella-type radial-wire conductor

must be sufficient to limit the surface potential to prevent a corona. A method developed by Wheeler⁶ provides a solution based on the average current flowing through the wires toward the ground per unit wire surface area. By using this method, the average voltage gradient on the conductor surface is

$$E_c \text{ (kV/mm)} = \frac{3\lambda^2}{2\pi h_e A_c} \sqrt{10P(\text{watts})} \times 10^{-6}$$

where E_c is the electric field intensity measured in kV/mm, A_c is the total wire surface in m^2 , and h_e and λ are measured in meters.

Electric power transmission cables such as concentric-layer, aluminum-clad steel or aluminum wire, aluminum-clad wire core, aluminum conductor, steel-reinforced type ropes could be used. The cables that have proved to be more suitable are aluminum-clad, steel-core wires (designated as AW), which are shown in Figure 27-6.

Usually a symmetric umbrella-type top-loading structure is used. However, non-symmetric top-loading could also be used in case of unavailability of ground space around the monopole. It is important to achieve sufficient top-load capacitance, C_0 , to achieve sufficient equivalent monopole height, h_e .

Antenna Insulators

An insulator typically comprises an insulating core that extends between two electrodes that are maintained at significantly different electrical potentials. Insulators have been made with

FIGURE 27-7 Cross section geometry of wire conductor

various materials. High-voltage electrical insulators for use at voltages in excess of about 1 kV, and typically at 24 kV, can be made from porcelain, glass fiber, or solid polymeric material. Porcelain has good electrical properties but is heavy and brittle, thus having low resistance to mechanical forces. Glass fiber rod impregnated with an epoxy resin is of lighter weight but generally has inferior electrical performance to porcelain in outdoor applications, or must be environmentally sealed. A composite insulator contains a structurally strong core or rod typically made of fiberglass, a series of electrically insulating sheds, and two metal end fittings crimped onto the exposed ends of the electrical insulator. Electrical polymer insulators are used in power transmission and distribution systems to provide mechanical support for the conductors and to provide electrical insulation between the high-voltage conductors and grounded tower structures. Polymer insulators are made by covering the outer periphery of a core member made of an fiberglass reinforced plastic (FRP) with shed portions made of silicone rubber. Solid polymeric material combines the advantages of light weight and good electrical performance, but has poorer load-bearing properties. Polymeric tubing and/or sheds (annular extensions) may be added to porcelain or glass fiber rods or incorporated into a polymeric insulator for enhanced performance. High-voltage suspension insulators are used to suspend power transmission lines from overhead supports on poles and towers. Suspension insulators used to be made of strings of porcelain insulators having a size and shape required of that material to provide the necessary mechanical strength, dielectric strength, and creepage distance. Nowadays, most suspension insulators are formed of a fiberglass-reinforced polymer rod and an external protective housing forming the weather sheds. The weather-shed housing is usually made of an elastomer or an epoxy material. Elastomer or epoxy weather-shed housings are designed to protect the fiberglass-reinforced rods from weather and electrical activity.

Insulators made of porcelain usually are used in separating active and passive wire elements. Also, cylinder-shaped porcelain insulators are used to achieve base feed in VLF-LF antennas. Other kinds of insulators also have been tried, such as fiberglass-reinforced plastic and oil-filled tubular porcelain also reinforced with a fiberglass strip providing potentially less weight. Three types of insulators are available:

- **Strain type** The porcelain body is subjected to tensile loads.
- **Fail-safe or compression type** The porcelain is supported in a frame that places the porcelain under compression.
- **Stick type** The working loads are taken by a high-tensile fiberglass band located within the oil-filled interior of the tubular porcelain body.

These insulators are illustrated in Figure 27-8.

RF Loss Mechanisms

To achieve high radiation efficiency, the antenna losses should be reduced. Assuming the antenna base current is I_0 , the total consumed power representing the nonradiated part of electromagnetic power is

$$P_{\text{loss}} = \frac{1}{2} R_l I_0^2 \quad (27-12)$$

The losses occurring in the low-frequency antenna and the corresponding contribution to loss resistance are accounted for on the following contributions:

$$R_l = R_{l-w} + R_g + R_{l-c} \quad (27-13)$$

FIGURE 27-8 Three type of insulators: (a) strain, (b) fail-safe, and (c) stick

where

R_{t-w} = Losses related to the or tower and wires (top-loading + supporting wires)

R_g = ground losses due to the imposed fields on the ground surface

R_{t-c} = tuning circuit and transmission line losses at the feeding structure

The conductivity losses of the tuning circuits and mast top-load conductors are computed easily by using circuit concepts and are usually small compared with ground losses.

Assuming the current distribution on the antenna conductors is known, the R_{t-w} , R_{t-c} can be computed using the conductor resistance per unit length ρ :⁷

$$\rho = \frac{1}{a} \sqrt{\frac{f \mu_0}{4\pi \sigma_c}}$$

where α is the conductor radius, f is the radiation frequency in Hz, $\mu_0 = 4\pi \times 10^{-7} \text{ (H/m)}$, and σ_c is the wire conductivity in Siemens/meter (S/m). By computing the total resistance along the wires constituting the antenna structure, the loss resistances can be computed as follows:

$$R_{t-w} \text{ or } R_{t-c} = \frac{\rho}{I_0^2} \int_{\text{conductor axis}} ds I^2(s) \quad (27-14)$$

where the integral is computed along the wire axis.

Computation of Earth Losses

Two mechanisms are involved in losses occurring in the ground medium in the vicinity of the antenna, namely the heating of the ground by horizontal current flow and the capacitive heating of the ground medium because of the vertical electric field imposed on the earth surface. The former loss mechanism prevails, and to compute the ground losses, the horizontal magnetic field near the antenna is computed by using the equation³

$$H_{\varphi} \approx \frac{I_0}{2\pi} \frac{h}{\rho(\rho^2 + h^2)^{1/2}} \quad (27-15)$$

where ρ is the horizontal distance from the antenna feedpoint. The surface loss in case of a surface resistance R_H is computed by a surface integral of the consumed power density on the ground surface:

$$P_H = \iint_{\text{Earth Surface}} d\rho d\phi \cdot \rho R_H H_{\varphi}^2 \quad (27-16)$$

where φ is the azimuth angle. The surface resistance (Ω) depends on the bulk earth conductivity σ (S/m), radiation frequency, f , as well as whether a conductor mesh ground system has been placed around the antenna. Assuming a number of N -conductor electrode system has been placed radially around the antenna following the work of Wait,⁸ the surface resistance can be computed as follows:

$$R_{H, \text{Electr.}} = 10^{-6} \rho^2 N^{-2} f^{3/2} \sigma^{1/2} \quad (27-17)$$

while at the earth medium outside the electrode region it is obtained by

$$R_{H, \text{earth}} = 2 \times 10^{-3} f^{1/2} \sigma^{-1/2} \quad (27-18)$$

Assuming the grounding electrode system has an outer radius of ρ_0 and introducing Eqs. 27-16 and 27-17 into Eq. 27-15, the earth loss resistance is found to be

$$R_g = P_H / I_0^2 = 10^{-6} N^{-2} f^{3/2} \sigma^{1/2} \rho_0^2 / (4\pi) + 10^{-3} f^{1/2} \sigma^{-1/2} (h / \rho_0)^2 / (2\pi)$$

This result is highly valuable because it provides the main loss component of LF antenna systems.

MF Antennas

The ability to achieve antenna sizes having electrical length up to $5/8 \lambda$ improves the antenna radiation efficiency in case of middle-frequency vertical monopole antennas operating at the frequency range 170–1000 MHz. This also allows the decrease of the interference phenomena occurring because of the almost-equal ground and ionosphere waves at 150–300 km at night. Anti-fading antennas attempt to improve the ground wave component by using collinear antennas such as those shown in Figure 27-9. Loading the antenna with a coil at its mid-height provides good anti-fading properties. Depending on the frequency and antenna height, two co-phased half-wavelength or three-quarter-wavelength current distributions could be used. Because of the rather large electrical length of MF antenna towers, top-loading is rarely used.

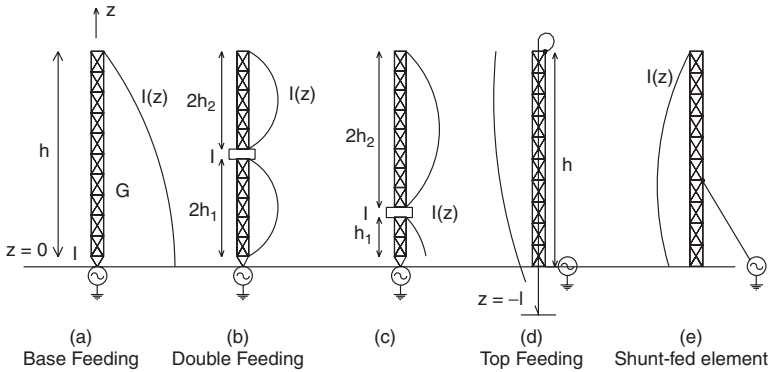

FIGURE 27-9 Various MF antenna design principles

In all practicality, the assumptions of sinusoidal current distribution along the antenna and of the earth's surface to be a perfect conductor provide a very good approximation in computing the radiated far field and the input resistance. In the simplest case of single width feeding assuming the antenna with current amplitude $I(t) = I_0 \cos(\omega t)$, the vertical polarized far field electric strength above the ground surface is

$$E_\theta = \frac{60F(\psi)}{r} \quad (27-20)$$

where

$$F(\psi) = I_0 \frac{\cos(G \sin \psi) - \cos(G)}{\sin(G) \cos(\psi)}$$

is the radiation pattern factor, $G = 2\pi h / \lambda$ is the vertical monopole electrical length, and ψ is the elevation angle shown in Figure 27-9.

The assumption of sinusoidal current distribution provides the antenna impedance with good accuracy^{7,8} of the real part of the impedance being equal to

$$R_0 = \frac{R_\Sigma}{2 \sin^2(kh)}$$

where the dipole (antenna with $2h$ length) loop resistance is

$$R_\Sigma = 30 \left\{ \begin{aligned} &2[C + \ln(2k_0h) - Ci(2k_0h)] + \\ &\cos(2k_0h)[C + \ln(k_0h) + Ci(4k_0h) - 2Ci(2k_0h)] \\ &+ \sin(2k_0h)[Si(4k_0h) - 2Si(2k_0h)] \end{aligned} \right\} \quad (27-21)$$

where the involved functions are defined as

$$Si(x) = \int_0^x du \frac{\sin u}{u}$$

$$Ci(x) = -\int_x^\infty du \frac{\cos u}{u}$$

and the Euler constant $C = 0.5772$. The reactance of the antenna can also be computed in a similar way.

Another approach to computing the input impedance has been the analysis of the antenna as a lossy homogenous long line with a complex propagation constant $\gamma = \beta + jk$, where $k = 2\pi/\lambda$ is the free space propagation constant and β is the attenuation constant along the antenna.⁹ Then the following relations are valid:

$$Z_1 = Z_0 \left(1 - j \frac{\beta}{k} \right)$$

$$Z_0 = 60(\ln(h/\alpha_e) - 1) \quad (27-22)$$

$$\beta = \frac{R_\Sigma}{h(1 - \sin(2kh)/(2kh))} \quad (27-23)$$

where α_e is the equivalent mast antenna radius. If the mast is being made of an n -polygon multiwire cage, the value of α_e is computed by the equation

$$\alpha_e = a(na_0/a)^{1/n} \quad (27-24)$$

where the terms a_0 and a are defined in Figure 27-10.

The antenna input impedance is computed by the relation of an open-circuited lossy line:

$$Z_{\text{input}} = Z_0(1 - j\beta/k) \coth(\gamma h) \quad (27-25)$$

The analysis of other types of MF antennas shown in Figure 27-9 can be easily carried out based on the perfect conductor ground impedance image theory and assumed sinusoidal current distribution. In Table 27-1 the far field strengths are given as a function of the elevation angle.

Directive broadcasting of MF antennas in broadcasting amplitude-modulated audio signals has been one of the first applications of antenna array theory. The possible directive MF arrays usually are realized by using two or more vertical monopole antennas while the possibility of using horizontal dipole element arrays also has been applied on a limited scale.

MF Vertical Array Antennas

Directional arrays composed of two or more masts are used to provide increased field strength or to minimize interference with coverage regions of nearby MF stations. Mutual coupling between array elements should be taken into account. For a two-element array, gain increase is 2–3 dB, and for four elements it is 4–6 dB. In the frequency region of 525–1605 kHz and power levels 1–2000 kW, many MF stations use array technologies mostly of two elements.

The analysis of MF arrays can be carried out by using the mutual impedance theory of linear antennas.^{7,8} The assumption of perfect conductor ground surface is reasonable since ground wire enrichment is used to achieve high

efficiency and to prevent raising the elevation of the radiation lobe of the broadcasting antenna. Mostly two-array element systems are used as shown in Figure 27-11. In this case both single-active element or two-active element arrays have been utilized. For two active monopoles the horizontal distance between the two masts is approximately a quarter wavelength, and the two monopoles should be excited by base currents of equal amplitude, with the reflector monopole having a phase lead of 90°. To achieve this condition, the mutual coupling between the two active elements should be taken into account.

FIGURE 27-11 Two-element directive MF antenna array geometry

The single-active element two arrays are simple, so they usually are the preferred solution in trying to achieve directive beam broadcasting. Assume the setup shown in Figure 27-11 where the monopole element 1 is active. The passive antenna is assumed to have a non-dissipating load with impedance value of jX_{2t} ; then, based on the linear antenna theory, the following equations are written:

$$\begin{aligned} V_1 &= (Z_{11} I_1 + Z_{12} I_2)/2 \\ 0 &= ((Z_{22} + jX_{2t})I_2 + Z_{12}I_1)/2 \end{aligned} \quad (27-26)$$

where V_1 is the driving voltage of the active element, I_1 and I_2 are the currents of the active and passive elements, respectively, while the z -parameters Z_{11} , Z_{12} , Z_{22} , are computed by using standard antenna theory.^{7,8} The input impedance of the active element is obtained easily:

$$Z_{in1} = Z_{11} - \frac{Z_{12}}{Z_{22} + jX_{2t}} \quad (27-27)$$

Furthermore, the ratio of the two currents is

$$m = I_2/I_1 = -\frac{Z_{12}}{Z_{22} + jX_{2t}} \quad (27-28)$$

If the passive element is short-circuited, then $|m| < 1$ always, and as the distance d (see Figure 27-11) increases, the current of the passive element diminishes, since the modulus of Z_{12} decreases. When the passive element is tuned, $Z_{22} = Im(Z_{22}) = -X_{2t}$, and the current in it reaches its maximum value at any inter-element distance d . If d is very small, then the passive element could attain larger current than the active element. For resonance the m ratio value is

$$|m| = |Z_{12}|/R_{22}$$

$$\text{phase}(m) = \pi + \tan^{-1}(X_{12}/R_{12})$$

By varying the distance d and selecting a slightly different height of elements, the passive monopole can operate as a director or reflector. To achieve reflector-type operation, the distance between d should be between 0.2λ and 0.25λ , and the passive element should be slightly higher than the active element. In the past, scaling model measurements have been utilized extensively in designing such arrays. Although scaling model measurements still are used to select and verify design parameters, the availability of highly accurate numerical codes based on method of moments provides more accurate results, as described briefly in Section 27.4.

MF Horizontal Arrays

MF signals can be propagated to long distances (2000–4000 km) by ionospheric reflection, usually during hours of darkness when ionosphere absorption is reduced. For long-distance MF broadcasting, it is possible to use horizontal polarization and also to develop directional radiation patterns by using horizontal dipole array elements. This is useful for secondary coverage areas of MF stations. Usually, primary areas are covered

FIGURE 27-12 Horizontal MF array geometry utilizing sky wave transmission

by vertical polarized antennas, which, however, have shortcomings in covering distant regions (>1000 km) because the poor radiation pattern at higher take-off angles limits the signal strength received. In Figure 27-12 the realization of a horizontal array is shown where two broadside arrays parallel to earth surface dipoles are used. No surface-ground wave is induced, and only sky mode is emitted. The take-off angle is a function of the height above the ground of the dipole array at a given frequency.

Antenna Tuning

In all VLF and LF antennas, the antenna height being much smaller than the wavelength of the antenna input presents an impedance $Z_{in} = R + jX$ with few ohms of the real part and a capacitive reactance up to a few thousand ohms. Taking into account the modern solid-state power amplifiers of $50\text{-}\Omega$ output impedance, you need to use matching circuits. In Figure 27-13 a common antenna impedance matching circuit is shown. In all cases a mechanical switch should be placed at the antenna input to protect maintenance personnel during service operations with the antenna system to prevent possible high voltages induced on the tall antenna structure.

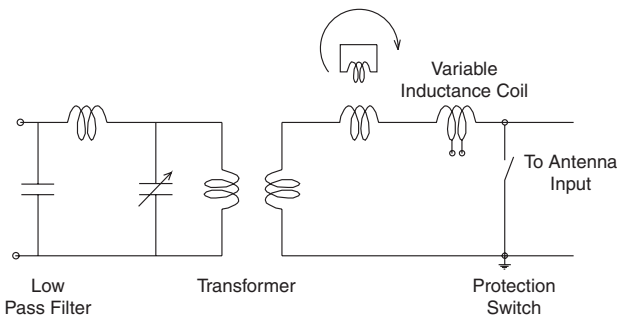

FIGURE 27-13 VLF/LF antenna input impedance matching circuit

As shown in Figure 27-13, a fixed and variable inductive serial network element is used to compensate the highly capacitive load of the antenna. A step-up transformer using low-loss core material is used to increase the low resistance impedance to a higher value near the commonly used 50- Ω transmission line wave impedance connecting the power amplifier with the antenna system. Considering that the distance of the antenna to a 10–100-kW amplifier could be up to 500 m, a matching of better than –20-dB return loss is very important. This requires a coarse- and fine-tuning variation of the matching circuit inductance. A common practice to achieve fine variation of the serial inductance element is to use an air core variable transformer, known as *variometer*, with a short-circuited secondary element. By rotating the secondary element and varying the coupling coefficient of the transformer, a fine change of the inductance is obtained. An additional tuner circuit, such as shown in Figure 27-13, is used between the transmission line and the transformer unit to achieve proper impedance matching of the whole system. To achieve an overall low loss, the antenna tuning circuit elements should be designed and constructed of large-diameter hollow copper wires or even pipes.

An important issue is the protection of the antenna and especially of the power transformer–power amplifier unit from direct lightning strikes on the antenna mast. Gas discharge spark gap protection could be used in regions with high thunderstorm activity. The Tee or Pi-type LC matching networks usually are used in tuning circuits for VLF/LF and MF antennas. In case of power exceeding 50–100 kW, gas-filled capacitors are used to provide protection from induced arcs. All the tuning circuit network elements should be installed into a shielded room that is grounded to the earth and grounding conductor grid.

Environmental Considerations

During the last decades the scientific community and the public have paid increasing attention to possible negative health effects of electromagnetic radiation. Regarding low frequencies and in particular because of the extensive use of industrial electrical energy of 50/60-Hz extremely low frequencies (ELF), there has been extensive study and argument about negative health effects primarily attributed to the magnetic field component of ELF fields. Considering that VLF, LF, and MF fields are quite close to 50/60 Hz, the issue of possible health effects near broadcasting antenna fields are of concern. Various international and government bodies during the last decades have regulated the exposure of the general public and employers to electromagnetic radiation. Presently the most stringent standards are those of European Commission Directive 519-12/7/1999, which sets reference levels concerning the rms electric field strength of 87 V/m and magnetic field strength of 5 A/m. Considering that the vertical monopole top-loaded antenna is the most used antenna and because of the very high capacitive input impedance in the vicinity of the antenna, under the top-loading structure the electric field could have significant values while the magnetic field is comparatively very weak. Therefore, care should be taken to check the electric field near the antenna. Both theoretical and experimental results show that outside of the top-loading region the antenna electric field doesn't violate the 87-V/m standard.

27.4 NUMERICAL COMPUTATIONS OF LOW-FREQUENCY ANTENNAS

The most suitable numerical computation method of analyzing and designing low-frequency antennas is the method of moments (MoM) using a Pocklington integral equation. The analysis of a finite length thin cylindrical dipole antennas has been a fundamental research topic in the history of applied electromagnetism.

In applying the method of moments the radiation problem is formulated by modeling the active parts of the conductor structure by linear overlapping cylindrical segments being smaller than $\lambda/20$. If the number of linear segments is N , then each segment is characterized with its length l_i , ($i = 1, 2, \dots, N$) and radius a_i , ($i = 1, 2, \dots, N$). For mast structures consisting of multisegment tubular cage structures, the radius a_i is computed by Eq. 27-24, while for the top-loading or other wires the actual radii are used. Then the integral equation, taking into account the validity of the condition $a_i \ll \lambda$ and $a_i \ll l_i$, is written as follows:

$$\left(k_0^2 + \frac{\partial^2}{\partial s^2}\right) \sum_{i=1}^N \int_{s=0}^{l_i} ds' K(\vec{r}_j, \vec{r}_i') I_i(s') = -E_{s0}^j(s) \quad (27-29)$$

where the kernel function is the Green's function of the infinite dimension and conductivity of the earth surface averaged over the wire conductor periphery. If the earth medium is assumed to be homogenous and of finite conductivity, the Green's function still is available by taking into account the Sommerfeld integral as an additional term. The s and s' variables represent the *observation* and *source* points on the wire structures, respectively. The right-hand side represents the *imposed* electric fields on the antenna structures and more particularly the applied voltage on the antenna driving points. To determine the unknown current distributions, following the method of moments (MoM) developed during the 1960s–1990s, a set of linear “physical” basis functions are selected to describe the current distribution in terms of a linear sum with unknown weighting coefficients. Then a linear system of equation is obtained after an inner product by a set of “testing” functions of this integral equation of the equation on each segment. In case both “describing” and “testing” belong to the same family, a highly numerically stable procedure is developed, providing accuracy exceeding 1 percent, which is known as the Galerkin method. The selection of physical describing and testing functions require that the engineering inside be pertinent to the problem. An important issue is the stability of the Galerkin method because of the satisfaction of the variational condition, and the accuracy is valid for global quantities such as the radiation pattern and input impedance. Various commercial codes have been developed and are available based on the MoM.

27.5 VERTICAL MAGNETIC LOOP AND HORIZONTAL SLOT ELF AND VLF ANTENNAS USING NATURAL STRUCTURES

Traditional antenna engineering at the low-frequency spectrum mostly uses vertical monopole antennas even as low as 16-kHz radiation frequencies. The limitation imposed by tower heights of 400–500 m makes it rather difficult to construct antennas radiating less than 10 kHz since the achievable efficiencies are very small and the required power levels are excessively high. During the last 50 years various alternatives to vertical monopole antennas have been tried experimentally. Considering all possible small electrical antennas on the perfect conductivity ground surface and derived from electrical and magnetic dipoles and the complementary slot antennas, as illustrated in Figure 27-14, we can state the following radiation modalities:

- Vertical monopole, with its image doubling the antenna electrical length, which has been the basis of low-frequency antenna technology the last 100 years
- Horizontal magnetic loop or electric dipole antennas, both placed near the earth surface and both being non-radiating structures because the image currents are opposite to the antenna currents
- Vertical magnetic loop antenna, which excites an image loop antenna inside the earth, enhancing the primary source
- Horizontal slot antenna, which, as in the preceding case (c), could provide radiating structure

FIGURE 27-14 Possible radiating mechanisms at very long wavelengths

Review of all possible radiating mechanisms apart from the traditional vertical monopole antenna, already analyzed in previous sections, and considering the possibility of building such antennas based on the previously mentioned principles (c) and (d) providing radiation capabilities, gives the following possibilities:

- Vertical magnetic loop, which could be constructed by placing a conductor on a mountain or an island and grounding the ends of the wire. The loop is excited by a serial generator, as shown in Figure 27-14a.
- Horizontal slot antenna, which could be constructed using an island or a peninsula and exiting by a shunt voltage source, as shown in Figure 27-14b.

Both possibilities have been investigated by several researchers during the past 50 years. The best-known case has been the U.S. Navy Extremely Low Frequency (ELF) project, which was proposed in the 1950s by Christofilos, and aimed to emit as low as 70–80 Hz. The vertical magnetic loop was obtained by running parallel wires and grounding them deep inside the earth, which had low conductivity earth in the specific used area. The possibility of utilizing a tunnel and circling a wire around the above mountain has been investigated in New Zealand, and interesting results have been demonstrated in the frequency region of 1–10 kHz providing a proof of concept of a vertical loop antenna. The few reported measurements using vertical magnetic loop antennas confirm the viability of developing broadcasting antennas in the 1–10 kHz frequency region with sufficient efficiency, provided loops with effective area of 1–5 km² are used.

The possibility of developing a horizontal slot antenna using rocky islands and peninsulas also has been investigated by several researchers measuring the input impedance of the wire located in the throat of a narrow island. Measurements of radiated field strength have been carried out on a rocky, narrow (average width 200 m) peninsula of 2.5-km length in the frequency region of 3–10 KHz. Although, based on visual intuition, the possibility of achieving a large size slot radiator is attractive, in practice this is not the case since underground structures penetrated by seawater effectively short circuits the slot radiator and decreases the antenna efficiency to a very small value. Indeed the impossibility of operating the slot mode ELF antenna was predicted in the early 1960s.¹⁰

28.1 INTRODUCTION

The high-frequency (HF) band (2–30 MHz) is widely used for communications and broadcasting. Long-distance communication relies on (virtual) reflection from the ionosphere, a region of ionized particles created by the interaction of the solar wind of high-energy charged particles with upper layers of the atmosphere. The ionosphere is a variable and turbulent medium, and successful communication relies on matching the frequency of transmission and antenna characteristics to its behavior.

There is a substantial difference in practice between public broadcasting operations and point-to-point or point-to-multipoint operations. Broadcast transmissions intended for public reception operate at high power levels to deliver strong signals to distant receivers equipped with simple low-gain omnidirectional antennas. To ensure good audibility, high transmitter powers are used, and these are associated with high-gain directional transmitting antennas whose function is to optimize the signal strength laid down in the target area as well as to conserve spectrum resources by avoiding laying down signals outside the target area. It is common to transmit the same program material simultaneously on more than one frequency band, and the chosen bands may change over the course of a day to match changing propagation conditions. A typical broadcasting station is equipped with a suite of high-gain antennas firing in the directions of interest, often with facilities to modify the beam directions at will in azimuth (and sometimes elevation) direction. Major stations may also be equipped with a rotating high-gain antenna. All the antennas will be of broadband design, allowing them to be used on a number of different broadcast frequency bands, sometimes simultaneously.

International broadcasting is a high-cost activity, with large investments in both transmitters and high-gain antenna arrays and with the high energy costs of operating transmitters with output powers up to 500 kW. The advent of digital transmission permits the reduction of transmitter powers, but this technical possibility will only be secured by international agreement as well as by a change in perception that the station with the strongest signal wins the listeners.

Professional point-to-multipoint services make use of cooperation by the connected stations, and the advent of channel sounders and automatic link establishment (ALE) facilities has led to the availability of reliable communications with relatively low transmitted powers. The advent of digital modulation schemes, adaptive modems, and ALE has provided more reliable communications with increased data throughput, greatly increasing the potential applications of the HF band. *Ionospheric Radio*¹ and the *High-Frequency Radio Automatic Link Establishment (ALE) Application Handbook*² serve as excellent introductions to the subject of modern HF communications.

The amateur radio service has used the HF band for many decades and has proved fertile ground for experimentation with antennas, both of conventional and unorthodox design, especially in the areas of compact antennas and multiband antennas with low to medium gain.

The distinguishing features of HF antennas are their form of construction (usually from wires), their electrical proximity to ground (which determines many of their radiation characteristics), and the way in which antenna performance must be married to a knowledge of the ionospheric path that will support the intended transmission.

28.2 SPECIFYING THE RIGHT ANTENNA FOR THE JOB

The ionosphere has an effective refractive index that depends on height, and an incident electromagnetic wave is progressively refracted. Depending on the ionization density, frequency, and angle of incidence, the signal may pass through the reflecting layer or may be

diffracted through a sufficient angle that it returns to earth. If the incident and emerging ray paths are projected back toward the ionosphere, we can define a “virtual height” that we can regard as being the height of an imperfect reflecting mirror. The ionization density and refractive index are a complex function of time of day, season of year, geographical position, solar activity, and frequency. Four layers are of importance: The *D*-layer (the lowest) absorbs transmissions at MF frequencies during the day, but is transparent when its density falls at night. The *E*, *F*₁, and *F*₂ layers are important for HF transmission and are further discussed below.

The HF band has unique transmission properties and continues to be intensively used. The proper selection of antennas is an important means by which spectrum utilization is maximized. The use of directional transmitting antennas not only increases the signal-to-noise ratio on the wanted path, but it also reduces the signal strength laid down in regions where the signal is not needed and may interfere with other users; directional receiving antennas reduce the extent of interference suffered from other users.

The first step in choosing an antenna is to determine the optimum working frequency (OWF) for the ionospheric path involved. Computer programs are readily available that estimate path losses at different frequencies and the reliability of service for the chosen transmitter power and specified antennas at both ends of the link.^{3,4} The antennas must support the whole range of frequencies that may be needed at any time of day, season of the year, and phase of the 11-year cycle of sunspot activity. The same computer program will identify the probable active ionospheric propagation modes and indicate the corresponding elevation takeoff angles (TOAs) that must be supported by the antennas.

Figure 28-1 shows the path geometry for a one-hop path. The height of the *E* layer is about 100 km. The *F*-layer is more complex in structure and variable in height, particularly with respect to the local solar zenith angle. First-order estimations can be made on the rough assumption that the *F*₁ and *F*₂ layers have virtual heights of approximately 250 km and 400 km. Multiple-hop propagation can be assessed approximately by using Figure 28-1 for each hop. For distances of more than 4000 km, maximum signal results from low-angle transmission in the range from 2 to 15°, with the lower angles generally providing the highest and most stable received power. Propagation prediction programs^{3,4} should be used to establish a link budget and to define the antenna parameters.

Paths of up to about 200 km require high takeoff angles, giving rise to the term *near vertical incidence skywave* (NVIS) paths. The different takeoff angles associated with various path lengths require that we use antennas with different elevation pattern characteristics to serve these paths.

FIGURE 28-1 Takeoff angles for one-hop ionospheric transmission as a function of virtual layer height. The example shows that the TOA for a 2000-km path with a virtual layer height of 300 km is around 12°.

The minimum azimuth beamwidth needed for reliable point-to-point coverage depends on the effects of irregularities and magnetic storms in the ionosphere. Azimuth directions of arrival may typically vary by $\pm 5^\circ$ because of these effects.⁵ This makes the use of antennas with extremely narrow horizontal beamwidths undesirable, especially on circuits that skirt or traverse the auroral zone where much higher angles of off-axis propagation are experienced. For broadcasting or point-to-multipoint services, the beamwidth must cover the target area with allowance for these path-deviation effects.⁶

High antenna gain is required for transmission when large effective radiated power is needed to overcome ionospheric transmission losses. For receiving, high directivity is desirable in the presence of interference, but low radiation efficiencies can often be accepted because in many circumstances the sensitivity of a receiving system is limited by external noise and not by the noise of the receiving system—this is explored later in Section 28.6.

For transmitting antennas, the acceptable input VSWR is usually determined by the characteristics of the transmitter. Modern solid-state transmitters will operate at full output power into a maximum VSWR of around 2:1; above this a transmitter may automatically reduce its output power to limit the voltages and currents in internal circuits.

The power rating of an antenna is determined by both average and peak envelope power (PEP). The average power determines the required current-carrying capacity of the antenna conductors, while the peak power determines the peak electric fields on the antenna, which set requirements on insulator and conductor configurations to avoid arcing or corona discharge, especially in wet weather or at locations where insulators may become contaminated with salt or pollution.

Mechanical requirements are usually determined by wind speed, ice loading, operating temperatures, and corrosive environments. Some applications demand limited antenna size or height, or the whole antenna system may need to be portable for military or emergency relief operations. The tensions in the components of an HF antenna are usually computed using a standard nonlinear finite-element software package. Care must be taken in design to ensure that all joints are fully articulated to avoid failure by the work-hardening of conductors. Insulating synthetic ropes are widely used to support radiating elements and transmission lines, but primary ceramic insulators (typically made from alumina, which has a low dielectric loss factor) are necessary at higher powers to avoid damage by corona discharge.

Many HF antennas are of electrically balanced design and are fed from a coaxial cable through a balun in the form of a transmission line device or a ferrite-cored transformer.

It has become common practice to load HF antennas with resistive or reactive loads; this technique increases the impedance bandwidth but reduces the available gain. The user should always check the power gain of loaded antennas when they are to be used for transmission.

28.3 ANTENNAS MOUNTED ABOVE GROUND

Effect of the Ground

HF antennas are usually operated less than two wavelengths above the ground, whose proximity modifies both the input impedance and radiation patterns. Although accurate evaluation of ground effects is difficult, many properties of HF antennas can be understood by regarding them as being situated over an infinite, flat ground plane. If the ground plane is perfectly conducting, its effect is to create an image of the antenna (see Figure 28-2). For ground of finite conductivity, simple image theory does not give an exact solution, but will often provide useful approximate results.

FIGURE 28-2 Direct and ground-reflected rays from an element mounted above ground

Radiation Patterns of Antennas Above Ground

To compute the signal from an antenna at an elevation angle θ° , we must add the ground-reflected wave to the direct wave, allowing for the amplitude and phase of the reflection coefficient of the ground. The proximity of the ground modifies the currents in the elements of an array placed close to it; so although an approximation can be obtained by this method, a full solution for arrays lower than about one wavelength requires the manipulation of the matrix of all the currents in the array including the effect of the ground.

The reflection coefficient for waves with horizontal polarization ρ_h is given by

$$\rho_h = \frac{\sin \theta - \sqrt{(\epsilon_r - jx) - \cos^2 \theta}}{\sin \theta + \sqrt{(\epsilon_r - jx) - \cos^2 \theta}} \quad (28-1)$$

and the complex reflection coefficient for waves with vertical polarization ρ_v is given by

$$\rho_v = \frac{(\epsilon_r - jx) \sin \theta - \sqrt{(\epsilon_r - jx) - \cos^2 \theta}}{(\epsilon_r - jx) \sin \theta + \sqrt{(\epsilon_r - jx) - \cos^2 \theta}} \quad (28-2)$$

where

$$x = 18 \times 10^3 \sigma / f_{\text{MHz}} \quad (28-3)$$

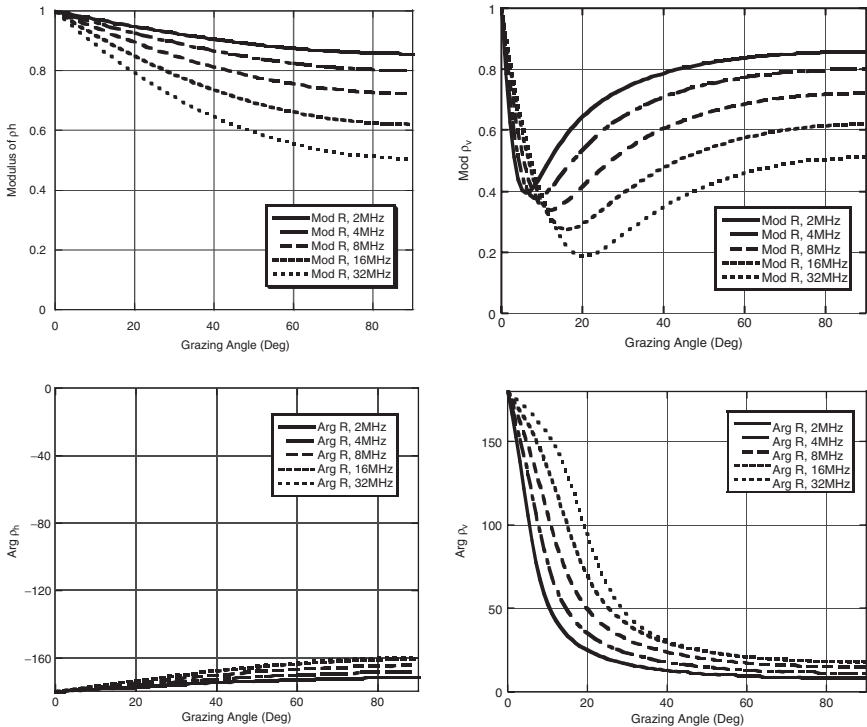

θ = grazing angle

ϵ = relative permittivity of the ground

σ = conductivity of the ground Siemens/meter (S/m)

f_{MHz} = operating frequency in MHz

The ground reflection coefficient for horizontally polarized waves is a well-behaved and slowly varying function. For vertically polarized waves both the magnitude and phase of the reflection coefficient vary with the grazing angle (θ) and the frequency. The angle

Magnitude and phase of reflection, H -polarizationMagnitude and phase of reflection, V -polarization

Reducing conductivity has a similar effect to increasing frequency—see Eq. 28-3.

FIGURE 28-3 Reflection coefficients for horizontal and vertical polarized waves on reflection by ground with $\epsilon_r = 5$ and $\sigma = 10$ mS/m (typical of fertile farmland)

at which the reflection coefficient is minimum is called the *Pseudo-Brewster Angle*, and at this angle the phase of the reflection coefficient is 90° . Figure 28-3 is calculated for $\epsilon_r = 5$ and $\sigma = 10$ mS/m. It will be seen from the form of x in Eq. 28-3 that the effects of falling conductivity and increasing frequency are similar, so over poor ground the values tend to fall even further from complete reflection as the ground absorbs more energy from the incoming wave.

By selecting the polarization and height of the antenna above the ground, we can effectively control the elevation angle of the main beam maximum (the TOA). The ground—even poorly conducting ground—acts as a good reflector at low angles of elevation for horizontally polarized signals, and the gain of a horizontally polarized antenna is effectively increased fourfold when the antenna is located above good ground. (The reader may consider how this comes to be true, as radiation is apparently only confined to one half-space, so why is the gain not merely doubled?) As shown in Figure 28-3, the magnitude of ρ_h is not strongly dependent on ground conductivity at low angles, but the contribution added by reflection from the ground falls off as the TOA increases.

For many types of horizontally polarized antennas the effective height of the radiating region above ground is fixed, with the result that the TOA falls as the frequency increases. This suits the general behavior of HF paths, because long paths with low TOAs generally operate at higher frequencies than high-TOA short paths.

FIGURE 28-4 Elevation patterns of a monopole over ground of different conductivities

The effect on a vertical radiator close to the ground is more complex because the current distribution on the element is modified by coupling to the ground, but the general principle still operates. The finite conductivity of the ground reduces the gain of the antenna at low elevation angles, raising the elevation main beam maximum. This can be seen in Figure 28-4, which also illustrates that the effect of finite ground conductivity can be reduced by the use of a ground mat, in this case comprising wires laid in the direction of propagation and typically spaced by around $\lambda/10$ at the highest operating frequency.

When thinking about the radiation patterns of HF antennas, it is important to remember that the fields in the azimuth plane ($\theta = 0^\circ$) may be very small, and it is usual to specify the “azimuth” pattern for some specified takeoff angle(s)—effectively the cuts of a cone on the solid 3D pattern.

Computer-Aided Design

HF antennas are often designed using computer programs that solve Maxwell’s equations numerically for arbitrary antenna geometries, including the effects of the ground and any ground mat.⁷ They calculate the current distribution on the antenna, and from this they derive the radiation patterns, making allowance for ground effects. In general the radiation patterns are computed to an acceptable degree of accuracy, but the computation of feedpoint impedances should be regarded as a good estimate, rather than reliable fact. It is often worth changing the segmentation of the model and details close to the feedpoint to check that the result is stable and is not sensitive to small changes in the way the real antenna is represented.

28.4 MAJOR FORMS OF HF COMMUNICATIONS ANTENNAS

Many HF antennas comprise derivatives of simple dipoles and vertical monopoles. To meet the requirements of extended bandwidth, these simple prototypes are modified into the forms shown in Figure 28-5.

FIGURE 28-5 (a) Dipole; (b) Multiple dipole; (c) Loaded dipole; (d) Fan dipole; (e) 3D biconical dipole

When additional gain is needed, or when it is desirable to form a directional beam, the most common practice is to use some form of log-periodic or curtain array. When an antenna is only required to receive signals, it is possible to use compact low-gain elements and to array these to provide the required directivity to enhance the received signal-to-noise ratio.

Dipoles and Dipole Derivatives

The simplest HF antenna is a wire dipole suspended above the ground (see Figure 28-5a). For NVIS use it should be no more than 0.35λ above the ground to avoid an overhead pattern null. The multiple dipole (Figure 28-5b) provides operation at several separate frequency bands, while the loaded dipole (Figure 28-5c), loaded fan dipole (Figure 28-5d), and biconical dipole (Figure 28-5e) will provide low VSWR over extended bandwidths.

Monopole Derivatives

These designs require a ground mat that forms the second terminal of the antenna and increases effective ground conductivity, enhancing radiation at low takeoff angles. A full ground mat for this purpose comprises a set of between 60 and 180 radial copper (or copper-plated steel) wires, $\lambda/4$ long at the lowest operating frequency, laid on the ground or buried within a few centimeters of the surface (deeper burial leads to losses in the ground above the wires). The inner ends of these wires are joined together at the base of the monopole; they form the second terminal of the antenna and are connected to the outer conductor of the feeding coaxial line.

The biconical monopole (see Figure 28-6) can be constructed using a single metallic mast placed on an insulated base. Internal resonances between the tower and the cone can be removed by connecting the mast to the cone at one or more points. In an alternative form of this antenna the mast is grounded and the lower cone wires are insulated and fed against ground. Midway up the mast the cone wires are connected to the mast to form an inductive loop. This acts as a matching device, allowing the antenna to provide a low VSWR when it is only 0.17λ high. Conical monopoles comprise only the lower half of the biconical antenna, and their mechanical construction can pose some interesting challenges.

FIGURE 28-6 A biconical monopole antenna

The azimuth pattern of conical and biconical monopoles is circular at all frequencies, but the elevation pattern changes with frequency in the manner shown in Figure 28-4.

Horizontally Polarized Log-Periodic Dipole Array (LPDA)

The basic LPDA (see Figure 28-7) comprises a series of half-wave dipoles spaced along a balanced transmission line and connected to alternate sides. Successive dipole lengths and spacings have a constant ratio τ (typically between 0.8 and 0.95). The bandwidth is limited by the lengths of the longest and shortest dipoles. The number of radiators depends on the frequency range and the value of τ . The parameters τ and α , as discussed in detail in Chapter 13, determine the gain, input impedance, and maximum VSWR of the antenna.^{8,9}

FIGURE 28-7 A transposed-dipole LPDA

At any given frequency only those dipoles approximately $\lambda/2$ long are excited, and these form a single active region. The active region moves along the curtain from the longest to the shortest dipole as the frequency is increased. Because of this movement, it is possible to mount an LPDA so that the electrical height of the active region is constant (the apex of the antenna is placed at ground level) or variable by raising the apex so the active region at the HF end of the array is higher (in terms of the wavelength) than at the lower frequencies. This allows the takeoff angle to be optimized to some extent to match the path characteristics. It is important to choose τ and α carefully because of the possibility of unwanted resonant effects—energy that normally radiates from the active region excites a second active region where the radiators are $3\lambda/2$ long, causing impedance and pattern perturbations.

The antenna is fed close to the shortest element. The balanced feedline is loaded by the elements that modify its effective characteristic impedance. Careful attention to detail is needed if the antenna is to provide a low VSWR across the whole HF band; parameters requiring careful optimization include the characteristic impedance of the feedline and the distances by which it extends beyond the array at both ends. The input impedance of a horizontally polarized LPDA is strongly dependent on the height of the array above ground, and problems can be experienced over sloping ground. (Raising the HF end of the array is usually less problematic than a configuration in which the HF end of the array is electrically closer to the ground.)

A vertically polarized array can be formed by rotating an LPDA into the vertical plane and deforming its shape so the lower end of each element is at the same distance above ground—typically about 1 m. The dipoles are suspended from an insulating catenary attached to a mast positioned behind the longest element; the input end of the feedline is supported on an insulating pole close to the front of the antenna, while the far end of the transmission line is attached by insulators to the supporting mast.

A shorter form of vertically polarized LPDA can be constructed by placing the main feedline parallel with the ground and using only quarter-wavelength radiating elements—effectively a log-periodic monopole array. A practical difficulty with this array is the need to provide the effective 180° phase shift along the feedline between the radiating elements; this has been overcome by various methods including loading or meandering the transmission line between the elements. The complexities of feeding, together with the requirement for a ground mat, have limited the use of this form of array to circumstances in which the height of a standard LPDA is unacceptable—for example, close to airports.

Adequate VSWR performance can be obtained when each radiating element is constructed from a single wire. A long thin element has a high characteristic impedance, and the voltage at the open end is very high even for modest input powers; for peak powers above about 20 kW it may cause corona discharge problems at the open ends. The power rating of the antenna can be increased by forming each element from a number of parallel wires forming a cage perhaps 5–20 cm in diameter. Cage elements have wider impedance bandwidths, so the maximum VSWR of an array can be lower than that possible with single wire elements. Other forms of radiating element and feed systems such as trapezoidal or triangular teeth can be used for the same purposes. A typical horizontal LPDA using half-wave radiators has a gain of 10 to 12 dBi and an azimuth beamwidth of 60° – 80° ; its TOA depends on the height of the active region and can be adjusted by changing the inclination of the antenna relative to the ground. A vertical half-wave LPDA has a typical gain of 11 dBi and an azimuth beamwidth of 110° .

Transformations of the LPDA

The basic topology of the LPDA has proved very adaptable, and the antenna preserves its wideband characteristics even when subject to transformations that provide a variety of

FIGURE 28-8 Transformations of the standard LPDA (a), (b) and (e) NVIS derivatives, using the ground to reflect the downward-directed primary radiation. (c) A common single-mast horizontally polarized version. (d) Sometimes used for high-power rotatable antennas. The arrows indicate the general directions of fire.

new properties. Some of these are shown in Figure 28-8, which shows various ways in which the two half-curtains of the standard LPDA can be mutually rotated and the radiating elements realigned. Horizontally polarized LPDAs can also be stacked above one another to obtain increased gain or arrayed in the azimuth plane to provide omnidirectional or sector coverage.

Rotatable LPDAs

Rotatable LPDAs are often used when the direction of transmission must be changed from time to time and a compact antenna is required—they have been a common sight on the roofs of embassy buildings in capital cities worldwide. For input powers below about 10 kW these antennas often make use of tapered tubular radiating elements but may also be made from wires tensioned by insulated supporting catenary ropes. The antenna has constant physical height above ground, so its electrical height increases with frequency. As a result, elevation grating lobes form at higher frequencies, reducing gain in the principal lobe and introducing nulls at elevation angles that may be required to serve active propagation modes. These antennas are often mechanically complex, with 3D systems of supporting ropes to support the weight of the radiating elements. They are not easy to erect because they are large, heavy, and fragile; they require regular maintenance. The rotating mechanism may be situated at ground level or at the masthead; in both cases careful design is necessary to manage the large torque generated during rotation and periods of high wind.

The large dimensions of a rotatable LPDA can be reduced by loading or folding parts of the longer elements. To minimize antenna dimensions, the highest possible lower-frequency bound should be adopted for any application.

Spiral and Conical Log-Periodic Antennas

A major problem at many HF communications stations is a lack of land available for the required number of transmitting antennas. To help solve this problem, multimode antennas

FIGURE 28-9 Multimode spiral antenna (*Courtesy of TCI*)

have been developed that permit several HF transmitters to feed one antenna simultaneously and that provide good isolation between the transmitters. A commonly used structure for such an antenna is a four-arm spiral, as illustrated in Figure 28-9. An antenna of this type operating from 2 to 30 MHz with a gain of approximately 7 dBi can be designed with a height of 37 m and a diameter of about 115 m. Smaller antennas may operate to higher low-frequency limits or may use resistive loading to achieve acceptable VSWR values, reducing their radiation efficiency and power gain.

The four-arm spiral can be excited in four independent modes, three of which are balanced and one that is unbalanced. The balanced modes are horizontally polarized and omnidirectional in azimuth at all elevation angles. The unbalanced mode is vertically polarized and also omnidirectional¹⁰ (see also Chapter 13). In practice the orthogonality of the normal modes can provide interport isolation between 20 dB and 30 dB.

The most common feed system excites the three balanced normal modes. Two of these modes radiate energy directly overhead, and the third mode has a null at the zenith. The configuration shown in Figure 28-9 provides a low TOA at higher frequencies and high TOA at lower frequencies. Excitation of these modes requires that the antenna be equipped with a combination of hybrid and balun transformers.

Some multimode spiral antennas are inverted with their apex located near the ground. This arrangement produces TOAs that are nearly constant with frequency. Other configurations of multimode spirals also excite the fourth (unbalanced) mode, in which the tower and antenna are excited as a vertical radiator.

28.5 OTHER TYPES OF HF COMMUNICATIONS ANTENNAS

Vertical Whip

The vertically polarized whip antenna, usually 2–5 m long, is widely used because it is simple, inexpensive, and easy to mount on a vehicle or the roof of a building. An electrically short whip has a narrow impedance bandwidth and low efficiency; an associated tuning unit is needed to match it at the required operating frequency. The tuning unit may

be automatic in operation, but is not usually fast enough to support frequency hopping, and its input power is usually limited to a few hundred watts. Whips are commonly used on vehicles, but they suffer the disadvantage that their radiation pattern has a deep overhead null, limiting their effectiveness for short NVIS paths. It is common to see whips bent over the top of the carrying vehicle in an effort to reduce the overhead null, but this unfortunately further reduces their bandwidth and efficiency.

Traveling Wave Antennas

A traveling wave antenna comprises some form of leaky transmission line fed at one end and terminated by a resistive load at the remote end. It behaves ideally like a matched transmission line and has a relatively constant input impedance over a very wide bandwidth. Its gain, efficiency, and radiation patterns vary significantly with frequency, reducing its useful operational bandwidth to about an octave.

The rhombic antenna was widely used for point-to-point communication links. It has generally been superseded for transmitting use by the LPDA, which is smaller and requires less expensive supporting structures, and by LPDAs or active loop arrays for receiving.

The sloping-V comprises two wires connected to a feedline at the top of a supporting mast, the wires being arranged in a V-shape in plan with their ends grounded through terminating resistors (each typically 300 Ω). As long as the two legs have an electrical length longer than about two wavelengths, it provides a very simple and quickly deployed antenna with some directional characteristics and modest gain.

The inverted-V comprises a single wire element fed at ground level, suspended above ground at its midpoint, and terminating at ground level in a resistive load. A single or multiple wire ground mat is needed to provide the second terminal for both the input and the terminating resistor. The radiation from a long wire has a main lobe firing obliquely off the axis of the wire; an optimum geometry aligns the wires so the directions of radiation of the two wires coincide. The sloping- and inverted-V, which can be viewed as half-rhombic antennas, find application as quick-erect broadband antennas for transportable operations.

The Beverage antenna comprises a single wire (or more than one connected in parallel) mounted a few meters above ground level. It is terminated with a resistive load at one end and fed at the other end. It provides a simple low-cost directional receiving antenna for use at the lower end of the HF band (or in the MF band).

Loop Antennas

When space is very restricted or an unobtrusive antenna is essential, a small loop can be used as a transmitting antenna. A small vertical loop in free space has a frequency-independent radiation pattern. Its performance can be approximated by a half loop mounted on a conducting plane (see Figure 28-10b). The radiation resistance of a loop is proportional to $A^2 f^4$, where A is its area and f is the frequency, so the radiation resistance of small loops is very low at low frequencies. The minimum acceptable size is determined by the bandwidth needed at the lowest operating frequency—a bandwidth of 2 kHz can be provided by a loop 1 m high and 2 m wide. The loop has a narrow impedance bandwidth, and it must be tuned at each operating frequency (see Figure 28-10c). A variable capacitor tunes the main radiating loop to resonance while a small coupled drive loop transforms its resistance. It is possible to tune the antenna automatically using a microprocessor-based system that monitors the current in the loops and sets the capacitor to an appropriate value—as with the short whip, a stepper motor is too slow for frequency-hopping applications.

FIGURE 28-10 Vertically polarized transmitting loop: (a) azimuth radiation patterns at different elevation angles; (b) half loop mounted on ground plane; (c) equivalent circuit of half loop on ground plane

The small radiation resistance of the loop at low frequencies makes it inevitable that resistive losses reduce efficiency. Losses are minimized by using a high- Q vacuum capacitor and by ensuring that the current paths in the loop and ground screen have high conductivity. At 3 MHz the efficiency of a well-designed loop will be about 5 percent. Because the radiation resistance of the loop increases with the f^4 but the resistive losses increase only with \sqrt{f} , efficiency rises rapidly with increasing frequency, reaching about 50 percent at 10 MHz and 90 percent above 18 MHz.

There is continuing interest in using loops as NVIS antennas for vehicular use.¹¹

28.6 HF RECEIVING ANTENNAS

The HF environment is generally very noisy, the principal sources of noise being solar and galactic activity, tropical thunderstorms, and human-made noise. If we receive a signal on a very short dipole and gradually increase its length, the resulting signal-to-noise ratio rapidly increases, but once the incoming signal is large enough to dominate internal receiver noise no further increase occurs.

Noise Limitation

F_e is the level of external noise in a 1-Hz bandwidth relative to kT_0 , where $10 \log_{10} kT_0 = -204$ dBW. F_e can be determined from published noise maps¹² or by direct measurement by using a calibrated receiver and antenna. Figure 28-11 shows a typical example of the frequency variation of atmospheric noise; rising noise at low frequencies conveniently compensates for the diminishing effective height of a small loop. Atmospheric noise levels vary with geographical location, season, and time of day. The local human-made noise level depends on whether the receiving site is in an urban, suburban, or rural location; in urban areas it can exceed the atmospheric noise level.

FIGURE 28-11 Example of an external atmospheric and galactic noise figure: (a) atmospheric daytime noise; (b) atmospheric nighttime noise; (c) galactic noise; (d) worst noise condition. For data related to specific locations see "Radio Noise."¹²

The receiver noise figure F_r is obtained from the receiver specification. The transmission-line noise figure F_t is the reciprocal of its attenuation expressed in dB. For systems with filters, preamplifiers, etc., the noise figure F_{rt} can be determined by computing the noise figure for the equivalent cascaded network.

The antenna noise figure F_a is given by

$$F_a = D - G + L_M \quad (28-4)$$

where

D = directivity, dBi

G = gain, dBi

L_M = mismatch loss = $10 \log_{10} (1 - |\rho|^2)$, dB where ρ is the voltage reflection coefficient

The quantity $D - G$ can be expressed in terms of the efficiency η by using the relation $D - G = -10 \log_{10} \eta$. The efficiency includes resistive losses in both the antenna and the surrounding ground, which may be significant when earth conductivity is low and there is no ground screen.

When $f_e < f_a f_i f_r$, the receiving system is externally noise-limited because the external noise exceeds the internal noise. When $f_e = f_a f_i f_r$, the system is internally noise-limited, and system performance can be improved by reducing the antenna or equipment noise figures. In many geographical locations, atmospheric and noise levels from human activity are extremely low, so receiving systems must have low noise figures to avoid internal noise limitation.

Conventional receiving antennas, designed for transmission, can also be used for reception. These are very efficient, with noise figures often less than 3 dB, making them suitable for use at very quiet receiving sites. Because a high HF receiving-antenna noise figure is often acceptable, a receive-only antenna can be inefficient. Consequently, it can be small and if necessary can be resistively loaded to improve its performance.

Receiving Loops

A practical antenna having a noise figure near the upper limit allowable for most situations is the small vertical loop. A typical loop about 1.5 m in diameter, mounted about 2 m above the ground, has a radiation pattern covering both low and high elevation angles. Successful use has been made of balanced loops (which have classical bi-directional azimuth patterns) and unbalanced loops (which have cardioid azimuth patterns).

The noise figure of a loop depends strongly on its area and the operating frequency. A loop 1.5 m in diameter has a noise figure of about 50 dB at 2 MHz and 20 dB at 30 MHz. It is common to connect the loop to the coaxial feeder cable using a broadband low-noise amplifier that should have good linearity to ensure that intermodulation products are not produced in the intended signal environment. The amplifier typically has a gain of 10–15 dB and serves to match the loop to the feedline and to establish the receiver system noise figure.

A number of loops can be arrayed to provide a variety of directional radiation patterns. In most arrangements mutual coupling between the loops is negligible, and simple array theory will predict the radiation patterns. Beams are formed by bringing the coaxial cable from each loop into a beamforming network typically constructed using small ferrite-cored hybrid combiners. The most common arrangement comprises eight loops in an end-fire array with spacing between loops of about $\lambda/2$ at the maximum operating frequency. If balanced loops are used, the array can be made bi-directional by splitting the signal from each loop and feeding two beamforming networks. Four bi-directional arrays can be arranged in a circular rosette that provides eight independent beams covering 360° in azimuth. Unbalanced loops have been successfully used to form end-fire, broadside, planar, and circular arrays.

Adaptive Antennas

The availability of cheap microprocessors has made it possible to use active antenna elements as the basis of adaptive antenna arrays. In an adaptive system the amplitudes and phases of the signals from a multi-element array are adjusted dynamically to give a radiation pattern maximizing the wanted signal and minimizing interfering co-channel and adjacent-channel signals. The low mutual impedance between small loops makes them ideal as components of an adaptive array.

Circular Arrays

Arrays of circularly disposed monopoles or LPDAs are used in monitoring or emitter-locating systems (see Chapter 47). A typical array comprises 18 to 36 elements. The output of each element is fed into a beamformer containing delay lines and power splitters forming a narrow azimuth beam. It is possible to generate N equispaced beams simultaneously in an N -element array by splitting the power from each element N ways.

In arrays of LPDAs it is usual to point the elements radially inward. This configuration keeps the effective electrical diameter of the array nearly frequency invariant, making the azimuth beamwidth nearly independent of frequency and eliminating azimuth grating lobes. The disadvantage of the inward-looking array is that each element fires through those opposite, and this complicates the calculation of the radiation pattern.

28.7 BROADBAND DIPOLE CURTAIN ARRAYS

Broadband dipole curtain arrays are used for high-power HF ionospheric broadcasting. A rectangular array of dipoles is mounted about $0.25\lambda_0$ in front of an untuned reflecting screen consisting of closely spaced horizontal wires (see Figure 28-12). This provides an

FIGURE 28-12 Basic HF dipole curtain array (antenna shown is designated HRS 2/4/h)

independent choice of azimuth and elevation patterns, the possibility of steering (slewing) the beam direction in azimuth or elevation, high power gain, wide impedance bandwidth, and high power-handling capacity.

Standard Nomenclature

Dipole curtain arrays are described by the internationally agreed nomenclature HRRS $m/n/h$, where

H denotes horizontal polarization

R denotes an array having a reflector curtain

R (if not omitted) denotes that the direction of radiation is reversible

S (if not omitted) denotes that the beam is slewable

m is the width of the horizontal aperture in half wavelengths at the design frequency

n is the number of the dipoles in a vertical stack

h is the height of the lowest dipole above ground, in wavelengths at the design frequency

The design frequency f_0 is approximately equal to $\sqrt{f_1 f_2}$, where f_1 and f_2 are the lower and upper frequency limits; λ_0 is the corresponding design wavelength.

Radiation Pattern and Gain

The TOA (θ_{\max}) and first null elevation angle depend on the average electrical height of the dipoles in the vertical stack and are given approximately by

$$\text{TOA} = \sin^{-1}(f_0 \lambda_0 / 4fH_{\text{avg}}) \quad (28-5)$$

$$\text{Null} = \sin^{-1}(f_0 \lambda_0 / 2fH_{\text{avg}}) \quad (28-6)$$

TABLE 28-1 Takeoff Angle of Dipole Array with Reflecting Screen

Number of elements in vertical stack n , half-wavelength spacing	Height above ground of lowest element in wavelengths, h			
	0.25	0.5	0.75	1.0
1	45°	29°	19°	15 and 48 [†]
2	22°	17°	14°	11°
3	15°	12°	10°	9°
4	11°	10°	8°	7°
5	9°	8°	7°	6°
6	7°	7°	6°	5°

[†]Two lobes present

The TOAs at f_0 are given for several configurations in Table 28-1. The lower and upper -3 -dB points are located at approximately $\theta_{\max}/2$ and $3\theta_{\max}/2$, respectively. The level of the minor elevation lobes is determined by the number of dipoles in the stack and their spacing.

The azimuth half-power beamwidth depends primarily on the width of the array, but also depends weakly on the TOA. The beamwidth at f_0 is approximately 76° for arrays one-dipole wide, 50° for two-elements wide, and 24° for four-elements wide, with beamwidths at other frequencies (f_{MHz}) being obtained approximately by multiplying these values by f_0/f . Dipole arrays with adjustable horizontal beamwidth have been constructed that use an RF switching system to excite one or more pairs of vertical stacks.

The gain at f_0 of an array of half-wave dipoles is shown in Table 28-2. The approximate gain at frequencies different from f_0 can be obtained by adding $20 \log(f/f_0)$ to the values in the table.

Slewing

Early forms of dipole curtains used full-wave dipoles. They had narrow-bandwidth feed systems and thin dipoles, so they were capable of operating only in one or two broadcast bands. The radiation patterns were slewed in azimuth by up to 15° using a switched feed arrangement

TABLE 28-2 Gain of Dipole Array with Perfect Reflecting Screen (dBi)

to provide a phase difference between the two lateral halves of the array. If greater slew angles are attempted, the horizontal pattern develops large secondary lobes that reduce gain by up to 3 dB and may interfere with co-channel transmissions from other stations. To achieve larger slew angles it is necessary to reduce the horizontal spacing between the dipoles. In modern arrays the dipole length is usually slightly less than $\lambda_0/2$, and the spacing between the stacks is $\lambda_0/2$. The slewing system (see Figure 28-13) enables slew angles to be as large as $\pm 30^\circ$. Systems with up to five slew angles are in common use.

Dipole arrays can be slewed vertically to change their takeoff angle and consequently the distance to the optimum reception area. Vertical slewing is accomplished by altering the excitation phases of the dipoles in each vertical stack using a switching system operating on the elevation feedlines.

Bandwidth

The bandwidth of a dipole array depends on the bandwidth of the dipoles (the fatter the better) and of the feed system. The feed system is usually in the form of a branched tree system (see Figure 28-13) using wideband transmission-line transformers (tapers or multi-section designs).¹³ A well-designed broadband dipole array has a VSWR of 1.5:1 or less in its operating bands. For some arrays and slews, mutual impedances cause some dipoles to exhibit a negative driving-point resistance that can cause large currents to circulate in the feed system. Large circulating currents produce high voltages in parts of the array and rapid changes in antenna input impedance, often accompanied by high input VSWR. Arrays must be designed to eliminate these resonances or to move them to frequencies outside the operating bands.

Practical Considerations

To achieve wide bandwidths, broadband arrays are constructed as fat multiple-wire cage dipoles in the form of rectangular boxes or cylinders. The dipoles are usually folded to raise their input impedances and to provide additional impedance compensation. A folded dipole operates simultaneously in two modes. The radiating mode depends only on the length and

equivalent diameter of the dipole cage. The nonradiating transmission-line mode comprises currents that flow in a loop around the dipole and through the short circuits at the end. The impedance variations of the two modes tend to cancel, so the transmission-line mode can be used to compensate and to tune the radiating mode. This compensation is optimized by moving the folded-dipole short circuit away from the end of the dipole toward the feedpoint.

HRS 4/4 arrays can be designed to have a power rating of 750 kW average (4MW PEP), which is large enough to accommodate two fully modulated 250-kW AM transmitters fed into the antenna simultaneously by using a diplexer. HRS 4/6/h arrays can be designed to handle the power of two diplexed 500-kW transmitters.

The octave bandwidth of a dipole array allows three antennas, 6/7/9/11-MHz, 9/11/13/15/17-MHz, and 13/15/17/19/21/26-MHz, to cover the whole international broadcast spectrum, with multiple-antenna coverage of many of the bands.

28.8 SITING HF ANTENNAS

Sloping and Hilly Terrain

The ground over which an antenna is mounted is seldom flat and uniform. This is of special significance when designing an antenna with a very low takeoff angle. At low elevation angles the zone over which ground reflections add to the direct signal extends far in front of the antenna, and any non-uniformities will affect the shape of the resulting elevation patterns.^{14,15}

Ground Conductivity

For vertically polarized antennas, high ground conductivity is important for the effective operation of transmitting antennas. Vertical transmitting antennas mounted very near seawater, which has a high conductivity (4 S/m), do not require ground screens for radiation-pattern enhancement. For most types of soil, conductivity is significantly smaller than this value, so metallic ground screens are sometimes used when a low takeoff angle is needed. For horizontally polarized antennas, good ground conductivity is not important, although the ground losses below the antenna can be reduced by the use of a screen of wires parallel with the direction of polarization.

Coupling Between Co-Sited Antennas

When energy is coupled between one transmitting antenna and another, it can cause the generation of intermodulation products that can interfere with other spectrum users; it can also cause the incorrect operation of reflected power protection circuits. A typical minimum acceptable coupling is between -20 dB and -30 dB, depending on the technology of the transmitters, but greater isolation will be needed if the transmitter powers involved are substantially different.

Receivers are not tolerant of high signal levels presented at their inputs. When high power transmitters are in use, very high levels of isolation are needed to avoid blocking and cross-modulation being caused in the receiver. The small effective height of active loop receiving antennas results in lower internal intermodulation products than may be provided by an LPDA or other more conventional receiving antenna.

For antennas in each other's far-field region, an estimate can be made using the standard Friis transmission equation:

$$P_r/P_t = G_r G_t (\lambda/4\pi r)^2 \quad (28-7)$$

where

P_r/P_t is the numerical ratio of received to transmitted power
 G_r and G_t are the respective power gains of the two antennas
 r is their separation (m)
 λ is the wavelength

When antennas are cross-polarized in the direction joining them, an additional isolation of 10–20 dB can be assumed. The magnitude of the coupling depends on the polarization of the antennas. For vertically polarized antennas the coupling factor is

$$C_v = 20 \log_{10} (\lambda/8\pi d) + G_t + G_r \text{ dB} \quad (28-8)$$

where

d = spacing between antennas
 G_t = gain of transmitting antenna, dBi
 G_r = gain of receiving antenna, dBi

When antennas are only a few wavelengths apart, the mutually induced currents may cause modification of the expected radiation patterns. If this is likely to be important, a computer analysis may be necessary to assess the possible extent of the interaction.

Side-by-Side Antennas

Horizontally polarized antennas with directive radiation patterns can be placed side by side, often using common towers, with an isolation exceeding 20 dB. Equations 28-7 and 28-8 do not apply in this situation because the antennas are too close. Coupling should be calculated by using computer analysis.

29.1 INTRODUCTION

The VHF and UHF bands are used for a wide variety of point-to-point and broadcast services with huge economic and social value, generating requirements for many different types of antennas. This chapter includes subjects dealt with in separate chapters in earlier editions of this Handbook and has been extended to cover recent developments in base station antennas, emphasizing methods and techniques that can be applied to these and to many other practical antenna designs. We first review matters of reliability, hardware design, construction, and cost, and then examine the design of antennas for typical applications. Antenna arrays for broadcasting and for mobile communications share many design methods, and engineers working with one of these will find many useful ideas by looking at the methods that have been applied in the other application.

29.2 DESIGN FOR RELIABILITY

Any broadcast or communication system must provide an adequate level of reliability and availability. A link may become unusable if the signal-to-noise ratio falls below the design level; it is important that the design objectives for a system specify the fraction of time for which this may occur. A downtime of 0.01% or even less may be necessary for a link to a lifesaving emergency service, but 1% downtime may be as little as can be economically justified for a radiotelephone in a boat used for leisure-time fishing.

Fading due to statistical fluctuations in the propagation path is usually guarded against by a fade margin in the power budget. In mobile systems it is standard practice to use a diversity system to reduce the impact of fading on system reliability. This takes advantage of the low correlation between fading events over two physically separate paths, at two frequencies, or for two polarizations.

Antenna failure is an important cause of system unavailability. In critical systems reliability is often increased by using two separate antennas fed through a hybrid combiner so that in the event of the failure of one antenna the system continues to operate with a reduced level of signal. When designing an antenna it is very important to understand the user's requirement for reliability and to ensure consistent performance in every delivered unit. These objectives are achieved by understanding and guarding against the mechanisms that lead to failure and inconsistency.

It is very difficult to predict the reliability of an antenna by any formal method, and users will review a proposed design in the light of their experience, looking particularly for weaknesses that may have caused them problems in the past. No telecommunications or broadcasting operator wants antennas to fail in service, and well-designed antennas can provide reliable operation over many years even in difficult climatic conditions. Over-design is expensive and is not necessary; under-design costs more money and endangers vital services. The challenge for engineers new to the field is to develop an intuitive feeling for best practice in this area. The close relationship between mechanical design and electrical function means that antennas must be designed from the outset with their mechanical construction in mind. A good antenna design brings together the best practice in electrical, mechanical, and production engineering.

We now examine important causes of antenna system failure.

Wind-Induced Mechanical Failures

The oscillating loads imposed by wind on antennas and their supporting structures cause countless failures. Aluminum and its alloys are very prone to fatigue failure, and the antenna engineer must be aware of this problem. To achieve real reliability:

1. Examine available wind-speed data for the location where the antenna is to be used.
2. Consider possible local effects such as turbulence around tall buildings or accelerated airflow over steeply sloping ground.
3. Choose suitable materials for critical high-stress components, and use de-rated permissible stress levels to allow for fatigue.
4. Check antenna designs for mechanical resonance.
5. Damp out, stiffen up, or guy parts of the antenna system that are prone to vibration or oscillation.

Base station antennas for mobile radio usually appear to be immune from wind-induced failure, but a large, heavy antenna mounted only on brackets at each end forms a mechanically resonant structure that imposes large fluctuating loads at the support points. The occasional occurrence of bracket failure has led some networks to adopt the practice that every antenna is secured by a stainless steel safety lanyard to prevent a failure in which a roof-mounted antenna could fall into a busy street. More extensive information on design against wind failure will be found in Simiu and Scanlan.¹

Corrosion

The effects of corrosion and wind-induced stresses are synergistic, each making the other worse. They are almost always responsible for the eventual failure of any antenna system. Every antenna engineer should also be a corrosion engineer; it is always rewarding to examine old antennas to see which causes of corrosion could have been avoided by better design. The essence of good corrosion engineering is

- Selection of suitable alloys for outdoor exposure and choice of compatible materials when different metals or alloys are in contact. A contact potential of 0.25 V is the maximum permissible for long life in exposed conditions.
- Specification of suitable protective processes—electroplating, painting, galvanizing, etc.

There is an enormous variety in the severity of the corrosion environment at different locations, ranging from dry, unpolluted rural areas to hot, humid coastal industrial complexes. Detailed information on corrosion mechanisms and control is provided in Uhlig² and Fontana.³

Ultraviolet Degradation

Plastics do not corrode, but they degrade by oxidation and the action of ultraviolet light. These effects are reduced by additives to the bulk materials. The extensive use of plastics in buildings and other outdoor applications has led to the availability of well-stabilized grades of polystyrene (PS), unplasticized polyvinyl chloride (UPVC), acrylonitrile butadiene styrene (ABS), and aminoisoprene-styrene copolymer (ASA). At higher frequencies the lower dielectric loss of PS makes it an obvious choice for radomes, but all these plastics are useful for radomes and other external components.

Fiberglass (GRP—glass reinforced plastic) is widely used in antenna structures and radomes. For radomes it is usual to specify polyester resin and type-E glass to ensure the lowest losses. GRP must always be protected against UV degradation by specifying a suitable stabilizer in the gel-coat. A radome often has a significant effect on the impedance of the antenna elements inside it, so care must be taken to make sure that the potentially high water absorption of polyester resin does not impair the function of the antenna. Vinyl ester resins have much lower water absorption than polyester resins; although slightly more lossy they can be used where water absorption may be a problem.

Water Ingress

Antennas are exposed to the action of rain and of wide daily and seasonal temperature cycling. Water will penetrate incorrectly designed external joints and fill internal voids in antenna or feed components. The designer must ensure that any voids are either self-draining or are hermetically sealed—there is no reliable alternative.

Ice and Snow

The accumulation of ice and snow on an antenna causes an increase in the input voltage standing wave ratio (VSWR) and a reduction in gain. The severity of these effects, caused by the capacitive loading of antenna elements and absorption of radio-frequency (RF) energy, increases as the frequency rises. It is important to check that the antenna and its mounting are strong enough to support the weight of snow and ice that will accumulate on them. This is vital because even when the risk of a short loss of service due to the electrical effects of ice can be accepted, the collapse of the antenna is certainly unacceptable! Ice falling from the upper parts of a structure onto antennas below is a major cause of failure; safeguard against it by fitting lightweight antennas above more solidly constructed ones, or provide vulnerable antennas with shields to deflect falling ice. On tall structures, falling ice creates a danger at ground level; feeder gantries must be robust enough to prevent damage by falling ice, and personnel must be kept clear of areas where falling ice presents a hazard.

In moderate conditions, antennas may be provided with radomes to cover either the terminals of driven elements or whole antennas. In more severe conditions heaters may be fitted inside antenna elements or to prevent the buildup of ice and snow on radomes. A wide range of surface treatments has been used to prevent the adhesion of ice; some of these show initial promise but become degraded and ineffective after a period of exposure to sunlight and surface pollution. Flexible radome membranes and non-rigid antenna elements have been used with some success.

Sand and Dust

Antennas in desert areas are subject to sand-laden wind, which rapidly abrades many surfaces. Fine dust accumulates in any unsealed cavity.

Breakdown under Power

An inadequately designed antenna will fail by the overheating of conductors, dielectric heating, or tracking across insulators. The power rating of coaxial components may be determined from published data, but any newly designed antenna should be tested by a physical power test. An antenna under test should be expected to survive continuous operation at 1.5 times rated mean power and at 2 times rated peak voltage; for critical applications even larger factors of safety should be specified. For multichannel systems with n channels:

$$\begin{aligned}
 p_{\text{average}} &= p_1 + p_2 + \dots \\
 &= np_{\text{channel}} \quad \text{if all channels have equal mean power} \\
 v_{\text{peak}} &= v_1 + v_2 + \dots \\
 p_{\text{peak}} &= (\sqrt{p_1} + \sqrt{p_2} + \dots)^2 \\
 &= n^2 p_{\text{channel}} \quad \text{if all channels have equal power}
 \end{aligned}$$

In-service failures of high-power antennas often occur at the joints of internal conductors. The passage of high currents through spring connections generates heat, which in turn reduces the temper of the spring, resulting in increased joint resistance and further heating; this leads to a runaway failure. Systems subject to large thermal cycling generate relative physical movement between conductors caused by differential heating and thermal expansion; this movement can cause wear and loss of contact integrity.

External insulating components are subject to the action of water and ice; as well as reducing the surface resistance of the material, water absorption can greatly increase the dielectric loss factor of insulating materials such as fiberglass. Exposed components carrying high surface fields must be designed very conservatively, and materials that are likely to suffer surface tracking should be avoided wherever possible.

Lightning Damage

Antennas mounted on the highest point of a structure are prone to lightning damage. The provision of a solid, low-inductance path for lightning currents in an antenna system reduces the probability of severe damage to the antenna. Electronic equipment is best protected by good antenna design and system grounding, supplemented (for low-power systems) by gas tubes connected across the feeder cables. Figure 29-1 shows a typical system with good grounding to prevent side-flash damage and danger to personnel.^{4,6}

Precipitation and discharge noise are caused when charged raindrops fall onto an antenna or when an antenna is exposed to an intense electric field in thunderstorm conditions. Precipitation noise can be troublesome at the lower end of the VHF band and may be

FIGURE 29-1 Typical example of good grounding practice

experienced frequently in some locations. When problems arise, antenna elements may be fitted with insulating covers. These prevent the transfer of charge from individual raindrops into the antenna circuit.

Passive intermodulation products (PIMs) are generated when radio-frequency currents flow across any joint between conductors. They will generally encounter some nonlinearity in the resistance of the joint, caused by the presence of oxide layers on the conductors and made worse by the increase in current density because of the micro-scale roughness of the contacting surfaces. It has been a longstanding practice to use single antennas for the transmission of multiple radio and TV signals, but the only limit on PIM was the radiation of unwanted spurious signals, perhaps 100 dB below the wanted signals. The advent of mobile radio base stations led to the use of a single antenna for transmission of multiple carriers in duplex operation and use of the *same* antenna for multichannel reception. This has led to the usual adoption of the requirement for PIM to be lower than -153 dB with respect to 2×20 W carriers. This ratio ($10^{15.3}$) is approximately the ratio of the distance from the earth to the sun compared with the thickness of a piece of thin paper, so achieving this limit on a consistent production basis presents a major challenge.

The achievement of low PIM depends on following clear rules in design and at all stages of production:

- Avoid any interconductor joint that is not essential to the electrical operation of the antenna.
- Ensure that every essential joint is tightly compressed and that the force on the joint does not depend on any compressible or creep-prone material.
- Avoid dry solder joints—well-soldered joints seem to cause few problems.
- Ensure PCBs are cleanly etched and well washed after processing.
- Protect all essential joints from corrosion (and wherever possible from contact with water).
- Avoid the use of metals with nonlinear conductivity or contact potentials—nickel is a known PIM source, and aluminum joints must be provided with corrosion protection and high contact forces.
- Maintain a high level of cleanliness in storage and assembly areas.

Coaxial Connectors A wide range of coaxial connector interfaces is available, and the choice between them will usually be made on the basis of the mean power ratings that the connectors must support. For permanent installation, most tower-mounted installations use Type N, 7/16-DIN, and the familiar range of bolted EIA flange connectors. If a connector is underrated, the spring inner conductor components will overheat; this leads to softening of the metal from which they are made, reduction of the contact pressure, and consequent increase in contact resistance leading to even more heating and eventual failure. The quality of the fitting of connectors is important in achieving low PIM, low VSWR, and long-term reliability.

For long-term reliability it is standard practice to provide additional weatherproofing to connectors, either by fitting a purpose-designed shrink-on boot or by wrapping with tape. Self-amalgamating tape provides physical protection, but some types do not form a waterproof bond at the connector surface; they should be overwrapped with a layer of petroleum jelly-impregnated tape, which remains waterproof for decades. Where a cable is terminated directly into connection points on the antenna—for example, in domestic radio and television antennas, it is worth applying silicone sealant to the end of the cable and the terminals of the antenna to prevent water penetrating the cable and increasing its loss.

Coaxial Cables For applications at VHF and above, the ratings of cables and connectors are generally determined by their attenuation or the mean power they are required to carry. The maximum power rating of a cable is determined by many factors:

- *The cable diameter* Large cables have lower surface current densities and more surface from which heat can be radiated or conducted.
- *The loss factor of the dielectric* Foam dielectrics have lower losses than the same material in solid form.
- *The thermal conductivity of the dielectric* Heat generated in the inner conductor must escape through the dielectric and the outer part of the cable.
- *The operating frequency* As the frequency rises, the skin depth on both inner and outer conductors diminishes, so resistive losses increase, reducing the ability of the cable to carry power.
- *The ambient temperature* The cable has a fixed maximum internal operating temperature, so in high ambient temperatures it can carry less power.
- *The thermal environment of the cable* Cables installed underground, in floor ducts, or in full sunshine, may require additional derating factors to allow for these conditions. It may be economic to fit a sunshade over a cable rather than to use a larger cable.
- *The maximum operating VSWR* The cable will become hottest at points of maximum current. In general the effect of an operating VSWR σ will be that the maximum power of the cable is reduced by a factor $1/\sigma$. The possibility of operation with a high VSWR caused by fault conditions or ice accumulation must be considered. The VSWR for this calculation should be based on the maximum VSWR into which the transmitter will operate before protective trips reduce its output power. At UHF the axial thermal conductivity of a large cable allows heat to flow away from the points of maximum current, reducing the derating factor.
- *Fault conditions* In fault conditions the power division ratio of a junction may effectively change, increasing the power into parts of the antenna. Any fault that increases the power in part of the antenna must be considered when choosing cable power ratings.
- *Peak voltages* The peak voltage rating of a cable may be exceeded before its mean power rating is reached, so its peak voltage rating or equivalent peak power rating must be checked against the operational requirement. Peak power rating limitations are common at MF and HF and may determine the choice of cables for multichannel VHF and UHF antennas.

Derating factors for these effects are applied cumulatively, so the effective power rating of a cable may be far lower than that given by the power/frequency curve in the cable specification. In a complex antenna system the cables at every level of the feed system must be assessed separately. Information on derating factors will be found in manufacturer's catalogs—often in inconspicuous tables at the back.

Large coaxial cables are heavy and difficult to bend. It is essential to allow adequate bending radii and enough clearance along the cable route to allow it to be installed and formed into position. It is always worth consulting an experienced installer to check the feasibility of complex cable runs. Arrangements for lifting and supporting cables should always be planned by reference to manufacturers' specifications.

Cables for receiving antennas are selected on the basis of their attenuation per unit length (dB/m). The least lossy cables for a given outside diameter are those with helical or foam polyethylene dielectrics. Cables with continuous copper outer conductors have the best screening against pickup when passing through regions of strong

signals—perhaps past transmitting antennas. More flexible cables have braided or tape screens, with multiple screens used for improved shielding when necessary. Some low-cost cables have sparse braids that offer relatively poor immunity to pickup of noise and spurious signals.

Large antenna systems often comprise multiple radiating elements connected by coaxial cables that may be prone to damage by wind vibration, falling ice, and personnel climbing within the array during installation or maintenance operations. To ensure high reliability, secure the cables adequately and route them where they are unlikely to be trodden on or used as “handles.” Staff working on these antennas must be trained to appreciate these issues.

Antenna Design for High Operating Power Many of the factors just listed are relevant when designing an antenna to handle any power that is high enough to cause local heating and damage to its components. A small antenna operating at 2 GHz and carrying 100 W may be vulnerable to power failure if the designer failed to recognize the need to limit power dissipation and to avoid thermally insulating the components that will generate heat under power. A multichannel GSM omnidirectional antenna designed to carry 500 W provides a critical test of the designer’s understanding of thermal design.

For components that will operate at elevated temperatures, make sure the chosen materials will not degrade at their expected operating temperature and that when power is turned on or off, the resulting thermal expansion/contraction can be accommodated without causing stresses. Where thermal expansion may cause relative movement between parts, the design must allow for this by providing a reliable low-resistance current path and avoiding wear by repeated small movements.

Power Testing There is no substitute for conducting a power test, either on a complete antenna or on critical components like radiating elements and power splitters. The mean and peak power levels for the test should be chosen to provide the factors of safety suggested in this section. To provide in-service reliability it is important to understand the operating temperatures that may be experienced by internal components, relating this to the softening point of plastics and to the maximum service temperature for spring connections and solder joints. The tools for temperature measurement include infrared thermal cameras for external components and thermochromic paints and stick-on labels for internal components. Thermochromic labels may heat up by dielectric heating in high RF fields; take care that as far as possible they are protected from them.

When conducting a power test, monitor the temperature of the largest masses to make sure the test is long enough for everything to reach thermal equilibrium. Record the ambient temperature at the time of the test, as the critical parameter is the temperature rise above the ambient temperature recorded at various points of the system; if the antenna will be used in a higher ambient temperature than during the test, allow for this when deciding on service ratings.

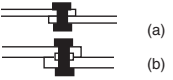

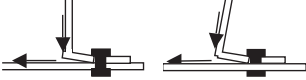

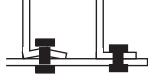

Installation Design and Practice An excellent guide to good practice is provided by the *ETSI Guide*.⁷ Large antennas will be transported in sections and reassembled on site, so all components must withstand transport and rough handling. They must be designed such that reassembly can be carried out on site by an antenna rigger who has no knowledge of the subtle points of antenna design. Components should fit together only one way (the right way) and any (unavoidably) interchangeable parts must be very clearly marked. Any components that were earlier tested as subassemblies should be marked so the same components are reassembled in the same way.

29.3 SOME UNIVERSAL PRINCIPLES

The mechanical design of any antenna system needs to provide a number of basic features:

- Repeatability of electrical characteristics between manufactured samples
- Robustness to withstand transport and installation
- Stability of electrical characteristics in service
- Resistance to lightning damage
- Low RF losses
- Low levels of passive intermodulation products

TABLE 29-1 Typical Mechanical Details Illustrating Good Design Principles for Antenna Design

Detail	Practical Imperfections	Preferred Detail Example
<p>1</p>  <p>Strip conductors joined to one another or to ground.</p>	 <p>Contact pressure at circled point is not defined. Loss, power rating, and PIM are uncertain. Impedance changes if contact point moves.</p>	 <p>(a) (b) (b) Can also be achieved by bending or pressing strip end(s).</p>
<p>2</p>  <p>Right angle connection between flat conductors.</p>	 <p>Any lack of square or deflection of the joint displaces the contact point: loss, PIM, unstable Z.</p>	 <p>Move the fixing closer to the bend, or press the flange to define the contact point.</p>
<p>3</p>  <p>Connection through a dielectric layer.</p>	<p>Most thermoplastic materials creep under pressure, so the joint integrity is lost and heating occurs. Brittle material may be fractured if joint is over-tightened.</p>	 <p>Add a sleeve over the fastener to remove stress from the dielectric and to form a stable current path.</p>
<p>4</p>  <p>Clamping through a dielectric layer.</p>	<p>The problems are the same as those of the preceding example, but this is worse because the pressure under the fastener is higher for a given joint closure force.</p>	 <p>Add a sleeve and a washer to reduce pressure; also observe precautions as in (1).</p>
<p>5</p>  <p>Current path relies on contact through thread.</p>	<p>This is particularly to be avoided. It shares the problems of (3), and the point of current flow between the screw and the upper conductor is undefined. Don't rely on current flowing from a screw into the threaded component.</p>	 <p>Defined current path.</p>
<p>6</p>  <p>Spring plug contact is smaller than hole.</p>	<p>These examples are exaggerated to show clearly what is happening.</p> <p>Current path is incorrect: impedance uncertain and current density at contact point is high. Plug will overheat.</p>	 <p>Contact is at entry to hole. It is stable and less dependent on spring temper.</p>

Their relative importance varies with the application, but fortunately, the same design methods improve all these desirable features and, with experience, many of them can be incorporated into a design with minimal extra cost, adding real value to the product.

Many important design techniques relate to the configuration of joints between conductors, whether these are part of a radiating structure or an internal feed system. RF currents flow only in the surface of the conductors that carry them, so the achievement of our objectives depends on the way in which the conductor surfaces relate to one another at every interconnection. There must be a well-defined surface current path, maintained independently of production tolerances and bearing sufficient mechanical pressure to ensure a stable current path whatever forces the joint may experience on account of temperature change, vibration, wind load, or other causes. It is essential to remember that in the real world no surfaces are flat—they are always rough and slope in one direction or another. No surfaces are exactly square, and no conductors are completely rigid. Table 29-1 shows examples that illustrate simple principles that must be followed in every antenna design. These examples are not exhaustive. If the reasons for avoiding the details in the left-hand column are appreciated, a whole variety of good solutions may often be found. The criticality of these details increases as the power and/or design frequency increase, or as the requirement for low PIM or resistance to lightning damage becomes more severe.

29.4 PERFORMANCE, RELIABILITY, COST, AND THE CHOICE OF MATERIALS

On many occasions the antenna designer will receive a complete electrical and mechanical specification for an antenna and will create a design that provides the best ratio of performance to cost. On other occasions the designer will have knowledge of the system requirement for the antenna and can optimize the technical and economic aspects of the antenna design together with its supporting structure, cables, and associated hardware; this process often provides more value to the user because the designer can balance a variety of parameters that contribute to the performance and costs of the system.

The reliability of antenna systems continues to increase, reflecting the availability of improved manufacturing techniques, better materials, and the experience of designers and users. There is a huge repertoire of solutions to obtain any needed electrical performance, so much of the antenna designer's time is now spent matching available design concepts to low-cost materials and production methods. Customers' expectations of "more for less" apply to antennas just as they do to any other product. Products that demand hours of patient adjustment to finesse them to meet their specification are not commercially viable; someone will have designed a simple product that works every time—the target we must achieve! In many respects broadcast services operate under the most difficult constraints, as they must provide a very high standard of coverage in a target region while observing stringent restrictions on signals radiated outside the target. This is made difficult because their target regions are often defined by commercial and political constraints that don't fit well with antenna design equations.

The designer must provide the required overall performance for the lowest cost. Reliability of 100% is often very difficult and costly to achieve and is only necessary for a small number of services. By comparison, 99.9% availability will entirely satisfy many users and can be provided much more readily; the user may be unable to justify the high cost of that extra 0.1%.

Cost-effective design is only obtained by:

- Identifying the availability and coverage needed
- Determining the environment at both ends of the path
- Estimating the propagation characteristics of the path and judging the reliability of the estimates
- Selecting equipment and antennas to meet the communications and reliability objectives

This is a general process, applicable to point-to-point and broadcast systems. For a point-to-point system we may have control of the equipment at both ends of the link, and resources can be balanced to provide the best solution. In a broadcast or mobile radio system, coverage plans are based on assumptions about the effective isotropic radiated power (EIRP) of the transmitter, the height and gain of the user's antenna, and the sensitivity of the receiver.

Trade-Offs

For any major scheme it is always advisable to work through the following checklist:

1. Examine the interactions of structure height, transmitter power, feeder attenuation, and antenna gain.
2. Consider using split antennas and duplicate feeders to increase reliability.
3. Consider the use of diversity techniques to achieve target availability instead of a single system with higher power and gains.
4. Review the propagation data, especially the probability of multipath or co-channel interference. Don't engineer a system with 99.9% hardware availability and find 3% outage due to co-channel problems. Check the cost of antennas designed to reduce co-channel problems by nulling out the troublesome signals and the use of diversity techniques to combat multipath fading.
5. Visit the chosen site—if that's not possible, request maps and photographs of the site and its surroundings. General wind data are useless if the tower is near a cliff edge—a careful estimate of actual conditions must be made. A nearby industrial area may mean a corrosive environment, and nearness to main roads indicates a probable high electrical noise level. Look for local physical obstructions in the propagation path. Check access arrangements to confirm assumptions that it will be possible to transport the antenna to site without taking it to pieces.
6. Don't over-design to cover ignorance. Find out!

Cost Issues

A glance through the early chapters of this Handbook demonstrates that many different types of antenna can be used as the basis of design for most applications. The choice between approaches sometimes relates to physical attributes, for example, to minimize dimensions or to ensure robustness. In the majority of cases the designer must compare a number of possible approaches and select candidates for further development on the basis of their suitability for production—the potential for using low-cost techniques and materials and avoiding critical tolerances to ensure reproducibility in production. However hard the path, it is never good enough to produce just “a design that works.”

There are no unique solutions to minimizing costs. The optimum design for any application will depend on labor and material costs in the location where production will take place, although a design that offers the user a higher performance/price ratio may succeed over a simple minimum-cost approach. A design that minimizes the number of components—using each physical component to deliver multiple functions—often provides a result with low cost, high reliability, and clear customer appeal. For a design that is going to be produced in large numbers, figure out the cost of materials, and count the number of parts, holes, fasteners, and critical dimensions. Then rework the design several times to reduce them all!

A major contribution to excess cost is overspecification of mechanical tolerances in an effort to control production variability. There is no substitute for carrying out a sensitivity analysis to check the dependence of a design on component tolerances (both mechanical and electrical)—this allows noncritical parameters to be assigned relaxed tolerances, and the design of critical areas can be reviewed to find less sensitive solutions. It is easy to assume that components manufactured using CNC (computer numerical control) machines have vanishingly small mechanical tolerances, but the designer who relies on this will soon be disappointed. Always ensure that the mechanical engineer who will translate your favorite electrical design into hardware understands which tolerances are critical, which must avoid cumulative errors, and which can be relaxed. Materials that appear interchangeable to a mechanical designer may be very different in electrical properties.

Design for Production Many antenna designs are created to be manufactured in large volumes. Not only must the designer devise a structure with all the right electrical properties—patterns, gain, VSWR, and the rest—but it must be possible to produce the design using standard industrial processes. The performance of a prototype must exceed that required in production by a large enough margin so that almost none of the units produced will be outside the required performance specification. The cost of producing the design in the target volumes, including the costs of scrap and reworking any failures, must meet the requirements of the market and the shareholders.

It is not efficient to begin a design using one technique and collection of materials, and then to decide late in development that to meet production demands the techniques and materials must be changed. An understanding of production techniques that would be economic given the forecast production volumes and rate of production must *precede* electrical design. At every step of electrical optimization the designer must bear in mind the practicability of converting the ideas into producible hardware and must understand the consequences of dimensional tolerances and variable material properties. The design task includes identifying areas of greatest risk and modifying the design to reduce their potential effects; changing materials or processes should only be considered if no cost increase would result.

Materials When selecting materials for antenna construction it is increasingly necessary to consider the need to design for recycling and to ensure that products do not contain toxic materials. The European RoHS directive and initiatives in China, Japan, and some states of the United States have led to the elimination of toxic materials from electrical and electronic products; this trend will continue, embracing a wider variety of products and potential toxins. The approach of many major international companies is to insist on compliance with at least the RoHS limits⁸ for any product they purchase. More extensive checklists follow the Japan Green Procurement⁹ or EIA recommendations.¹⁰ This process is seen as responsible citizenship rather than simply compliance with regulations. The currently restricted materials include lead, mercury, hexavalent chromium, cadmium, PBBs, and PBDEs (compounds previously used as flame-retardants in plastics). As well as prompting the move to lead-free solders, the regulations have changed practices in metal finishing, and

in the stabilization and fireproofing of resins, adhesives, and plastics. Design for recycling is a developing art that will continue to challenge old assumptions about the way materials are selected, components are assembled, and products are packed. Designers everywhere need to be aware of the rules that their companies must conform to when trading in international markets. The Internet is an excellent source of information about current legislation and best practice, both in your country and in international trade.

Conductors The conducting materials used for the construction of most VHF/UHF antennas include galvanized steel, aluminum alloys, and copper (usually in the form of transmission lines and printed circuit laminate). Other materials—including zinc, brass, and stainless steel—are sometimes used in special applications, and also to provide protective coatings. The results of using materials with lower conductivities must be understood in the context of the intended operating frequency and power. At UHF most of the current may flow in the plating rather than the base material, so plating materials must be chosen with their conductivity in mind. Efforts to enhance the conductivity of a less conductive base material are not very reliable; the conductivity of a plated metal (for example, silver) may be lower than that of the material in bulk because of the nature of the crystalline structure of the plated coating.

Insulators Most insulators are made from a surprisingly small range of materials. Antenna system power ratings are often determined by dielectric heating, so for many applications the choice of insulating materials is limited to a small group of low-loss materials: polyethylene (PE), polypropylene (PP), polystyrene (PS, or better, high-impact polystyrene—HIPS), and polytetrafluoroethylene (PTFE). Of these the first three are readily available at low cost and can be molded into complex shapes. PE, PP, and PTFE change shape significantly under prolonged mechanical loading (a process known as *creep*), especially at elevated temperatures. PTFE has a thermal coefficient of expansion that is nonlinear over the usual range of ambient temperatures. PE, PP, and PS suffer surface tracking when exposed to high electric fields—especially if the surface is exposed to rain—and tracking immediately carbonizes the surface, leading to rapid failure. PTFE can be used successfully with significantly higher tangential electric fields along the surface than the other materials. When designing with plastics it is advisable to specify the exact material (including manufacturer and grade). Permittivity and dielectric loss may vary between different grades of the same generic material, especially if recycled material has been included. Ceramic insulators are expensive and are not commonly used in VHF/UHF antenna systems. When using a material for the first time always check its relative permittivity, loss factor, and water absorption.

Printed Circuit Boards These are increasingly used for the construction of antennas at frequencies from the UHF TV band upward. They provide a low-cost method of reproducing large volumes of devices with tight tolerances for use at low and medium powers. The main problems associated with their use are as follows:

Power limitation is caused by lossy dielectric, limitation of current density in narrow conductors, and high field strengths associated with the inevitable sharp edges of etched conducting tracks. When working with laminates based on PTFE or other high-temperature materials, remember that the failure point of the laminate may occur at a very high temperature, so the power rating of an antenna may be limited by the power capable of unsoldering the input connector. Unless provision is made to transfer heat from the critical components, failure may occur at a much lower power than expected.

Performance variability is caused by tolerances in the dielectric constant of the laminate, etching tolerances (over-/under-etch), and problems on long antennas caused by stretching of the photographic film carrying the negative image of the tracks. Errors in

registration between the faces of double-layer structures and tolerances in the positions of holes and other features must not be overlooked. When manufacturing long boards with close tolerances it is important to keep the film negatives for different layers together, so that any stretch does not cause progressive registration errors, and they should preferably be stored flat or laid out flat for some time before they are used. Under- and over-etching cause the width of microstrip lines and other features to vary and can be detected by positioning telltale features at strategic locations. Gap-and-track or wedge features can make very small under-/over-etch clearly visible to the naked eye.

Mechanical stability When designing with PTFE-based laminates it is very important to remember the very poor creep strength of this material, even when reinforced with glass. No electrical connection should rely on compression of the laminate—it will simply flow away, and the integrity of the electrical contact will be lost.

None of these limitations is insuperable, but every designer must understand them, control their extent, and manage their effects. This becomes more critical as the operating frequency is increased. There are few fixed rules, as many of the effects depend on the processes used by the board fabricator and the etching shop. The mobile radio base station market has driven many changes in the cost and variety of available materials and the availability of processors who can cope with boards up to 2.5 m long.

Computer Design Tools

The art and science of antenna design has been hugely advanced by the availability of powerful low-cost computers and specialist electromagnetic simulation packages. For some purposes a computer model will provide a highly accurate estimate of the performance to be expected from a real antenna and allows optimization to meet a practical requirement. Some antennas are still too complex to model as a whole (for example, a large multi-tier TV broadcast array), and the whole design problem must be divided into separate areas for optimization—in this case the design of the panel and the power dividers, the optimization of the geometry and excitation of a tier of the array to create the required azimuth radiation pattern, and the design of the excitation of each tier to provide the required elevation radiation pattern. Simulation is very useful for investigating the effects of mechanical and material tolerances.

As the operating frequency increases, the precision with which an antenna is modeled becomes increasingly important, especially in the input region. Software tools can analyze the performance of an antenna structure but in general are unable to synthesize antennas or arrays to meet specific requirements. A computer does not understand how an antenna works, or which aspects are important to the user; it simply predicts the performance of the input structure.

In the frequency bands addressed by this chapter, moment-method and time domain simulation tools are useful. Full 3D tools are needed for many applications, but 2D or 2½-D tools are useful for some antenna structures and microstrip feed systems.

Computer analysis of aerodynamic and structural design is usually carried out using finite-element methods and allows designers to optimize the shape of critical antenna components. A wide variety of commercial software is available, and every organization engaged in antenna design needs to have access to programs appropriate to the complexity of the work in which it is engaged.

The designer should always view simulation outputs showing the fields, currents, or mechanical stresses present in an antenna design. An intuitive feel for their behavior is one of the hallmarks of the successful designer.

29.5 SAFETY: RADHAZ

The maximum permitted RF field and power flux levels to which personnel may be exposed are specified in various national and international regulations¹¹ and corresponding national standards. These ensure that the effects of the electromagnetic fields on the human body are controlled at a level at which no health effects are known to occur. Those working around LF, MF, and HF antennas should also recognize that the limiting parameter may be the intensity of the H -field rather than E -field or power flux density. Antenna engineers and riggers are probably the most exposed group in the population, and they should be particularly aware of the exposure standards and the need to avoid overexposure of themselves and others.

Antenna engineers become accustomed to working with antennas carrying powers that may be sufficient to cause death or serious injury. Whether climbing close to broadcasting antennas or mobile radio base stations, or conducting power tests in a laboratory, all those working with live antennas need to be made aware of the potential hazards created by non-ionizing radiation. When possible all power should be removed from antennas before climbing near them; transmitters should be locked off, and the person working on the antenna should take the keys or the fuses so that no one can inadvertently apply power while work is in progress. When it is necessary to pass close to operating antennas a competent person should calculate the probable exposure to high fields, and the personnel concerned should carry personal alarms to warn them if they move into areas of unacceptably high field strength. When designing new antennas that are intended to allow internal access (like VHF/UHF panel arrays), care must be taken to make sure that internal access ways are well enough screened to allow safe access, if necessary after reducing normal operating power to permit access. Explicit advisory notices must be placed at the base of the antenna supporting structure to advise workers of the necessary precautions to ensure their safety.

Routine production testing of the passive intermodulation performance of base station antennas creates a significant hazard, and facilities must provide foolproof protection of personnel using the facility and reassurance for those in the vicinity; this can be provided using infrared beams or pressure-sensitive mats to switch off the power in the event that someone is too close to the antenna under test.

Public concerns regarding the possible hazards posed by radio installations appear increasingly likely to be unfounded.¹² Typical power flux densities to which the public is exposed are usually three orders of magnitude below the international limits. Antenna engineers have a responsibility to provide others with accurate estimates of exposure levels and to monitor the developing research literature on potential health effects.¹³⁻¹⁵ Field strengths many wavelengths distant from an antenna—for example, at points on the ground or on nearby rooftops—can be calculated on the basis of the power flux per unit area. The power flux through the surface of a sphere of radius r surrounding an isotropic radiator radiating W_t watts is $W_t/4\pi r^2$ watts per square meter. For an antenna with gain G , the power flux is $GW_t/4\pi r^2$ W/m². By knowing the mean input power to the antenna, its gain in the direction of interest, and the distance to the point of potential exposure, the likely power flux can be calculated and compared with that permitted. At points close to the antenna a simple and reasonably accurate power density estimate is obtained by assuming that W_t watts flow out through a cylindrical surface with the same length as the antenna and a width equal to the distance between the 3-dB points at the relevant distance from the antenna. Assume a back-to-front ratio of only 10 dB for persons close to the antenna, because they cannot be expected to stay in the rear minimum.

29.6 PROPAGATION

The study of propagation effects in the VHF/UHF bands is beyond the scope of this chapter, but all designers of systems required to produce reliable end-to-end connection need to familiarize themselves with tropospheric effects, terrain blocking, and the effects of the built environment. While the prediction of loss over a point-to-point path is relatively straightforward, the prediction of coverage for broadcast and cellular systems has to be approached on a statistical basis to allow for the variations in the position and path conditions to large numbers of users. The possibility of signal impairment by multipath propagation affects many systems. When designing antennas for a long link, consider the possible effects of fading and ducting, in which typical signal levels are either reduced, causing the potential loss of established links, or increased, causing potential co-channel interference from distant users of the same frequency.

Propagation effects influence antenna system design in a variety of ways including the provision of adequate gain and fade margin, the height at which antennas must be mounted, the choice of polarization, and the provision of space, polarization, or frequency diversity. Detailed prediction of coverage areas of broadcast and cellular systems is usually carried out using computer simulations, and a wide variety of planning tools is available, embodying terrain models of various degrees of detail and sophistication. A comprehensive set of graphical data is provided in Shibuya.¹⁶

Use of the finite resource of the electromagnetic spectrum is optimized not only by the adoption of optimum modulation systems and signal formats, but also by the choice of antenna characteristics. Frequency reuse in cellular systems is managed by the positioning of base stations, antenna pattern specifications, and the use of elevation downtilt. The avoidance of co- and adjacent-channel interference in domestic TV systems is managed by the radiation pattern specifications applied to broadcast stations and domestic receiving antennas.

Choice of Polarization

Base stations for mobile services formerly used vertical polarization because it was simple to provide omnidirectional antennas at the mobile terminals and the base station. Cellular systems now often use 45°-slant linear polarization because the signals received from a typical mobile on a pair of antennas polarized at +45° and -45° have sufficiently low correlation to provide useful diversity gain. Circular polarization is often used for radio services to reduce the influence of the polarization of the receiving antenna and to make it easier for the untrained user to find a consistent high-quality signal.

There is sometimes an advantage in using horizontal polarization for obstructed point-to-point links in hilly terrain, but the choice of polarization is often determined by the need to control co-channel interference. Orthogonal polarizations are often chosen for antennas mounted close together in order to increase the isolation between them.

The use of circular polarization (CP) can reduce the effects of destructive interference by reflected multipath signals, so CP should be considered for any path where this problem is expected. CP has been used with success on a number of long grazing-incidence over-sea paths where problems with variable sea-surface reflections had been expected to be troublesome. Both ends of a CP link must use antennas with the same sense of polarization. In some countries circular polarization is used for TV services, but for this application the receiving antenna is usually horizontally polarized.

29.7 POINT-TO-POINT LINKS AND BROADCAST RECEIVING ANTENNAS

Most low/medium gain antennas are of end-fire design. When higher gain is needed, it is usually obtained by forming arrays of basic end-fire antennas. The antenna styles described here are only a small subset of all the possible designs, but they represent a large proportion of antennas used worldwide for practical applications.

In some countries, bowtie dipole and corner reflector designs are popular for domestic TV reception, and they are described later in this section. From a cost/performance point of view they have little significant advantage. Simple log-periodic antennas will cover the UHF band. A variety of hybrid Yagi-Uda, log-periodic, and other solutions is used to provide multiband operation over the VHF and UHF bands. Many of these designs have only modest gain, but the high signal levels available outdoors in many cities allow them to provide adequate reception. In situations with co-channel interference or multipath (ghosting), a more conventional antenna with a narrower azimuth beamwidth and lower sidelobes is often preferred.

Yagi-Uda Antennas

The Yagi-Uda antenna is the most successful general-purpose directional antenna design at frequencies up to at least 2.5 GHz. It is inexpensive and simple to construct, and will provide gains of up to about 17 dBi (or more if a multiple array is used). Its bandwidth can be chosen to suit the application; almost an octave bandwidth can be achieved, but at the expense of a lower gain than can be provided over a narrower band. At low frequencies the realizable gain is limited by the physical size of the antenna; in the upper UHF band a reflector antenna may be simpler, less costly, and more reliable if a large gain is required.

Yagi-Uda antennas provide unidirectional beams with moderately low side and rear lobes. The characteristics of the basic antenna can be modified in a variety of ways, some of which are shown in Figure 29-3. The basic antenna (*a*) can be arrayed in linear or planar arrays (*b*). When the individual antennas are correctly spaced, an array of N antennas will have a power gain N times as large as that of a single antenna, less an allowance for feeder losses. Table 29-2 indicates typical gains and arraying distances for Yagi-Uda antennas of various sizes. Different array spacings may be used when a deep null at a specified bearing is required, but the forward gain may be slightly reduced.

To achieve closely definable radiation patterns it is important to feed the radiating element using a suitable balun to avoid unwanted radiation from the feed cable. Typical Yagi-Uda antennas will provide cross-polar discrimination (XPD) of at least 20 dB in the main beam direction; higher XPD can be obtained by observing good symmetry and a well-balanced feed/balun system.

Yagi-Uda antennas can be built to support high input powers, and they are commonly used for directional broadcast transmission. Only one element and its drive circuit must be specially designed to support high input power.

The bandwidth over which the front-to-back ratio is maintained may be increased by replacing a single reflector rod by two or three parallel rods (*c*)—as often used for domestic TV receiving antennas. The back-to-front ratio of a simple Yagi-Uda antenna may be increased either by the addition of a screen (*d*) or by arraying two antennas with a quarter-wavelength axial displacement, providing a corresponding additional quarter wavelength of feeder cable to the forward antenna (*e*). A well-designed screen will provide a back-to-front ratio of as much as 40 dB, while that available from the quadrature-fed system is typically 26 dB.

FIGURE 29-2 Configurations of Yagi-Uda antennas: (a) Standard six-element antenna; (b) Stacked and bayed arrays; (c) Double reflector rods; (d) Reflector screen; (e) Increased F/b ratio by $\lambda/4$ offset; (f), (g), (h) Arrangements to produce azimuth radiation patterns for special applications

TABLE 29-2 Typical Data for Yagi-Uda Antennas

Number of Elements	Typical Gain, dBi	Spacing for Arraying, λ
3	7	0.7
4	9	1.0
6	10.5	1.25
8	12.5	1.63
12	14.5	1.8
15	15.5	1.9
18	16.5	2.0

Circular polarization can be obtained by using crossed Yagi-Uda antennas: a pair of antennas mounted on a common boom with their elements set at right angles. The two antennas must be fed in phase quadrature or be fed in phase and mutually displaced by a quarter wavelength along the boom. (Using the in-phase method the equality of the phases and current amplitudes on the two components is less disturbed by the VSWR of the individual antennas as long as they are identical.)

There has been some interest in slow-wave end-fire arrays that use long, closed forms for their elements, such as rings or squares. They have not proved popular in practice, probably because they have narrower bandwidths than an optimal Yagi-Uda antenna and are more complex to manufacture. The domestic TV receiving antenna market is sometimes subject to fashion, and some interesting local variants are seen in cities round the world.

Log-periodic antennas are widely used for applications in which a large frequency bandwidth is needed. The gain of a typical VHF or UHF log-periodic antenna is about 10 dBi, but larger gains can be obtained by arraying two or more antennas. The disadvantage of all log-periodic designs is the large physical size of an antenna with only modest gain. This is because only a small part of the whole structure is active at any given frequency.

The most common design used on the VHF-UHF bands is the log-periodic dipole array (LPDA). (See Chapter 13 and Kraus and Marhefka.¹⁷) After selecting suitable values for the design ratio τ and apex angle α , the designer must decide on the compromises necessary to produce a practical antenna at reasonable cost. The theoretical ideal is for the cross-sectional dimensions of the elements and support booms to be scaled continuously along the array; in practice, the elements are often made in groups by using standard tube sizes, and the support boom is often of uniform cross section. The stray capacitances and inductances associated within the feed region are sometimes troublesome, especially in the UHF band, and can be compensated only by experiment. The coaxial feed cable is usually passed through one of the two support booms to avoid the need for a wideband balun.

Printed-circuit techniques can readily be applied to LPDA design in the UHF band and above, as the antenna is easy to divide into two separate structures that can be etched onto two substrate surfaces. At the lower end of the VHF band the dipole elements may be constructed from flexible wires supported from an insulating catenary cord.

A typical well-designed octave-bandwidth LPDA has a VSWR less than 1.3:1 and a gain of 10 dBi. Log-periodic antennas have been widely used both as TV receiving antennas and also as transmitting antennas at low-power relay stations in the VHF and UHF broadcast bands. LPDAs are produced commercially for surveillance and measurement applications with bandwidths exceeding a decade. Other log-periodic designs that can be found in Chapter 13 are less common in commercial application in the VHF/UHF bands, probably for reasons of cost and windload.

Helices A long helical antenna has an easily predicted performance and is simple to construct and match. A VSWR as low as 1.2:1 can be obtained fairly easily over a frequency bandwidth of 20%, and wider bandwidths are possible if the helix is tapered or stepped in diameter. Conductive spacers may be used to support the helical element from the central support boom, so the antenna can be made very robust. At higher frequencies it may be more convenient to support the helical element by winding a conducting tape onto a dielectric rod or tube. The maximum gain that can be obtained from a single helix is limited by the physical length that can conveniently be supported, typically ranging from 12 dBi at 150 MHz to 20 dBi at 2 GHz.

Helices can be arrayed for increased gain; to obtain correct phasing the inputs must be driven in phase, and the start position of each helix in the array must be the same. Low gain helices—in particular, short quadrifilar helices—find application as reflector feed units and as antennas for small satellite terminals.¹⁸ Ceramic-loaded quadrifilar helices have been used as receiving antennas for GPS systems.¹⁹ For further information on the design and performance of helices see Chapter 12.

Bowtie Dipoles and Reflectors

Arrays comprising a column of bowtie dipoles mounted in front of a reflecting screen are common as horizontally polarized domestic TV receiving antennas in some countries. The triangles can be approximated with wire mesh, provided the mesh spacing is less than one-tenth wavelength, or by a fan of rods connected at the feedpoint. Flare angles between 60° and 80° combined with a half-length up to 0.58λ provide satisfactory input impedance and radiation patterns. To provide more gain and an increased front-to-back ratio, dipoles are usually stacked vertically and mounted approximately 0.25λ in front of a reflecting screen made from parallel rods spaced 0.1λ apart (at f_{\max}). In this configuration the dipoles are fed by an open balanced transmission line. The measured gain for one and two dipoles over a flat screen is also shown in Figure 29-4. Commercially available antennas typically have a VSWR less than 2.0, a front-to-back ratio greater than 15 dB, and sidelobe levels less than 13 dB below the peak gain over 90% of the UHF band.

Corner Reflectors Well-designed corner-reflector antennas are capable of providing high gain and low sidelobe levels, but below 100 MHz they are mechanically cumbersome. Before using a corner reflector, make sure that the same amount of material could not be more effectively used to build a Yagi-Uda antenna, or perhaps a pair of them, to do the job better.

In the UHF band, corner reflectors can be very simply constructed from solid or perforated sheet and a variety of beam-widths and back-to-front ratios obtained by the choice of the apex angle, spacing of the dipole from the vertex, and the width of the reflector. The apex of the corner is sometimes modified to form a trough (see Figure 29-5). The provision of multiple dipoles extends the antenna aperture and increases the available gain.

Panel Antennas An antenna that comprises a reflecting screen with simple radiating elements mounted over it, in a

FIGURE 29-3 Bowtie dipole

FIGURE 29-4 Gain characteristics: (a) Bowtie dipole ($\alpha = 70^\circ$, $A = 190$ mm); (b) Bowtie dipole in front of screen (550×480 mm); (c) Two tiers stacked 600 mm apart in front of a screen

broadside configuration, is generally termed a *panel antenna*. An array may comprise one or more panels connected together.

Typical panels use full-wavelength dipoles, half-wave dipoles, or slots as radiating elements (see Figure 29-6). For some applications they have advantages over Yagi-Uda antennas:

- More constant gain, radiation patterns, and VSWR over a wide bandwidth—up to an octave
- More compact physical construction—the phase center is maintained closer to the axis of the supporting structure, providing better control of the azimuth radiation pattern
- Very low coupling to the mounting structure
- Low side lobes and rear lobes

FIGURE 29-5 Corner and trough reflectors

FIGURE 29-6 Panel antennas: (a) Two full-wave dipole elements; (b) Two batwing slot elements; (c) Skeleton-slot elements

Panel antennas for frequencies in the UHF band lend themselves to printed-circuit design methods, as the radiating structures, feedlines, and matching system may all be produced by stripline techniques. At lower frequencies the radiating elements are often mounted at voltage minimum points using conducting supports, so a strong, rigid construction can be produced. A solidly built but lightweight panel for a military application is shown in Figure 29-7a. Here an all-welded aluminum frame and a skeleton-slot radiator are used so that the antenna will resist rough use in the field. Panels are often used as building blocks for complex arrays for radio and TV broadcasting.

Paraboloids The design of a high-gain antenna may be reduced to a problem of illuminating the aperture necessary to develop the specified radiation patterns and gain. The size of the aperture is determined only by the gain required, whatever type of element is used to fill it. As the cost of the feed system and the radiating elements doubles for each extra 3-dB gain, a stage is reached at which it becomes attractive to use a single radiating element illuminating a reflector that occupies the whole of the necessary antenna aperture. The design task is reduced to choosing the size and shape of the reflector and specifying the radiation pattern of the illuminating antenna. If the antenna aperture is incompletely filled or its illumination is non-uniform, the gain that is realized decreases. The ratio of the achieved gain to the gain obtainable from the same aperture when it is uniformly illuminated by

FIGURE 29-7 Robustly constructed antennas for military use: (a) Skeleton-slot-fed panel (225–400 MHz); (b) Grid paraboloid (610–1850 MHz) (Courtesy of Jaybeam Ltd.)

TABLE 29-3 Typical Paraboloid-Antenna Configurations

Frequency (MHz)	Diameter (m)	f/d ratio	Construction	Feed Type
200	10.0	0.5	Mesh paraboloid	4-element Yagi-Uda
700	3.0	0.25	Solid skin	Dipole and reflector
900	7.0	0.4	Perforated steel sheet	Horn
610–960	1.2	0.25	Grid of rods	Slot and reflector
1500	2.4	0.25	Solid skin	Dipole and disk
1350–2500	1.2	0.25	Grid of rods	LPDA

lossless elements is termed the *aperture efficiency* of the antenna. In a receiving context, this quantity represents the proportion of the power incident on the aperture that is delivered to a matched load at the terminals of the antenna.

In the VHF and UHF bands, a reflector may be made of solid sheet, perforated sheet, wire mesh, or a series of parallel curved rods. As the wavelength is large, the mechanical tolerance of the reflector surface is not very demanding, and various methods of approximating the true surface required are possible. Table 29-3 indicates some of the combinations of techniques currently in use and illustrates the diversity of the methods that are successful for various purposes.

Grid paraboloids are attractive to produce because the curvature of all the rods is exactly the same; only their length varies across the antenna. A typical example is shown in Figure 29-7b. The main deficiency of grid paraboloids is the leakage of energy through the surface, restricting the front-to-back ratio that can be achieved. For example, at 1.5 GHz a front-to-back ratio of -30 dB is a typical limit. If a greater front-to-back ratio is needed, it may be possible to adopt an offset geometry. Alternatively, the reflector bars can be extended in depth, or an orthodox continuous skin of solid or perforated sheet can be used in place of the grid; the consequent increase in weight and wind-loaded area must be accepted as a necessary penalty for improved electrical performance. Electrically small reflectors have poor radiation pattern performance because the feed has physical dimensions independent of the reflector diameter, so feed blockage is more troublesome and leads to high sidelobes.

Radomes are frequently fitted to feeds or complete antennas in order to reduce the effects of wind and snow. They may be made from fiberglass or in the form of a tensioned membrane across the front of the antenna. In severe climates it is possible to heat a radome with a set of embedded wires, but this method can be applied only to a plane-polarized antenna.

Point-to-point links using tropospheric-scatter propagation require extremely high antenna gains and typically use a reflector that is an offset part of a full paraboloidal surface constructed from mesh or perforated sheet. Illumination is provided by a horn supported at the focal point by a separate tower. For a full discussion of the design of reflector antennas refer to Chapter 15.

29.8 OMNIDIRECTIONAL ANTENNAS

Simple Low-Gain Antennas The simplest types of antennas will provide truly omnidirectional azimuth coverage only when mounted in a clear position on top of a tower. Figure 29-8 shows standard configurations for ground-plane and coaxial dipole antennas and demonstrates that these forms are closely related. They are cheap and simple to

FIGURE 29-8 Low-gain base-station antennas: (a) Standard ground plane with radials; (b) Ground plane with sloping radials; (c) Ground plane with closed ring; (d) Coaxial dipole

construct, and may be made to handle high power. Exact dimensions must be determined by experiment, as the stray inductance and capacitance associated with the feedpoint insulator cannot be neglected. The use of a folded feed system can provide useful mechanical support and gives better control over the antenna impedance. (Both the relative diameter of the feed and grounded conductors and the point of their interconnection can be varied.) The operational bandwidth of the coaxial dipole d depends critically on the characteristic impedance Z_0 , of the coaxial section formed by the feedline (radius r) inside the skirt (radius R). If this section has too small a Z_0 , radiating currents will flow on the outside of the feeder line unless the skirt length is exactly $\lambda/4$. The impedance, gain, and radiation pattern of the antenna then become critically dependent on the positioning of the feedline on the tower, severely limiting the useful bandwidth of the antenna.

Discone Antennas The discone and its variants are the most commonly used low-gain wideband antennas. The useful lower frequency limit occurs when the cone is a little less than $\lambda/4$ high, but the upper frequency limit is determined almost entirely by the accuracy with which the conical geometry is maintained near the feedpoint at the apex of the cone.

Discones may be made with either the disk or the cone uppermost. The support for the upper part of the antenna usually takes the form of low-loss dielectric pillars or a thin-walled dielectric cylinder, fitted well outside the critical feed region.

Variants of the basic discone use a bicone in place of the conventional cone and replace the disk by a short cone with a large apex angle. At the lower end of the VHF band discone antennas can be mounted at ground level, so a minimal skeleton disk that couples to the ground may be used if some loss of efficiency and the propagation effects associated with a low antenna elevation can be accepted.

Collinear Arrays The ground plane and coaxial dipole have about the same gain as a half-wavelength dipole. When more gain is needed, the most popular omnidirectional antennas are simple collinear arrays of half-wave dipoles. The original array of this type is the Franklin array shown in Figure 29-9a. This design is not very convenient owing to the phase-reversing stubs that project from the ends of each half-wave radiating section, but various derivatives are widely used. The arrangement at Figure 29-9b uses non-inductive meander lines to provide phase reversal; that at c is a rearrangement of the original, while those at d and e use coaxial line sections. Arrangements such as these may be mounted in fiberglass tubes to provide mechanical support, and the designs at b , c , and f are suitable for production by printed-circuit techniques. In each of these arrangements, the elements are connected in series; an input-matching section transforms the input impedance of the lower section, which may be $\lambda/2$ or $\lambda/4$ long, to 50 Ω . A set of quarter-wavelength radial

elements or a quarter-wavelength choke is used to suppress currents on the outside of the feeder cable. The maximum useful gain available from these arrays, typically about 10 dBi, is limited by two factors:

- There is mechanical instability in a very long antenna with a small vertical beamwidth.
- The available excitation current diminishes away from the feed as a result of the power lost by radiation from the array.

In the case of the coaxial-line designs, each section is shorter than a free-space half-wavelength so that the correct phase shift is obtained inside the section. The examples shown would typically provide a gain of 9 dBi at the design frequency. The useful bandwidth of series-fed collinear antennas is inherently narrow because of the phase error between successive radiating sections that occurs when the frequency is changed from the design frequency. The typical behavior of the major lobes of the vertical radiation pattern of these arrays is shown in Figure 29-10. A further problem with long arrays is that as the array length is increased, the series connection of the elements results in an increased input impedance; as the transformation ratio of the input feed network increases, so the input impedance bandwidth is reduced.

Parallel-Fed Arrays Much greater control is obtained by using an array of fat dipoles with an internal, branched, parallel-connected feed system. Arrays of this type provide stable gain, radiation patterns, and input VSWR over wide bandwidths. A well-optimized eight-element array is able to provide acceptable gain (~10 dBi), radiation patterns, and input VSWR (< 1.7) over the band 225–400 MHz and is suitable for ground-to-air communications; at

FIGURE 29-10 Vertical radiation pattern of a typical end-fed array

FIGURE 29-11 Pole-mounted dipoles: (a) Inline; (b) Four dipoles spaced around a pole; (c) Eight dipoles spaced around a pole

this frequency the diameter of a structural GRP radome is around 250 mm. Antennas may be designed using a combination of parallel and series feeding; for example, an array can be designed as two end-fed arrays end-to-end, and fed in the center where they join. As requirements for elevation pattern stability increase, the array must be further subdivided into parallel-fed units.

Dipoles on a Pole A simple offset pole-mounted array is shown in Figure 29-11a. This will provide a gain of about 10 dBi in the forward direction but typically only 4 dBi rearward, depending on the pole diameter and the spacing between the dipole and the pole axis. An attempt to avoid this problem is shown in Figure 29-11b, but this type of antenna has distorted vertical radiation patterns caused by the phase shifts that result from the displacement of the dipoles; gain is also reduced to about 6 dBi for the four-element array shown.

The solution in Figure 29-11c, in which dipoles are placed in pairs and are cophased, is more satisfactory, as the phase center of each tier is concentric with the supporting pole. However, the antenna is relatively expensive, as in this arrangement eight dipoles provide only 6-dB gain over a single dipole.

One possibility is to use the inline stacked array in Figure 29-11a and to place the base station toward the edge of the service area. The rearward illumination may be improved if the spacing between the dipoles and the pole is optimized for the pole size and operating frequency.

Analytical solutions to the azimuth pattern are available, and simpler computer programs provide results in good agreement with measurements. When designing the feed networks for multi-element arrays of this type, take care to allow for the effects of mutual impedances, especially when unequal currents or asymmetric geometries are used.

Antennas on the Body of a Tower Figure 29-12a shows a measured horizontal radiation pattern for a simple dipole mounted from one leg of a lattice tower 2-m face width. The distortion of the circular azimuthal pattern of the dipole is very typical and is caused by blocking and reflection from the structure. By contrast, Figure 29-12b shows what can be achieved by an antenna comprising three dipole panels mounted on the same structure. The penalty of adopting this improved solution lies in the cost of the more complex antenna, so before an optimum design can be arrived at, the value of the improved service must be assessed.

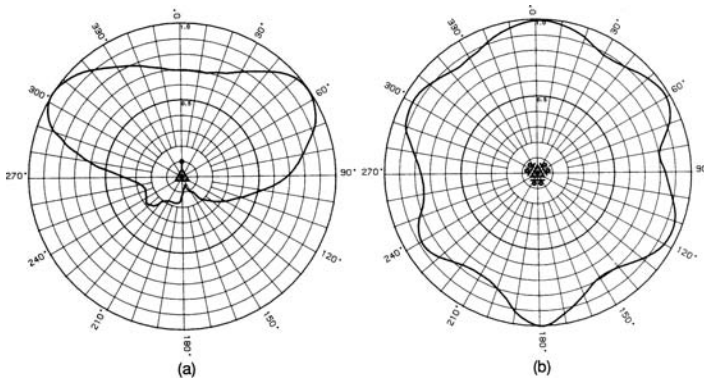

FIGURE 29-12 Typical azimuth patterns of (a) VHF dipole mounted off one leg of a triangular mast and (b) three dipole panels mounted on the same structure (linear field plot)

The horizontal radiation pattern of a complete panel array is usually predicted from measured complex radiation-pattern data for a single panel, using a suitable computer program. For each azimuth bearing, the angle from each panel axis is found, and the relative field in that direction is obtained. The radiated phase is computed from the excitation phases and physical offsets of the phase centers of the individual panels.

Depending on the cross-sectional size of the structure, the most omnidirectional coverage may be produced with all panels driven with the same phase or by a phase rotation around the structure; for example, on a square tower the element current phases would then be 0, 90, 180, and 270°. When phase rotation is used, the individual elements may be offset from the centerlines of the faces of the structure to give a more omnidirectional azimuth pattern, as in Figure 29-13.

A panel array comprising four tiers, each of four panels, is an expensive installation, but if properly designed, it can have a useful bandwidth of as much as 25%. This allows several user services to be combined into the same antenna, each user having access to a very omnidirectional high-gain antenna.

Groups of panels may be arranged and fed to produce an azimuth pattern tailored to the arbitrary requirements of the service area or to provide nulls necessary to meet co-channel protection objectives. Panel arrays are discussed in further detail with reference to their use by broadcasting services in Section 29.9.

VHF/UHF base-station antennas are sometimes situated on the bodies of large towers, perhaps up to 10 m in diameter. It is not economically possible to provide smooth omnidirectional coverage from such a large structure. However, by use of some lateral thinking, it may be possible to

FIGURE 29-13 Plan arrangement of an omnidirectional panel array on a large tower

make a virtue out of a necessity. It is often possible to provide solid coverage of an arc of 270° , or to use two frequency channels, providing overlapping coverage in the region of greatest traffic. If the station operator can guarantee the rearward null in the azimuth patterns at both frequencies, the frequency planner may benefit, and the operator may get two channels where they matter most.

Special-Purpose Arrays For applications in which the largest possible coverage must be obtained, the azimuth radiation pattern of the antenna must be shaped to concentrate the transmitted power in the area to be served, for example, an airway, harbor, or railroad track. Energy radiated in other directions is wasted and is a potential cause of interference to others.

Antennas with cardioidal azimuth radiation patterns are useful for a wide range of applications. Simple two-element arrays (dipole plus passive reflector) or dipoles mounted off the face of a tower may be adequate, but a wider range of patterns is available if two driven dipoles are mounted on a single supporting boom and excited with suitably chosen currents and phases.

When a signal must be laid down over an arbitrarily shaped area of terrain, Yagi-Uda arrays or LPDAs may be arranged as at Figure 29-2*f* and *g*. Due allowance must be made for the separation of the phase centers of the antennas when computing the radiation patterns. As an approximate guide, the phase center of a Yagi-Uda antenna lies one-third of the way along the director array, measured from the driven element. Further tiers of antennas may be used to increase the gain of the system without modifying the azimuth radiation patterns.

29.9 ANTENNAS FOR BROADCAST SERVICES AND BASE STATIONS

One of the characteristics shared by broadcasting antennas and mobile base station antennas is that they are usually linear vertical arrays of some form of standard radiating element. This format derives from the requirement to lay down a signal over some defined area of the surrounding terrain while concentrating the radiated energy into a well-focused beam in the elevation plane; radiation skyward is wasted, so the objective is to concentrate as much energy as possible toward the outer edges of the served area (sometimes, but not necessarily, the horizon). The characteristic of linear arrays is that the radiation patterns obtained in the vertical (elevation) plane and the horizontal (azimuth) plane are mathematically separable. That is, the elevation pattern is determined by the way in which the radiating elements are physically arranged and electrically fed in the vertical plane—the nature of the individual elements only matters to the extent that the pattern is the product of the elevation pattern of the individual elements and the array factor generated by the chosen spacing and complex feed currents. The azimuth pattern is independent of the way in which successive vertical tiers are fed and only depends on the arrangement of a single tier (bay) of elements. It is important to appreciate that this separability collapses if the main beam of the antenna is deflected downward away from the horizontal direction, or if the successive tiers of the antenna do not have identical azimuth patterns. The main difference between broadcasting and base station antennas is that in broadcast practice it is usual for antennas to have wider and more complex azimuth patterns than base station antennas.

Before looking at the methods for the design of these antennas it is worth reviewing some basic array theory. First consider an array of elements spaced in the vertical plane, providing omnidirectional azimuth coverage. If the aperture is large, say more than eight wavelengths, the total directivity is only a function of the length of the array. We can fill it

with elements with low directivity (isotropic radiators) or higher directivity (for example, vertical dipoles one wavelength long), but as long as we *fill* the aperture with elements, the directivity will be the same. (This doesn't apply in the same way to short arrays because the effective aperture can "overhang" the physical aperture by a more significant proportion.) As a rule of thumb, the maximum directivity of an omnidirectional array will be about 1.15 times per wavelength of vertical aperture. If the aperture is underfilled—the elements are too far apart—the result will be lower directivity because energy is lost from the main beam into characteristic high elevation sidelobes (grating lobes). Overfilling the aperture with elements produces no benefit in directivity and increases the coupling (mutual impedance) between adjacent elements, making it more difficult to control the excitation of the array.

In the azimuth plane the situation is different. If we select a radiating element whose property is to uniformly illuminate a 180° sector with no signal at all in the other half-space, then it is clear that such an element has a directivity of two (3 dB). Because directivity is properly defined as a 3D property, this ratio is commonly known as the *azimuth max-to-mean ratio*. It is numerically equal to the area of the circle circumscribing the polar radiation pattern when plotted in linear field coordinates, $E(\theta)$, to the area of the plotted radiation pattern itself (because both power and area are proportional to E^2). This makes it very easy to visualize what is happening.

The maximum total directivity of a vertical array is the product of the directivity in the elevation plane times the azimuth max/mean ratio.

Azimuth Pattern Shaping Each tier of an array may comprise a single radiating element; this is common in base station practice and for simple broadcast antennas. The desired pattern is often obtained by arraying elements against a mounting pole, or against a reflecting plane when more suppression of radiation is needed in the rearward direction. Where the required azimuth pattern cannot be achieved using a single radiating element (with or without a reflector) each tier is constructed from several elements, each often constructed in the form of a panel comprising an integrated radiating structure and reflector. Panels are usually designed to cover wide frequency bandwidths and to maintain very consistent radiation pattern, polarization, and impedance over the operating band. Typical panels cover entire broadcast bands. Designing arrays in this manner has the advantage that by using standard, highly optimized, mass-produced panels the antenna designer can construct a wide variety of azimuth pattern shapes. The adoption of sector coverage for mobile radio base stations has removed the requirement for separate panels, but the design of the radiating element has the same constraint of requiring constant performance over wide bandwidths. To reduce the mutual impedance between adjacent elements individual elements are often surrounded by fences or cavities.

Elevation Pattern Shaping

There is little point in directing the elevation maximum of our vertical array in exactly the horizontal plane: in flat terrain half the radiated power will be lost over the head of any ground-based receiver. The further we get from the antenna the more the curve of the earth will result in the main beam passing overhead. The main beam is therefore usually tilted downward, typically so the upper -3 -dB point lies in the horizontal plane; the exact tilt may depend on the relative elevation of the antenna and the served users. A further result of tilting the beam downward is to reduce the level of unwanted illumination of users located beyond the effective served area. The served area is always surrounded by a region covered by signals too weak to use but too strong to ignore; the size of this zone is reduced when beamtilt is used. For ground-to-air services a small upward beamtilt is sometimes applied.

A column of elements with identical currents in each radiating element creates an elevation radiation pattern with a simple $(\sin x)/x$ form. This pattern is generally modified to create some additional shaping by feeding the tiers of the array with currents of different phases and/or amplitudes. There is no unique solution to the creation of a radiation pattern with some arbitrary shaping (as we generally need to match only a requirement for amplitude and not for both amplitude and phase), so a variety of procedures can be adopted to derive a suitable set of element currents. Practical considerations include ensuring that the chosen function does not require very different currents in adjacent elements, which will exaggerate the effects of mutual impedances. The radiation pattern must not be sensitive to small changes in some of the array currents, as this may make it difficult to achieve the required pattern over a wide frequency band.

A simple method of filling nulls and suppressing sidelobes is based on the principle of superposition. Given that a uniform array has an elevation pattern in the form of a sinc function, supplementary excitations can be added to the principal excitation with chosen amplitudes and relative phases. To fill a null we apply a sinc function with its maximum directed at the angle of the null and with its phase in quadrature with the principal excitation; to suppress a sidelobe an additional sinc function is added with its maximum in the direction of the sidelobe and in antiphase with the main excitation. Additional sinc functions can be added to fill successive nulls or to suppress as many sidelobes as required. There is some interaction between the added sinc functions because each has its own sidelobes at -13 dB relative to its maximum, but by using a computer program the method can be implemented in an interactive manner. At the end of the optimization process the element currents associated with each sinc function are added vectorially to give the complex current that will be needed to generate the specified pattern.

When assessing the performance of an array it is useful to obtain a sample of the radiating currents from each element by using inline couplers or external sampling loops. The currents can be displayed in polar coordinates using a vector network analyzer to allow the designer to verify that the actual currents are close to the design currents and to maintain the correct relationship within some acceptable limit over the operating frequency band. The sensitivity of the radiation pattern to small variations in the element currents can be investigated using a Monte Carlo analysis in which random variations in amplitude and phase, with a known standard deviation, are applied to the array currents, and the resulting patterns are evaluated for compliance with the target specification. The most common reason for element currents deviating from their design values is the imperfect impedance match of the elements; this causes the power division at each junction to deviate from the expected value in a manner that is often strongly frequency dependent. The design of many radiating elements in broadcast and base station arrays is often governed by the requirement that individual elements (or element groups) have a sufficiently low VSWR to allow radiation pattern constraints to be met over extended bandwidths. The use of Wilkinson power dividers can limit the extent of current variation, but unless good matching is achieved this may be at a price of losing RF power into balancing loads.

Impedance Characteristics The maximum permissible input VSWR of an antenna is determined by the effect that a significant reflection would have on the transmitted signal. The applicable criterion is commonly more stringent than considerations of transmitter currents and voltages or of maximum power transfer to the antenna. With respect to the input impedance of the whole array, there are several important considerations:

The radiation of signals with relative time delays If we examine the typical arrangement shown in Figure 29-14, we see that a transmitted pulse, which may be part of any analog or digital transmission, travels from the transmitter to the antenna, experiencing some loss and transit time in the interconnecting cable. If the antenna has a return loss L db,

FIGURE 29-14 Transmitter feeding a mismatched load

a signal L dB below the forward signal at the antenna now moves along the cable in the reverse direction. After suffering a delay t and attenuation A , the signal encounters the output port of the transmitter. In general the impedance looking back into a transmitter is very far from $50\ \Omega$, so much of the signal is now reflected with reflection coefficient r dB. After again passing along the cable, the signal originally reflected at the antenna is reradiated with a relative level of $-(L + 2A + r)$ dB and a delay of $2t$ relative to the original signal. The significance of both the amplitude and the relative delay of this secondary signal depends on the signal format being transmitted. In analog TV and digital systems using high-order digital modulation formats it is the essential determinant of the required antenna reflection performance, especially for antennas fed by long, low-loss cables.

Frequency-dependent load impedance at the transmitter If the antenna input impedance differs from the characteristic impedance of the main feeder, the impedance seen by the transmitter varies with frequency. (The impedance of the antenna forms circles round the center of the Smith Chart.) The result of a transmitter working into an impedance that varies with frequency is often to distort the output waveforms in both phase and amplitude. Again the effect and its acceptable limits depend on the signal format. With some systems it is usual to adjust the transmitter characteristics to compensate for some degree of distortion caused by the varying load impedance, but the extent to which this can be done is limited, especially when the antenna is connected by a long, low-loss cable.

Cable power ratings The effective power rating of a cable is reduced when it is operating at a high VSWR, as the high-current points in the standing wave cause hotspots on the cable; for this reason the cable rating must be reduced by a factor of $1/\text{VSWR}$.

These effects usually define the required impedance characteristic of the whole antenna. The effect of reflection loss only becomes significant at high values of VSWR, the rule-of-thumb values being 0.5 dB at 2:1 and 1 dB at 2.6:1 (return losses of 9 dB and 7 dB, respectively).

There is a further reason why the VSWR of individual elements needs to be controlled. If two loads are connected in parallel at a transmission line junction, the current division at the junction is in inverse ratio to the (complex) impedances seen at the inputs to the separate branches. If we join two mismatched antennas to a junction through cables of *equal* length, this presents no particular problem. Although mismatched, the impedances are equal so the current divides equally in amplitude and phase. If the lines connecting the loads to the junction are of *unequal* length—perhaps because we require a phase shift between the currents in the connected elements—the impedances presented at the junction are no longer equal because they lie at different points on a circle round the center of the Smith Chart. The result is that the load currents will be neither equal nor of the expected relative phase, modifying the radiation pattern of the arrayed elements in a manner we may not have expected. This imposes a new criterion for the input match of the radiating

elements, depending on the accuracy with which design currents must be achieved and maintained over extended bandwidths in order to create the required radiation patterns. If the equality of the currents must be preserved despite mismatched impedances, the use of a hybrid junction or Wilkinson splitter will reduce the unwanted effect of the mismatch on the power division.

In situations in which antenna matching is very critical it is common to use a variable transmission line device to center the complex impedance plot of the antenna relative to the exact Z_0 of the coaxial feedline. The variable components may take the form of short sleeves (“slugs”) fitted to the inner conductor of a section of transmission line—the equivalent of small patches on a microstrip line. Where close impedance matching is needed at a number of different frequencies, a long section of transmission line is used and is fitted with several slugs at different computed positions.

Designing Radiating Panels

The commonest designs for radiating panels provide an azimuth beamwidth of 90° (total) at -6 dB relative to boresight. When two panels driven with equal co-phased currents are mounted close to one another on the sides of a square tower, the field in the diagonal direction is equal to the field in the main beam direction of each panel. A successful panel must have an azimuth beamwidth that is very stable with frequency, and the level of any subsidiary lobes must be very low. Typical panels comprise two full-wave dipoles mounted against a reflecting screen, usually made from solid sheet above about 400 MHz and formed from conducting rods at lower frequencies. Because antenna installers use horizontal bars as handholds and climbing steps, it is common to make these bars from hot-galvanized mild steel. In the UHF band the design and production of wideband panels with well-controlled azimuth beamwidth and low VSWR (typically $< 1.1:1$ over 470–860 MHz) presents an interesting challenge.

Combining Panels into Groups The most usual feed method is to connect all the panels that form one tier of an array together into one power divider, constructed from coaxial line sections for use at high powers or various forms of microstrip for low powers. The input ports of each tier are then combined, usually in a branched tree pattern. For base station antennas a single feed is usually provided to the whole array, while in broadcast practice it is usual to provide separate inputs to each (vertical) half of the whole array, and to connect the antenna to the final stage of combining at ground level. This configuration gives access to the two separate half-antennas, allowing some redundancy in the case of failure of some part of the array, and access for maintenance when one half array is disconnected and grounded—in these cases the gain of the antenna is obviously reduced when only one half is driven, but loss of some coverage is better than no transmission.

It is obviously also possible to combine a broadcast array by interconnecting all the panels on each face with a power division network and then to interconnect the faces in a final stage of combining. This method is not favored because it uses more cable, and a single fault may grossly modify the azimuth radiation pattern. When multiple radiating elements on each panel are used to create circular polarization it is usual to combine the elements of each panel together before feeding them from the main feed network.

For analog TV transmissions it is necessary to achieve a very low VSWR across each transmission channel, and arrays often have extremely wide bandwidths. For this reason the phase rotation method shown in Figure 29-15 has been extensively used. It can be extended by feeding adjacent tiers in phase quadrature (and rotating them mechanically by 90°) and repeating this with successive groups of two and four tiers. Complete half antennas are often fed in phase quadrature without a corresponding mechanical rotation to

provide elevation beamtilt equal to half the total elevation beamwidth. These methods are not so easily applied when the azimuth radiation pattern is directional.

Directional radiation patterns are achieved by a combination of several methods:

- Adjustment of the amplitude and phase of panels forming each tier of the array
- Adjustment of the physical positions of the panels in each tier
- Use of unequal number of panels on different faces of the array (in this case the physical configurations of different tiers are not identical)

Azimuth pattern requirements are driven by a mixture of the minimization of interference with stations operating on the same or adjacent channels (which may be contained in international regulatory requirements), topography, and the distribution of the target population. Azimuth patterns can be predicted by computer programs (which often make use of measured data from individual panels) but usually need validation by practical measurement—at least of an appropriate subsection of the complete array. The most common sources of difference between predictions and measurements occur when:

- The array has substantial physical displacement of panels—potentially allowing blockage of one panel by another.
- Current paths in the screening surfaces are physically interrupted; such a problem occurs in a horizontally polarized array if the screening panels are not bonded to one another at each corner, when the gaps at each corner operate as slot radiators that were not included in the computer prediction.
- Radiating elements with imperfect matching are connected together by cables of unequal length (see above).

High-power broadcast arrays require very careful attention to mechanical design details, and the advice in Table 29-1 needs to be thoroughly applied. The accumulation of ice and snow will change element matching with the result that radiation patterns, gain, and input VSWR will all be degraded. High voltages at element feedpoints are likely to create dielectric heating, and any insulators are likely to suffer surface tracking both from exposure to the weather and accumulation of contaminants from urban rain, birds, and salt spray at coastal locations. This problem can be addressed by the use of a radome, fitted either over the whole array or over the elements or their feedpoints—in this last case the radome must be sufficiently large that it does not experience strong surface fields, or the result will be failure by surface tracking.

Omnidirectional Broadcasting Antennas Broadband high-power omnidirectional antennas are usually built from tiers of four (occasionally three) panels that may have linear or circular polarization. Depending on the cross-sectional size of the structure, the most uniform omnidirectional coverage may be produced with all panels driven with the same phase or by a phase rotation around the structure; for example, on a square tower the element current phases would then be 0° , 90° , 180° , and 270° . When phase rotation is used, the individual elements may be offset from the centerlines of the faces of the structure to give a more omnidirectional azimuth pattern, as in Figure 29-13.

Omnidirectional vertically polarized antennas can be produced by mounting two vertical dipoles either side of a supporting pole, carefully choosing the spacing to provide a uniform azimuth pattern. If the support is too large (in wavelengths), then three or more dipoles may be needed to provide uniformity.

Horizontally polarized omni antennas can be constructed using a *turnstile* format in which two separate elements are arranged at right angles and fed in phase quadrature.

An alternative method is to create a *square loop* from four horizontal half-wave dipoles fed in phase. This produces a good omnidirectional azimuth pattern but the large capacitive coupling across the corners of the array limits the achievable impedance bandwidth (see Figure 29-15a). Circularly polarized antennas are sometimes based on loop-dipole derivatives and short radial-firing multiple-start helices. These are often mounted off the side of the supporting structure, providing quasi-omni patterns with degraded polarization circularity.

An omnidirectional array can be designed using broadband panels with crossed-dipole elements, but this arrangement is costly and has a very substantial weight and windload. The pole-mounted Lindenblad array²⁰ (see Figure 29-15b) is formed from four half-wave dipoles mounted on a square that is a half-wavelength across, with the elements lying at 45° to the horizontal and driven with equal cophased currents. When viewed from the side of the square, it is easily seen that the geometry ensures that the vertical and horizontal field components are equal in magnitude and have a quarter wavelength relative to the physical displacement of their phase centers. The arrangement provides an omnidirectional azimuth pattern with low ripple and good polarization purity. An array comprising multiple tiers, centrally mounted on a supporting pole, can provide high gain and low VSWR across the whole FM radio band 97.5–108 MHz and is suitable for high-power multi-channel operation.

A short four-start helix can be imagined as a derivative of a Lindenblad antenna using curves radiating elements. A modified form of Lindenblad array is sometimes used in which the four dipoles are fed with phase rotation, the spacing between dipoles reduced, and the tilt angle changed to around 30° . This provides hemispherical coverage but is not suitable for terrestrial broadcast use.

Feeding Multiple Arrays Simple low-power arrays operating at frequencies below 500 MHz are usually fed using a coaxial-cable branching network (see Figure 29-16). Stripline power dividers are attractive for applications above about 500 MHz and can be designed to provide arbitrary power division ratios and any required number of ports; they provide a high level of reproducibility in volume production and can be designed using readily available computer software. If an array is to operate at high mean input power, it may be necessary to use large-diameter fabricated coaxial transformers.

FIGURE 29-15 (a) A horizontally polarized square loop comprising four half-wave dipoles; (b) A circularly polarized Lindenblad array in which the dipoles are rotated by 45°

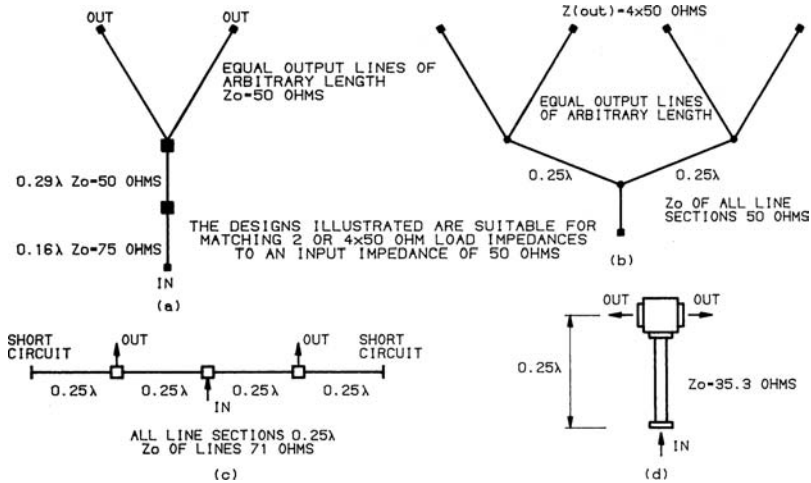

FIGURE 29-16 Simple branching feeder systems: (a) Two-way; (b) Four-way; (c) Two-way, compensated; (d) Two-way, high-power

Multiway broadband power dividers are usually designed using multiple quarter-wave sections to achieve a very low input reflection coefficient over a very wide bandwidth. The general principle used is illustrated in Figure 29-17. At the common point of the branching output lines the impedance is low and requires to be transformed up to 50Ω . If this is done in a single step over a wide bandwidth, the transformed impedance will take the form of an arc on the Smith Chart as in Figure 29-17a. A first transformation is made to an intermediate point on the Smith Chart, and this is followed by a second transformation with a similar impedance ratio. The action of the second quarter-wavelength is again to wind the intermediate impedance into an arc in which the angle traversed is proportional to frequency; this compensates the behavior of the first transformation, and the result is a very small impedance plot lying close to 50Ω (see Figure 29-17b). When large numbers of branch lines are to be fed it is good practice to transform the outgoing line impedances up before connecting them in parallel, to avoid the need to make lines with extremely low Z_o . Where large power division ratios are needed the outgoing impedances can be transformed up so

FIGURE 29-17 (a) The dispersive effect of a simple quarter-wave section over a wide bandwidth. (b) A two-stage transformation has been used in which the effect of the second section is to reduce the dispersion caused by the first section.

FIGURE 29-18 (a) Panel arrays of full-wave dipoles for 174–230 MHz and (b) bent half-wave dipoles for 87.5–108 MHz. The rigger is a reminder of the need to plan for safe access and to ensure that equipment cannot be damaged by being used as footsteps or handles. (Courtesy of Kathrein-Werke KG)

the impedances at the common point have the required ratio and are stable with frequency; this ensures that the power division ratio is stable. Designs of this type can be realized in coaxial or microstrip lines.^{21–24}

Alternative designs can be created by thinking in lumped element terms and using short lines of high Z_0 (inductors) and of very low Z_0 (capacitors). This technique can produce some very compact splitters with wide frequency bandwidths. Wilkinson power dividers have characteristics similar to those of a hybrid junction.

Figures 29-18 and 29-19 show typical examples of high power radio and TV broadcast antennas embodying many of the techniques that have been discussed.

29.10 BASE STATION ANTENNAS FOR MOBILE PHONE SERVICES

In many respects the design of base station antennas parallels that of a directional broadcast array. In both systems the shaping of the azimuth radiation patterns is used to control coverage and co-channel interference in the coverage area of other stations. Both systems employ columnar arrays of radiating elements in which the currents in different tiers are closely controlled in order to shape the elevation radiation pattern—elevation null-fill is used to avoid holes in local coverage. The main differences are the azimuth pattern (base stations have radiating elements firing in only one direction), transmitted power (a few hundred watts rather than tens of kilowatts), and the scale of production—these differences have led to the widespread use of microstrip techniques in both radiating elements and feed systems.

The use of circular polarization in many broadcast systems is paralleled by the use of polarization diversity in base station antennas (transmitting independent linear components rather than combining them in phase quadrature). Broadcast antenna engineers will find many interesting techniques in base station antenna design, where the changing demands of customers and intense competition have fostered rapid development of simple but effective broadband methods adapted to large-scale production.

The parameters of a base station antenna are an essential means by which the coverage and capacity of the network are optimized. Space-diversity receive systems employing two vertically polarized antennas are common in rural areas; in urban areas polarization diversity is often used and is provided by antennas supporting two orthogonal linear polarizations ($\pm 45^\circ$). Because of the closely spaced channels used by a base station, the transmitters are often combined using 3-dB hybrids (incurring a 3-dB loss). To minimize combining losses, all available antenna ports are used for multichannel transmission as well as for reception, so there are very stringent requirements on passive intermodulation products. The development of an increasing number of frequency bands for mobile radio has led to the development of dual-band antennas (usually 850/1900 MHz or 900/1800 MHz); the advent of 3G services in the 2100-MHz band has encouraged the development of wideband antennas operating over the ranges 826–960 MHz and 1710–2170 MHz.

Further developments in base station antennas include the use of remotely adjustable beamtilt, azimuth beamwidth, and azimuth pointing direction, and the integration of low-noise amplifiers into antenna systems. The continuing pressure to meet rising capacity and coverage needs has led to the development of inconspicuous “street-works” base stations with three sector antennas, each with remote tilt facilities, housed in a single radome and mounted on a street-lighting pole.

A **vertically polarized antenna** comprises an array of vertically polarized dipoles mounted in front of a reflecting screen and protected by a radome, usually made from UV-stabilized ABS or polystyrene. Successful designs have used

- Punched or pressed dipoles fed by miniature coaxial cables, using cable or microstrip power dividers
- Microstrip dipoles with a distribution network integrated in a single PCB or fabricated assembly
- Dipoles fed by suspended microstrip feeds, all cut from aluminum sheet
- Stacked patches with microstrip feed networks

FIGURE 29-19 Typical broadcast antenna installations on a concrete supporting structure. A UHF TV antenna is mounted on top of the tower. It is protected by a GRP radome that is provided with helical strakes to reduce its vulnerability to mechanical oscillation at certain wind speeds. Below this is a VHF FM radio antenna built from dipole panels, and below this is a variety of LPDAs. (Courtesy of Kathrein-Werke KG)

Dual-polar antennas have been produced using

- Crossed dipoles constructed by printed-circuit or sheet metal techniques, integrated with microstrip or cable feed systems.
- Squares comprising four half-wave dipoles, usually of stamped or cast metal construction with cable feed.
- Patch elements, usually air-spaced and standing 10–20 mm above the reflecting plane, fed as stacked patches or by some other indirect feed mechanism below them. (Directly edge-feeding a wideband patch gives rise to pattern squint at frequencies far from the design frequency.)

Dual-polar antennas require the specification of several additional parameters to ensure optimum operation in a mobile radio system:

Azimuth radiation patterns and gain are defined assuming the antenna under test is illuminated by a plane-polar signal with a polarization of either $+45^\circ$ or -45° . Because the sense of slant polarization in the rearward direction is opposite to that at 0° , the cross-polar rear lobe often limits network performance and should always be measured. Some networks define a sum-power limit, but this is pessimistic as no real antenna could receive the sum power in both polarizations. The azimuth pattern is defined and measured as a conical cut of the 3D solid pattern, with a half-angle equal to the complement of the nominal elevation beamtilt. Errors in the azimuth pattern relate to the design of the radiating elements and their immediate environment in the array.

Elevation beamtilt is conventionally defined in the sense that positive beamtilt is downward. The specified tilt must be achieved within some defined limit that must be maintained over the whole operating bandwidth. Changes in tilt result in uncertainty in the coverage footprint of the base station between transmit and receive frequencies and variable overlap with adjacent stations. The impedance matching of the upper and lower halves of the array is the first matter to investigate if an array has an unstable beamtilt; any significant mismatch will cause a frequency-dependent phase error between them.

Squint is the angle between the azimuth directions of the beams formed in the two polarizations, usually measured as the mean direction between the -3 -dB points of the azimuth patterns in each polarization. Squint is controlled by the electrical symmetry of the radiating elements and their means of excitation. It is usually greatest for large tilt angles because the use of $\pm 45^\circ$ polarization puts any element squint into the diagonal planes: the larger the elevation tilt, the more any element squint expresses itself in the azimuth pattern of the array.

Tracking is the gain difference between the two polarizations measured over some specified range of azimuth angles surrounding the main beam direction, so this parameter includes the effects of both squint and beam-center gain difference. If there are significant frequency-dependent tracking errors, a mobile may be handed-off into the cell on the basis of a strong signal in the broadcast control channel (BCCH), but if the polarization tracking is poor and the assigned channel is transmitted in the other polarization from the BCCH, the signal may be several dB below what would have been expected. Precise tracking is achieved by minimizing squint and making the $+45^\circ$ and -45° subsystems as mechanically and electrically equal as possible.

Cross-polar or interport isolation (XPI or IPI) is the attenuation measured between the $+45^\circ$ port and the -45° port. This is significant because of the practice of using both ports for transmission—the coupled energy between transmitters must lie below -30 dB because this is the level at which the transmitters meet their spurious emission specifications. This is a stringent requirement and various coupling compensation mechanisms are used, including tabs on the elements, rods, bars, and “mushrooms” placed between elements and along the edges of the antenna chassis, metal tapes inside radomes, and feedline coupling. The XPI usually increases with increasing elevation tilt because the phase shift across the array results in the coupled signals being increasingly out of phase.

Cross-polar discrimination (XPD) is the relative response of one section of the antenna to co- and cross-polar signals. A more logical parameter to define is *polarization orthogonality*, which is the parameter that permits the antenna to provide polarization diversity, but this is mathematically complex and is not easy to measure. It is a common feature of directional slant-polar antennas that their polarization on boresight is close to 45°, but as the observer moves away from boresight the polarization tends to become dominated by the vertical component (at 90° from boresight it is easy to understand that the polarization becomes completely vertical). In practice, the diversity gain obtained from a dual polar antenna does not fall significantly for values of orthogonality or XPD larger than about 10 dB,²⁵ so this parameter is *not* often defined or measured. The achievement of a large value of XPI does not ensure that the XPD is high, and the XPD should always be checked, especially if large amounts of compensation are necessary to achieve the required XPI.

A 45°-slant polarization has the unusual property that if the transmitting antenna has +45° polarization, the polarization appears as -45° to the antenna that receives it. A base station antenna is used for both transmission and reception, and there is no clear convention as to how ports should be labeled. If they are used or measured in any manner in which the distinction is relevant, the port naming should be regarded as arbitrary and the actual polarization checked.

Cross-band isolation is defined for multiband antennas to ensure that the signals presented to the base station filter system lie within the expected limits. In antenna terms, insufficient cross-band isolation is likely to indicate that currents in the high-band part of the antenna will excite radiating currents in the low-band elements, corrupting the high-band radiation patterns. If an antenna has adequate radiation patterns but some deficit in cross-band isolation, it is acceptable to add filtering in the feed system.

Some antennas are required to provide a single input port for both frequency band groups, in which case a diplexer will be needed to combine the feed systems of the high- and low-band arrays. This can be formed from high-pass and low-pass elements engineered in microstrip and needs sufficient isolation to prevent the radiation pattern distortion explained earlier.

Passive intermodulation products (PIMs) of all orders are generally required to lie below -153 dBc for two carriers at a level of +43 dBm (20W). For dual band antennas the first-order transmit-band products may lie in the receiver band and can be particularly troublesome ($900 + 900 = 1800$; $1800 - 900 = 900$). Good PIM performance is only achieved by the exercise of good design practices and of care and cleanliness in manufacture (see Section 29.2).

Input VSWR is usually required to be less than 1.4:1 across the relevant operating bands. It is usually most difficult to achieve this if the array has a 0° electrical beamtilt because all the elements are driven in phase so the reflections also arrive back in phase at the input. As the beamtilt is increased the reflections are no longer cophased, so the required VSWR is easier to achieve.

Some design margin is needed on these parameters between the specification and what is measured on prototypes and pilot production, in order to accommodate production variation without products failing to meet specification. In this respect PIM, XPI, and VSWR are the parameters most likely to vary significantly between samples; variation is controlled by adopting good design practices, ensuring components are accurately made, and educating production personnel about consistency and cleanliness.

Adjustable Elevation Tilt As noted earlier, the use of beamtilt has long been a feature of both base station and broadcasting antennas. The use of remotely controlled adjustable tilt for base station antennas was introduced as a method by which the network operator can control the area covered by a base station antenna. Reducing the transmitted power also reduces coverage in buildings and shadow areas close to the base station, while down-tilting the main beam allows close control of the position and depth of the overlap area

FIGURE 29-20 A typical array with adjustable electrical tilt, fed as five subarrays, each of two elements, using tapped-line phase shifters powered from a single drive motor. Feedlines are usually dimensioned so that when the phase shifters are at one end of their travel, the tilt is 0° .

between base stations. Electrical downtilt (produced by introducing a progressive phase shift over the aperture of the antenna) is used in preference to mechanical tilting because mechanical tilt changes the shape of the footprint as well as its size, and physically downtilted antennas are visually more obtrusive than untilted antennas. The requirement for very low PIM levels and substantial transmitted power has led to the development of electro-mechanical phase shifters driven by stepper motors. Three different forms of design are in general use: transmission lines whose electrical length is changed with moving dielectric loading, lines with capacitively coupled moving taps, and lines with trombone sections. In applying these to a linear array it is necessary to arrange that the phase shift for each element is proportional to its distance along the array. To reduce the total phase shift needed it is common to use a differential scheme in which, to tilt the beam down, elements at the bottom of the array are delayed in phase and simultaneously those at the top are advanced. To reduce the complexity of the phase shifters, the elements of the array are often grouped together into fixed subarrays of two or three elements, and variable phase shift is applied between them (see Figure 29-20).

Grouping elements into subarrays to some extent compromises the performance of the array; a truly linear phase shift produces lower elevation sidelobe levels even at extreme tilts (see Figure 29-21). An industry-standard digital control interface has been defined and implemented by all major antenna manufacturers—this interface²⁶ provides control for antennas, tower-mounted amplifiers, and other tower-top hardware.

FIGURE 29-21 Examples of the azimuth (left) and elevation patterns (right) of a base station antenna showing excellent consistency of beam shape and sidelobe levels over a range of electrical elevation beam tilt angles of 0° – 10° (Courtesy of Argus Technologies)

Extension of remote control techniques to the adjustment of azimuth pattern characteristics—beamwidth and pointing direction—is relatively easy and provides increased adaptive control of network optimization, allowing real-time response to changing demands for capacity and coverage in the network. Such techniques are based on cross-layer communication originating from radio resource management; they are symmetrical in their enhancement of uplink and downlink and are protocol independent. Antenna systems embodying them have been described as *semi-smart antennas*.²⁷

29.11 SYSTEM CONSIDERATIONS

Mounting Arrangements When mounting any antenna it is important not to impair its performance by the influence of the supporting structure. The inevitable effect of the supporting structure on the radiation pattern of a dipole has been referred to in Section 29.8. This effect is accompanied by a modification of the input impedance, which may be unwelcome if a low VSWR is needed. In any critical application the change of the radiation patterns and gain must be taken into account when estimating system performance. Impedance matching of the antenna must be undertaken in the final mounting position or a close simulation of it.

If Yagi-Uda arrays are mounted with their elements close to a conducting structure, they too will suffer changes of radiation patterns and impedance. The effects will be greatest if tower members pass through the antenna, as they do when an array is mounted on clamps fitted at the center of the cross boom. If at all possible, when an array is center-mounted, the member to which it is clamped should lie at right angles to the elements of the array.

Currents induced in diagonal members of the supporting structure will cause reradiation in polarization planes other than that intended. This will result in the cross-polar discrimination of the antenna system being reduced from that which would be measured on an isolated antenna at a test range. When polarization protection is important, the tower should be screened from the field radiated by the antenna with a cage of bars spaced not more than $\lambda/10$ apart, lying in the plane of polarization. (A square mesh is used for circular polarization.) Panel antennas are designed with an integral screen to reduce coupling to the mounting structure.

Long end-mounted antennas are subjected to large bending forces and turning moments at their support points. These forces can be reduced by staying the antenna, using nylon or polyester ropes for the purpose to avoid degrading its electrical characteristics.

In severe environments antennas may be provided with radomes or protective paints. It is very important that the antennas be tested and set up with these measures already applied, especially if the operating frequency is in the UHF band.

Coupling A further consideration when planning a new antenna installation on an existing structure is the coupling that will exist between different antennas. When a transmitting antenna is mounted close to a receiving antenna, problems that can arise include

- Radiation of spurious signals (including broadband noise) from the transmitter
- Blocking or desensitization of the receiver
- Generation of cross-modulation effects by the receiver

The last two effects depend critically on the isolation between the antennas and on parameters of the transmitters and receivers; these parameters are generally specified by their manufacturers.

FIGURE 29-22 Typical isolations between Yagi-Uda antennas

The isolation between two antennas may be predicted from Figure 29-22, measurements, or from standard propagation formulas. Antenna isolations may be increased by using larger spacings between them, arranging that they are cross-polarized, or by using arrays of two or more antennas spaced to provide each with a radiation-pattern null in the direction of the other.

An alternative method of increasing the isolation between the antenna-system inputs is to insert filters. If a suitable filter can be constructed, the antenna isolation may be reduced until, in the limit, a single antenna is used with all equipment, transmitters, and receivers coupled to it through filters. When receivers are connected to a common antenna, the signal from the antenna is usually amplified before being divided by a hybrid network. The number of services that use a single antenna can be extended to six or more, provided adequate spacings are maintained between the frequencies allocated to different users. The whole system is expensive, but the cost may be justified if the antenna itself is large or if tower space is limited.

Multiple User Systems To reduce the environmental impact and cost of antenna systems, users share antenna resources by installing a single broadband antenna system and using it to support multiple radio transmitters or receivers (or both). Not only does this practice reduce the profile of an antenna installation, but it also allows several services to make best use of locations where antennas can be most favorably sited.

30.1 INTRODUCTION

Digital terrestrial television broadcasting is being introduced in many countries. This is providing a variety of services on a single channel, such as high-definition television (HDTV) and multimedia data. Obtaining portable TV reception generally is difficult compared to obtaining fixed reception at home. For fixed reception, a directional antenna with high gain and a narrow beam width, such as the Yagi-Uda dipole array antenna, is used.¹ For portable reception, an omnidirectional antenna or low-gain antenna is used. The objective of this chapter is to describe portable reception antennas suitable for digital terrestrial TV, such as small antennas with amplifier circuits, mobile phone antennas, and reception antennas mounted on cars.

30.2 DIGITAL TERRESTRIAL TELEVISION IN THE WORLD

Table 30-1 shows the frequency allocation plan in the world.² In many countries (but not in the United States or Canada), the high-band VHF from 174 MHz to 240 MHz and the UHF band from 470 MHz to 862 MHz are used for the digital terrestrial television.

30.3 MINIATURIZATION TECHNIQUES FOR PORTABLE TV ANTENNAS

This section shows examples of small portable TV reception antennas such as the small antenna with amplifier circuit and the mobile phone antenna.

Small Antenna with Amplifier Circuit for UHF-TV

Figure 30-1 shows the structure of a coplanar waveguide (CPW)-fed dipole antenna and a loop antenna for a television receiver and DC-equivalent biasing circuits.^{3,4} The antenna element and CPW are printed on a polyimide film of thickness $45\text{ }\mu\text{m}$. The relative permittivity of film is 3.5. The characteristic impedances of CPW in two antennas are chosen as $75\text{ }\Omega$ for impedance matching to the coaxial feeder of the television receiver. The antenna element and CPW are covered by a film of thickness $50\text{ }\mu\text{m}$ for protection. The silicon transistor 2SC2585 or 2SC3604 is integrated at the feedpoint of the dipole or loop antenna, respectively.

One of the primary problems with the active antenna is that the unwanted radiation from the amplifier circuit and the bias line will perturb the antenna characteristics. To overcome this problem, the amplifier circuit is mounted on CPW. CPW also serves as a bias supply line to the amplifier circuit. The available power gain of 2SC2585 is 8 to 14 dB at frequencies from 90 to 770 MHz. The nominal value of the noise figure of this transistor is about 1.6 dB at 2 GHz. To suppress the undesired radiation from the amplifier circuit, the fixed-bias circuit with collector feedback, the simple biasing circuit, is adopted for the active dipole antenna. On the other hand, the available power gain of 2SC3604 is 24 to 18 dB at frequencies from 90 to 770 MHz. As the available power gain of 2SC3604 is larger than one of 2SC2585, the self-bias circuit is adopted to suppress oscillation and to increase stability. The nominal value of the noise figure of this transistor is about 1.6 dB at 4 GHz.

The input impedance and radiation field of dipole and loop antennas are calculated by using the computer program WIPL-D based on the Method of Moment.⁵ In the calculation, antenna elements are approximated by the wire antenna whose radii are $W_i/4$ ($i=1,2$). As the dielectric film is very thin, the existence of film is not considered.

FIGURE 30-1 Dipole and loop antennas loaded with amplifier circuits

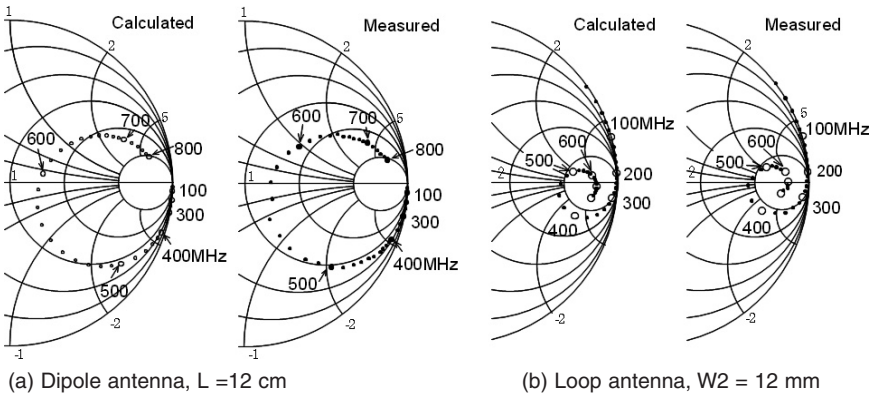

FIGURE 30-2 Input impedance of dipole and loop antennas

Figure 30-2 shows the input impedance characteristics of dipole and loop antennas. The calculated input impedances fairly agree with the measured results. Figure 30-3 shows the scattering parameters of transistors for active antennas. In the television 1–12 channel frequencies 90 to 222 MHz, the dipole antenna is not matched to the transistor circuit. Although the input reactances of dipole antennas are capacitive in the frequencies 90 to 222 MHz, those of loop antennas are inductive. This means that the conjugate impedance matching between antenna and amplifier is improved in the loop antenna. Figure 30-4 shows the calculated and measured actual gains expressed by relative values to the half-wave dipole antenna. As the impedance matching between a dipole of 24cm in length and transistor 2SC2585 is reasonable at the television 13–62 channel frequencies from 470 to 770 MHz in Japan, actual gains of more than 8 dBd are obtained. In the active

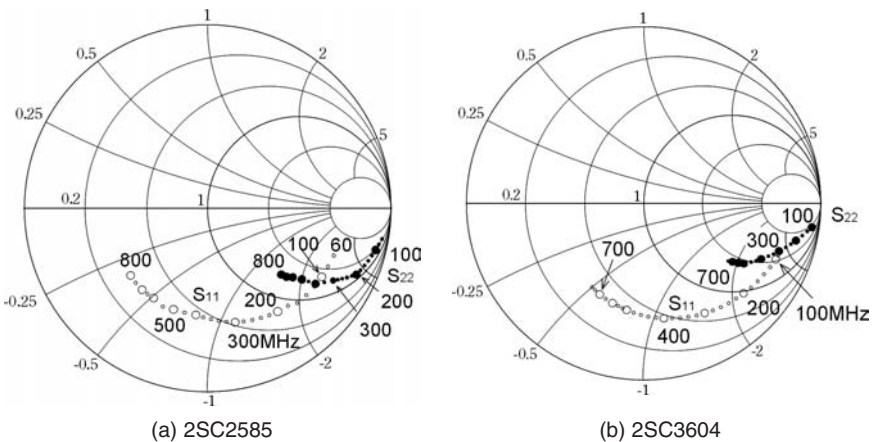

FIGURE 30-3 S parameters of silicon transistors

(a) Dipole antenna, $L = 12$ cm(b) Loop antenna, $W_2 = 12$ mm**FIGURE 30-4** Actual gains of dipole and loop antennas

loop antenna, the impedance matching between loop and transistor 2SC3604 is improved in the frequencies 90 to 222 MHz. Actual gains of more than 6.5 dBd are obtained for 13–62 channels, from 470 to 770 MHz.

Portable Antenna on Mobile Phone

Digital terrestrial television broadcasting in Japan is designed so that each channel is divided into 13 segments. Among these 13 segments, 12 segments are used for HDTV transmission and 1 segment is used for mobile receivers.⁶ Maximum video resolution is 320 by 240 pixels, and maximum video bit rate is 128 kbit/s. Maximum audio bit rate is 64 kbit/s and the additional data broadcasting occupies the remaining 60 kbit/s.

Digital Multimedia Broadcasting (DMB) is a digital radio transmission system for sending multimedia (radio, TV, and datacasting) to mobile devices such as mobile phones. Currently, DMB is being put into use in a number of countries such as South Korea, Germany, France, Switzerland, China, the UK, and Indonesia.⁷

Figure 30-5 shows an example of the embedded antenna for digital terrestrial broadcasting in Japan (one segment).⁸ Its size is 38 mm by 10 mm by 2 mm. Figure 30-6 shows the antenna module, consisting of the antenna, the tuning circuit, and the low noise amplifier (LNA). Figure 30-7 shows the antenna tuning. The antenna is directly connected with the LNA, and is tuned to be synchronized with the channel selection. The antenna gain is self-controlled with the sensitivity of the tuner module.

30.4 RECEPTION ANTENNA MOUNTED ON VEHICLE

This section shows examples of reception antennas mounted on vehicles, such as a window glass antenna, a diversity reception antenna system, and an adaptive beam-steering reception system.

Reception Antenna on Rear Window of Sedan-Type Car

Figure 30-8 shows an example of window-glass antenna printed on the rear window of a car, composed of four diversity reception antenna elements.⁹ TV antennas No. 1 and No. 2 are located close to the defogger (heater) element. TV antenna No. 4 is directly connected to a defogger element. Figure 30-9 shows the measured electric field radiation patterns in the horizontal plane. Figure 30-10 shows the average gain around all directions in the horizontal plane. The directivity is measured with a 10 dB amplifier circuit. In these figures, the angle is measured from the front direction.

Diversity Reception Antenna System

Figure 30-11 illustrates the diversity reception antenna system for TV.¹⁰⁻¹² The antenna elements are printed symmetrically on the left and right quarter windows of the car. The antenna consists of two parts: the slanted element consisting of three thin lines located

FIGURE 30-8 Window glass antenna printed on the rear window of sedan-type car

FIGURE 30-9 Measured electric field radiation patterns in the horizontal plane

close to the rear pillars, and a horizontal element printed at the center of the quarter glass. A switching diversity system was adopted because the synthetic diversity system was not sufficiently effective at suppressing multipath distortion. The switching diversity system can effectively follow changes in field strength by selecting appropriate antennas for better reception. The antenna switching is performed during every vertical blanking period in the TV video signals.

The diversity reception system for the terrestrial TV has been on the market since the middle 1980s.^{11,12} Two V-shaped pole elements were first used for TV reception. A new antenna system consisting of four antenna elements printed on the rear quarter window glass was developed in 1986. Subsequently, an adaptive array antenna for terrestrial digital TV broadcasting was developed, and you will soon be able to enjoy TV programs in high-quality digital while riding in an automobile.¹³

FIGURE 30-10 Average gain around all directions in the horizontal plane

FIGURE 30-11 Diversity antenna system for TV

On-glass Mobile Antennas for Digital Terrestrial Television

Figure 30-12 shows the geometry of the horizontally polarized on-glass mobile antenna.¹⁴ The antenna has been developed by modifying a batwing antenna.¹⁵ Batwing antennas have a broad bandwidth but are too large to be installed in vehicles, so development has focused on size reduction. The proposed antenna is normal to ground and fed by a coaxial cable. The antenna height, H , was reduced by bending the wires in that direction without narrowing the bandwidth. The height of the new antenna is approximately half of the original antenna height. The prototype antenna for field experimentation using a passenger van is shown in Figure 30-12b. Two antenna elements and a mesh ground plane were printed on the inside of the rear glass window of the passenger van. The dielectric constant of the glass was 6.7, and the loss tangent was 0.008. The thickness was about 5 mm, which is very thin compared with the wavelength of the UHF band. Experiments confirmed that the glass had a very small effect on antenna characteristics. The patterns were printed using silver paste, and the mesh ground plane was connected electromagnetically to the vehicle body upon installation of the window. The conductivity of the silver paste was about 2×10^6 S/m, which is lower than that of copper (5.813×10^7 S/m). Antenna gain loss was confirmed to be less than 0.3 dB within the frequency band by comparison with the measured results of an antenna composed of copper.

FIGURE 30-12 Geometry of on-glass antenna

FIGURE 30-13 Measured radiation pattern (vertical plane, 485 MHz)

Figure 30-13 shows the radiation patterns of the antenna installed on the left side of the passenger van at 485 MHz. As expected, the elevation pattern peak of E_θ , the co-polarization of DTV, was in the horizontal plane. Figure 30-14 shows the radiation patterns in the horizontal plane at 485 MHz. The antenna element printed inside the left side glass radiates strongly to the left side of the vehicle, and the element inside the right side glass radiates strongly to the right side. A peak gain of 4.5 dBi was achieved by each antenna element, further showing the suitability of this type of antenna for use in a diversity system.

A diversity system can achieve a high C/N ratio in built-up urban areas where multipath fading is strong. Maximum Ratio Combining (MRC) was selected as the signal processing method.¹⁶ The radiation pattern of MRC was estimated by combining the measured radiation patterns of four antennas installed on the passenger van, as shown in Figure 30-15. An average gain of 4.6 dBi was achieved on the horizontal polarization.

Figure 30-16 shows the average gain of the pattern. The solid line represents the gain of the proposed antenna and the dotted line represents a comparison using the average gain of four commercial pole antennas installed on the roof. These pole antennas were leaned at an angle of 45 degrees to the roof. The average gain of four crossed-dipole antennas installed on the corner of the roof was also measured at 485 MHz.¹⁷ From 470 MHz to 710 MHz, the average gain of the proposed antenna was greater than 3.1 dBi. This was 4.7 dB higher than that of the commercial pole antennas, which is the minimum value within the bandwidth. It was also 1.6 dB higher than the average gain of crossed-dipole antennas at 485 MHz.

FIGURE 30-14 Measured radiation pattern (horizontal plane, 485 MHz, element)

Modified H-shaped Antenna

Figure 30-17 shows a modified H-shaped antenna for automotive digital terrestrial reception.¹⁸ Two wires $a-b-c-d-e$ and $f-g-h-i-j$ are symmetrically placed around the center m of the antenna and connected by the wire $c-m-h$. The parts $a-b-c$ and $f-g-h$ of the two wires are longer than the parts $c-d-e$ and $h-i-j$. The antenna is placed in the xy plane. A control system for combining received signals is shown in Figure 30-17b. The received signals of the four antennas are down-converted, weighted, and combined. The weight vector for each signal is controlled, based on the MRC method. The four antennas mounted at the top of the front and rear windows are also depicted. The antenna plane, which includes the antenna element, is inclined from the horizontal plane in an actual car.

FIGURE 30-15 Radiation pattern (four-element array)

A design concept of the coverage in the xy plane is summarized in Figure 30-18. Mechanism of the antenna is described with Figure 30-17a and Figure 30-18. The antenna has three resonant modes. Each resonant mode is excited when a part of the antenna becomes a half-wavelength. The frequency band for digital terrestrial services is divided into three bands. The wire $a-b-c-m-h-g-f$ is resonated at the low frequency, which is series resonance. Parallel resonance occurs at the middle frequency. The two wires $a-b-c-d-e$ and $f-g-h-i-j$ are resonated. Series resonance occurs again at the high frequency, in which the wire $e-d-c-m-h-i-j$ is resonated. The radiation pattern of a single element is rotated clockwise with increasing frequency. The minimum level of relative amplitude increases when the maximum radiation is directed toward the x -axis direction. The four antennas are symmetrically placed around the x -axis and y -axis directions in Table 30-2, which is assumed to be equivalent to installation at the top of the front and rear windows. The symmetrical arrangement allows coverage of 360 degrees.

The wires shown in Figure 30-17a were etched on a typical FR4 substrate having dielectric constant of 4.6 and thickness of 0.8 mm. The width of the lines was 1 mm. The lengths L_L , L_S , and L_C were experimentally adjusted to 102, 67, and 30 mm, respectively, with constant value of $H = 60$ mm, since the value of H was specified for car installation. The prototype antenna has LC balun and a parallel feedline between the LC balun and the feedpoint m .

FIGURE 30-16 Average gain of the adaptive array pattern (E_ϕ)

FIGURE 30-17 Modified H-shaped antenna and control system for combining received signals for automotive digital terrestrial reception

The LC balun transforms impedance from $110\ \Omega$ to $50\ \Omega$ as well as balance-unbalance mode. The LC balun consists of a high-pass filter (HPF), a low-pass filter (LPF), and a T-junction. Both filters have the fifth-order Butterworth function. A 3 dB cutoff frequency is set at a low frequency of 272 MHz for the HPF and a higher frequency of 1228 MHz for the LPF of the frequency band from 470 to 710 MHz so that both filters may give flat amplitude and out of phase. Insertion loss of the LC balun was measured to be 0.3 dB across the frequency band. The parallel feedline has a length of 40 mm. The width of each line and the distance between the centers of the two lines were chosen to be 0.8 and 1.1 mm, so that characteristic impedance would be $110\ \Omega$.

Figure 30-19 shows the measured radiation patterns at the three frequencies. The figure-8 radiation patterns were rotated clockwise with increasing frequency as the calculation results predicted. VSWR was measured to be less than 3 from 470 to 710 MHz.

Four prototype antennas were mounted at the top of the front and rear windows of the car, as shown in Figure 30-17b. The distance between the edges of the metal roof and the nearest side of the prototype antennas was set at 20 mm. The spacings of antenna elements were, respectively, 600 mm in the x' -axis direction and 1600 mm in the y' -axis direction. Figure 30-20a–d show typical measured radiation patterns of the four prototype antennas in the ϕ' plane at 530 MHz. Each prototype antenna had gain to the x' -axis direction as well as to the y' -axis direction because the four antennas in free space had inclined figure-8 radiation patterns. The peak plot combined with the radiation patterns in Figure 30-20a–d is shown in Figure 30-20e. A near omnidirectional pattern was achieved in the ϕ' plane. In terms of vertical plane, gain of the peak plot decreased with increasing the angle θ' ,

FIGURE 30-18 Concept covering 360 degrees in the xy plane using the four antennas across the frequency band for DTV

FIGURE 30-19 Measured radiation patterns of a prototype antenna in the xy plane

FIGURE 30-20 Measured radiation patterns in ϕ' plane at 530 MHz. Four prototype antennas were mounted at the top of the front and rear windows of a car. Peak plot of the combined pattern based on the MRC method is also presented.

because radiation patterns of the mounted prototype antennas were affected by the effect of the car body. The values of the minimum gain of the peak plot were -2.3 dBi for $\theta' = 70$ degrees, -3.7 dBi for $\theta' = 80$ degrees, and -6 dBi for $\theta' = 90$ degrees.

Adaptive Beam Steering Reception System

To improve the reception quality of television on mobile terminals, the adaptive beam steering system has been studied in Japan.¹⁹

Figure 30-21 shows the adaptive beam steering reception system. This system adopts the diversity technique, combining received signals prior to FFT processing on the OFDM demodulator. The experiment was conducted in the Nagoya suburbs using a van with four antennas on the windows, and was focused on traveling on highways. From the experiment, it was shown that the mobile reception area using the adaptive beam steering system is almost the same as the fixed reception area.¹⁹

31.1 INTRODUCTION

Wireless systems are evolving toward multifunctionality. This multifunctionality provides users with options of connecting to different kinds of wireless services for different purposes at different times, whether in a city or on a battlefield. To reach their full potential, these systems require not only agile electronics and adaptive signal processing, but also reconfigurable antennas. Reconfigurable antennas can be used simply to reduce the number of antennas necessary for intended system function, but they can also be designed to serve much more complex roles. Some of these roles include use as programmable control elements with feedback to increase throughput, reduce errors and noise, and improve security, and use as reconfigurable hardware to extend the lifetime of the entire system. Examples of emerging applications include software defined radio, cognitive radio, multiple-input multiple-output (MIMO) systems, multifunction consumer wireless devices, and high performance phased arrays.

As one examines the development of reconfigurable antennas, and, in fact, antennas in general, one can see that each antenna is driven by specific applications or functionality. Indeed, there is no one ultimate application that would result in a super antenna that would be able to meet the specifications of every system. In this, antenna engineers are truly fortunate—practical issues, such as cost, weight, size, and complexity, make each new system or application a new challenge. Antenna reconfigurability can help to meet these challenges in new and exciting ways. This chapter describes the work of talented engineers and researchers in their efforts to develop reconfigurable antennas, from large apertures for communication and sensing satellites to single individual elements on small portable wireless devices. These examples, as well as others, are the first steps in establishing a strong foundation of antennas for fully multifunctional systems.

A Brief Definition of Antenna Reconfigurability

A reconfigurable antenna is one that has selectable or tunable fundamental characteristics, including operating frequency, impedance bandwidth, radiation pattern, and polarization. Typically, the goal is to change one or more of these characteristics independently of the others. The methods in which these characteristics are changed are electrical, mechanical, or electromechanical in nature, since fundamentally, antennas are electromechanical structures. However, given the wide range of intended applications and design specifications, engineers have developed an equally wide and varied collection of reconfiguration mechanisms.

In each of the following sections, theoretical foundations and examples of different kinds of reconfigurable antennas are presented. While there are many more reconfigurable antennas than can be discussed here, the selected subset of antennas is intended to provide a broad sampling of the rich history and future potential of these tools for communication, sensing, and security.

31.2 RECONFIGURABLE APERTURES

In concept, reconfigurable apertures represent the ideal functionality of reconfigurable antennas in that they allow the complete specification of radiating currents that can produce any desired frequency and radiation behavior. The challenge lies in developing real structures and control mechanisms that can support this functionality.

Motivation for Reconfigurable Apertures

As mentioned previously, each antenna is typically designed to deliver functionality for a specific application. In the case of aperture antennas, they are most often implemented for long distance, high gain applications intended for more expensive and specialized systems, such as satellites, long-haul land-based communications, and radar receivers. However, when the antenna is large in extent and is deployed in a hostile or remote location, reconfigurability plays a different role. In this case, it could lengthen the useful lifetime of the system by allowing for reprogramming/retasking, without the need for retooling or for a labor- and cost-intensive maintenance visit. The apertures discussed here implement a variety of approaches to enable this kind of reconfigurability.

Examples of Reconfigurable Apertures

Reflector antennas are perfect candidates for radiation pattern reconfiguration independent of frequency, since the reflective surface is physically removed and isolated from the primary feed. Mechanical deformations of the reflector (or subreflector) surface result in changes in the surface currents on the reflector, which in turn alter the aperture fields, and finally, the radiation pattern of the antenna. In one of the earlier examples of antenna reconfigurability using mechanical means, Clarricoats and his collaborators demonstrated radiation reconfiguration with a reflector antenna by changing the structure of a mesh reflector. Initially, manual adjustments in each meshed region of interest served to change the overall reflector contour, resulting in changes in beam shape and direction.¹ Later, the implementation of computer-controlled stepper motors, used for pulling lines attached to specific points on the reflector mesh, allowed for automatic pattern reconfiguration via electromechanical actuation.²

Recently, another group developed and expanded the functionality of a similar system for satellite applications by changing the shape of a subreflector, with the shape of the main reflector remaining fixed.³ A thin, flexible, conductive material composes the subreflector. The subreflector's shape is changed using piezoelectric actuators attached to its back surface. As the actuators deform the surface of the subreflector, the electromagnetic field illuminating the main reflector changes, which results in a desired radiation pattern. Figure 31-1 shows a subreflector system schematic.³ Enabling changes in the subreflector, rather than the main reflector, simplifies the antenna system fabrication and allows designers to implement main reflectors of varying geometries and deployments. This is especially important for reducing probabilities of failure during deployment or operation for space applications. One important goal of the antenna in this case³ is to achieve the desired reconfigurability with the minimum number of actuators. During the antenna system design, the positions of the actuators are determined using an iterative finite element algorithm. This algorithm determines where successive actuators should be placed in order to minimize the error between the desired and actual subreflector shape.³ In providing the ability to change the antenna's radiation pattern, this design approach can be used to effectively lengthen the useful lifetime of communication and relay satellites.

FIGURE 31-1 Reconfigurable subreflector system, including piezoelectric actuators and driver to deflect the surface of a Cassegrain subreflector (after G. Washington et al.³ © IEEE 2002)

Moreover, it can dramatically reduce cost by allowing antennas to be retasked via programming from the ground rather than requiring completely new satellites to enable new functions and all of the cost that this entails.

The next two examples of reconfigurable antennas may stretch the definition of an aperture in the traditional sense, but one can certainly consider them to be blank palettes for establishing desired current distributions that result in desired antenna behavior. In essence, these apertures are intended to create whatever antenna is necessary to achieve specific frequency, bandwidth, radiation, and polarization characteristics. The first is an antenna that uses switches (which can be based in solid-state, MEMS, or other technologies) for connecting small non-resonant conductive pads that create a large antenna aperture.⁴ The number of switches required for such an aperture can easily number into the thousands. Figure 31-2 shows a conceptual drawing of the aperture.⁴ The desired antenna configuration is found using a genetic search algorithm, which determines the needed combination of switch states across the aperture for achieving a specified performance goal.⁴ For each pass through the genetic algorithm, a finite-difference time-domain electromagnetic simulation is used to evaluate candidate designs. In general, narrowband configurations achieve more gain than wideband configurations, since wideband configurations implement fewer effective radiators in the aperture, which has a fixed physical size. While this aperture approach promises tremendous flexibility in terms of both frequency and radiation performance, it does have some inherent drawbacks. High frequency operation may be degraded as a result of the pad density and switch capacitance.⁴ Additionally, for designs at lower frequencies, the fixed physical size of the aperture may not be able to support high gain operation. Moreover, while the large number of switches between pads provides for graceful degradation of operation with switch failure, the complexity of the required bias networks to allow the switches to be individually addressable may make the final product too costly and bulky for its intended application.

The second related antenna aperture concept uses semiconductor plasmas to form antenna structures.⁵ Developed by researchers at the Sarnoff Corporation, this pixel approach to a reconfigurable aperture relies on high conductivity plasma islands that are formed and

FIGURE 31-2 Conceptual drawing of a reconfigurable aperture antenna based on switched links between small metallic patches (after L. N. Pringle et al⁴ © IEEE 2004)

controlled by DC currents that have been injected into high-resistivity silicon-based diode structures. While the fundamental concept—that of creation of conducting patches in an aperture—is identical to the last antenna discussed, this antenna aperture differs significantly in the technology necessary for achieving the desired current distributions. Figure 31-3 contains a detailed description of the structure, including the plasma injection driver configuration.⁵ While elegant in its conception, the embodiment is fundamentally just as complex as the previous example that uses many discrete switches. This means that many practical and technical issues exist with this approach, including the challenge of creating the necessary carrier densities in the silicon. However, it possesses one compelling feature that other reconfigurable apertures based on conductors do not have: when turned off, the aperture possesses an extremely low radar cross-section. Similar to the previous example,³ this approach to antenna reconfigurability may be more appropriate for creating intermediate apertures that are illuminated with more conventional sources. In this case, the plasma aperture could be used to reconfigure holograms for holographic antennas in which a basic source, such as a patch or horn antenna, is used to illuminate a hologram. The aperture field for the desired pattern is then produced through interaction with the plasma aperture, enabling beamsteering and beamforming without the need for expensive phase shifters. The plasma aperture could then be designed using iterative or other means and reconfigured to deliver performance comparable to traditional phased arrays.⁵⁻⁶

FIGURE 31-3 Depiction of a controllable plasma grid structure for a reconfigurable aperture: (a) The grid structure is fabricated on top of the silicon wafer. (b) A cross-section of the plasma grid structure shows the layer interconnection (after A. Fathy et al⁵ © IEEE 2003).

31.3 RECONFIGURABLE TRAVELING WAVE ANTENNAS

Traveling wave antennas are well known for delivering frequency-scanned radiation patterns. Introduction of reconfigurability into these structures adds another layer of functionality that can reduce some of the system costs inherent in previous designs.

Motivation for Reconfigurable Traveling Wave Antennas

Traveling wave antennas have been used with great success for delivering broadband beam scanning performance through frequency sweeps, without the need for phase shifters.

However, the necessity to change operating frequency to steer beams in a particular direction places burdens on both ends of a communication link. The reconfigurable traveling wave antennas discussed here have made real gains in delivering frequency-independent beam scanning, without compromising the effective operating bandwidth of the original base antenna.

Examples of Reconfigurable Traveling Wave Antennas

One recently-developed reconfigurable traveling wave antenna is a dielectric waveguide antenna, which relies on the mechanical perturbation of propagation constants at millimeter-wave frequencies.⁷ The widths of the gratings on a thin, moveable film placed over a dielectric image line are designed to gradually perturb the propagation constant along the line, as shown in Figure 31-4.⁷ Viewed in light of the antenna presented in the previous section, this film serves as an effective hologram for the desired pattern. Physical shifts of the grating film change the apparent grating spacings and result in a scanned beam at a single frequency. Scan angles of up to 53 degrees have been demonstrated with this design at 35 GHz, with lower scan angles achievable over an operating band between 30 and 40 GHz.⁷ An extension of this concept delivers scanned, dual beam performance over a similar frequency range.⁸ Employing the concept of the holographic antenna,⁵⁻⁶ its functionality could be expanded further by enabling reconfigurability of the film itself.

Another interesting reconfigurable traveling wave antenna, first developed in 1960, is the electromechanically scannable trough waveguide antenna.⁹ Based on an asymmetrical trough waveguide intended to feed a parabolic reflector,¹⁰ two different mechanisms were investigated to change the phase velocity in the guide, resulting in scanned radiation patterns at a single frequency. The first used the rotation of artificial dielectric structures along a longitudinal axis within the trough waveguide, and the second used a mechanical variation of the height of periodic structures located on the top of the center fin of the trough waveguide.⁹ While elegant in concept, the authors acknowledged that both approaches presented major mechanical problems. They were solved using cam and gear solutions, which proved to be somewhat cumbersome.

FIGURE 31-4 A traveling wave antenna based on moveable grating fed by a dielectric image line, capable of beam scanning at millimeter-wave frequencies (after K. Chang et al⁷ © IEEE 2002)

FIGURE 31-5 Trough waveguide dimensions (left), electric field lines of the dominant TE mode with equivalent structure for design and field distribution (middle), electric field lines of the TEM mode (right) (after G. H. Huff and J. T. Bernhard¹¹ © 2005)

Huff and Bernhard¹¹ begin with the concept of the electromechanically scanned trough waveguide⁹ and then propose the application of more modern perturbations and streamlined actuation mechanisms. This allows them to achieve beamsteering at a single frequency while preserving the wide bandwidth characteristics of the antenna. The fundamental structure remains the trough waveguide, however, as shown in Figure 31-5.¹¹ In this case, beamsteering is achieved using the micro-machined cantilever structures fabricated within the trough waveguide (shown in Figure 31-6),¹¹ to create perturbations suitable for electrostatic or magnetostatic actuation. Simulations with actuation of individual cantilevers or groups of cantilevers demonstrate beam scanning at single frequencies through broadside for this traveling wave antenna.¹¹

Other leaky wave antennas, which use tunable-impedance, ground planes to enable beam steering, have been developed.¹² Based on the same fundamental concept of controlling wave velocity changes as in the previous example, the structure¹² relies on a tunable-impedance surface equipped with hundreds of diodes to affect beam changes.

FIGURE 31-6 Trough waveguide with cantilever-type perturbations, showing staggered positions of actuated and rest states of the cantilevers (after G. H. Huff and J. T. Bernhard¹¹ © 2005)

31.4 RECONFIGURABLE ARRAYS

The signals used with phased arrays of antennas are already reconfigurable in their magnitude and phase. The addition of reconfigurability at the level of the individual array element promises to provide new levels of system performance.

Motivation for Reconfigurable Arrays

Of course, the one antenna topology that is already well known for its flexibility is the antenna array. This flexibility is traditionally delivered through control of the signal magnitude and phase of identical antenna elements, arranged either periodically or aperiodically, in a plane or conformally on a three dimensional surface. Historically used in defense-oriented applications, arrays are now being used in a much broader set of scenarios to provide additional functionality and security. The reconfigurable arrays described here expand typical array functionality in frequency and radiation performance, providing additional degrees of freedom for system designers and ultimately, system users.

Examples of Reconfigurable Arrays

One persistent issue with antenna arrays is their relatively limited frequency bandwidth. One way to improve the bandwidth of such arrays is to make the individual elements frequency reconfigurable. However, in arrays that have a ground plane, the presence of the ground plane at a fixed distance from the plane of the antennas does not enable the complete frequency reconfigurability present in the elements. In one case,¹³ a novel layered frequency-selective surface was implemented to support the performance of broadband reconfigurable antenna arrays. A diagram of the system concept is provided in Figure 13-7.¹³ With careful design, the frequency selective surfaces appear as magnetic ground planes and deliver nearly constant phase over a broad frequency band. This can enhance array gain, as shown in Figure 31-8,¹³ which would otherwise be limited by a fixed ground plane spacing. The same authors have applied this methodology to a wideband reconfigurable slot aperture.¹⁴

FIGURE 31-7 Depiction of a reconfigurable aperture (RECAP) array over a multilayer frequency selective surface (FSS)/frequency selective volume (FSV) structure (after Y. E. Erdemli et al¹³ © IEEE 2002)

FIGURE 31-8 Diagram illustrating the coherence of direct antenna radiation and reflections from the substrate that helps to provide broadband operation of reconfigurable arrays (after Y. E. Erdemli et al.¹³ © IEEE 2002)

Using another approach, pattern reconfigurable antennas were studied in small arrays.^{15–18} The individual element in the array is a reconfigurable spiral microstrip antenna, also called a reconfigurable magnetic line source antenna. This antenna, through the inclusion of solid-state or RF MEMS switches, delivers broadside and endfire radiation patterns.^{15–18} When arrayed, these elements can extend the scan capabilities over that achievable with a traditional planar phased array.^{15–18} A photograph of a 4×4 array of these elements is shown in Figure 31-9.¹⁸ Measured radiation patterns for the array, with all of the elements in broadside mode with uniform amplitude and phasing, provide a typical broadside pattern. With all of the elements in endfire mode with uniform amplitudes and 180 degree progressive phasing, the array produces a dual-beam endfire pattern.¹⁸ In this case, the patterns of the individual elements are used to reinforce the array factor created in the usual way with element amplitude and phasing. This example provides only a small sample of the array capabilities that can be achieved using individually reconfigurable antenna elements in arrays.

Reconfigurable arrays with electrically tuned or switched parasitic elements can provide a great deal of pattern variability while maintaining impedance match and bandwidth. Fundamentally, tuning of antenna radiation patterns in this manner relies on the mutual coupling between closely spaced driven and parasitic elements, resulting in effective array behavior from a single feed point. Therefore, changes in radiation patterns are achieved through changes in the coupling between the elements, which, in turn, change the effective source currents on both the driven and parasitic elements.

One of the fundamental examples of this antenna was proposed by Harrington in 1978.¹⁹ Shown in Figure 31-10,¹⁹ the single dipole element in the center of the array is driven, while tunable reactances on the surrounding parasitic dipoles couple to the source antenna and produce a directive beam in a desired direction. A waveguide-based reconfigurable array

FIGURE 31-9 Photograph of a 4×4 array of pattern reconfigurable elements that can be configured to deliver broadside, endfire, and scanned radiation patterns (after G. H. Huff¹⁸ © 2006)

FIGURE 31-10 A seven-element circular array of reactively loaded parasitic dipoles for reconfigurable beam steering and beamforming (after R. F. Harrington¹⁹ © IEEE 1978)

was also proposed for the same concept.²⁰ Since then, a number of reconfigurable parasitic arrays have been proposed and studied, using both switched and reactively loaded elements, which provide a wide variety of functionality.^{21–24}

31.5 RECONFIGURABLE MICROSTRIP ANTENNAS

Microstrip antennas are one of the most versatile types of antennas, suitable both as single elements in small devices and in large phased arrays. As a result, any current system that uses microstrip antennas has the potential to benefit from the addition of antenna reconfigurability.

Motivation for Reconfigurable Microstrip Antennas

In addition to their use in the large phased arrays described earlier, more and more microstrip antennas are found in portable/mobile devices for consumers. In these applications, reconfigurability can be implemented to select operating systems and reduce interference as well as to steer radiation patterns away from noise sources or users. Moreover, their well-known operational principles, illuminated through the cavity²⁵ and transmission line models,²⁶ lend themselves well to enable a wide range of reconfigurability. The examples here are confined to single element versions, but many of them can also be implemented in array formations as well.

Examples of Reconfigurable Microstrip Antennas

In work by Bhartia and Bahl,²⁷ the operating frequency range of a microstrip patch antenna was continuously tuned by using varactor diodes (varactors) at the radiating edges of the structure. The varactors operated with a reverse bias of between 0 and 30 volts that corresponded to capacitances of 2.4–0.4 pF. With a change in bias, the capacitance induced at the radiating edge is changed, resulting in a change in the effective electrical length of the patch. This allows for the continuous tuning of the operating frequency (though not typically of the instantaneous bandwidth) over a large band, which has been shown to be 20–30% depending on the type of microstrip antenna used.²⁷

FIGURE 31-11 Geometry of a dual-frequency microstrip patch antenna with a switchable slot (PASS) (after F. Yang and Y. Ramat-Samii²⁸ © *Microwave and Optical Technology Letters* 2001)

Another way to affect discrete changes in a microstrip antenna's electrical length is to change the path of radiating currents without changing the overall footprint of the antenna. An example of this approach was proposed by Yang and Rahmat-Samii for a microstrip antenna.²⁸ Starting with a standard rectangular microstrip antenna, a slot is etched in the patch so that it is perpendicular to the direction of the main current of the patch's first resonance, as shown in Figure 31-11.²⁸ A PIN diode is positioned in the center of the slot to change the current paths on the patch. If the diode is off, then currents travel around the slot and the antenna operates in a lower frequency band, while when the diode is on, the effective length of the patch is shorter and the antenna operates in a higher frequency band. The frequency ratio between the upper and lower operating frequencies is controlled by the length of the slot, and as long as the slot length is not too long, the radiation pattern of the original antenna is largely preserved.²⁸ A similar approach can also be used to reconfigure the polarization of microstrip antennas.²⁹

While many reconfigurable designs are based on patches such as these, other shapes and modes for microstrip antennas have been used to deliver different kinds of radiation pattern reconfigurability. For instance, one design for a square spiral microstrip antenna uses switches placed at particular positions in order to deliver a broadside or 45 degree tilted beam over a common frequency bandwidth.³⁰ The basic antenna structure consists of a single turn square spiral antenna on an electrically thin substrate, shown in Figure 31-12,³⁰ which exhibits a broadside radiation pattern in its fundamental state. To enable reconfiguration, the antenna is equipped with two switched connections: the first between the spiral and ground, as indicated by N (not grounded) and G (grounded) and a second in a small gap in the spiral arm as indicated by S (short) and O (open).³⁰ When the first switch connects the line to ground and the second switch opens the in-line gap, a 45° tilt from broadside in radiation pattern results. Additionally, with activation of only the second switch, this new configuration provides a broadside radiation pattern at a higher operating frequency of 6.0 GHz.³⁰ Others have also studied similar spiral structures that provide a wealth of possibilities for switched tilts in radiation patterns^{31–32} as well as examined reconfigurable behavior when the antennas are integrated into packages.³³ Antennas based on a similar structure have also delivered broadside to endfire radiation characteristics with RF MEMS switched connections.³⁴

In another example, Zhang et al³⁵ developed a microstrip pattern reconfigurable antenna based on parasitic element tuning. The antenna, shown in Figure 31-13³⁵ is composed of

FIGURE 31-12 Radiation pattern and frequency reconfigurable square spiral microstrip antenna showing switch placements necessary for reconfiguration (after G. H. Huff et al³⁰ © IEEE 2003)

FIGURE 31-13 Physical structure and parameters of the reconfigurable microstrip parasitic array. Switching or tuning of parasitic elements on either side of the driven element provides beam tilt capabilities over a common impedance bandwidth (after S. Zhang³⁵ © IEEE 2004).

a single linear element with two parasitic elements positioned parallel to the driven element. Changes in the parasitic element lengths, achieved either with electronic switches (for example, diodes, FETs, and RF MEMS switches)³⁵ or varactors,³⁶ change the magnitudes and phases of the currents on the parasitic elements relative to the driven element. Tilts in the main beam in one plane can then be switched³⁵ or swept³⁶ as the lengths of the parasitic elements are changed. This antenna, as with all parasitically tuned antennas, can be analyzed theoretically using coupling and transmission line models.³⁷

Since microstrip designs typically include a substrate material other than air, possibilities exist, in theory, for reconfiguring antenna behavior through material changes. One example³⁸ of a frequency-tuned ferrite-based patch antenna is presented, which provides a 40% continuous tuning range with the variable static magnetic field in the plane of the substrate and perpendicular to the resonant dimension of the patch. However, the radiation performance of the design left much to be desired, with cross-polarization levels that were significantly higher than those expected from a traditional rectangular microstrip antenna.³⁸

Others have also investigated the properties of ferrite-based microstrip antennas,^{39–40} with results indicating that factors including non-uniform bias fields, as well as the multiple modes and resulting field distributions excited in a bulk ferrite substrate, may preclude their use in practical applications. One exception to this could be a design for a polarization-tunable microstrip antenna. This antenna is based on static magnetic biasing of a ferrite film, which takes advantage of the frequency tuning of the cross-polarized component of the radiated field to deliver tunable changes in polarization.⁴¹ Frequency-tunable patch designs based on the use of ferroelectric substrates or thin films, which typically have much higher relative permittivities than traditional low loss substrates, also face similar practical challenges.

31.6 RECONFIGURABLE SLOT ANTENNAS

Slot antennas, in their roles as the complements of dipole antennas, find applications in a number of systems that require low profile, wide bandwidths, and bi-directional radiation patterns. It is straightforward to integrate slot antennas into existing conductive structures or ground planes without additional structural support.

Motivation for Reconfigurable Slot Antennas

Typically, reconfigurable slot antennas are used to enable frequency agility in a system, since they are straightforward to design, simple to construct, and compatible with a number of switch topologies. Examples of reconfigurable slot antennas described next, some of which cover four or more operating bands, illustrate not only fundamental design principles but also strategies for size reduction and direct switch integration.

Examples of Reconfigurable Slot Antennas

Switched frequency radiating slots with a variety of geometries and radiating properties have been proposed by a number of researchers. Gupta et al⁴² designed a frequency-reconfigurable compact rectangular ring slot antenna that was fed with a single slot-line or coplanar waveguide line. Figure 31-14 shows a photograph of the antenna.⁴² Reconfigured with a total of eight PIN diode switches, the lower of the two frequencies is

FIGURE 31-14 Photograph of a reconfigurable rectangular slot antenna in two different configurations that produce operation at two separate frequencies (after K.C. Gupta et al⁴² © IEEE 2000)

set by the perimeter of the outer loop. The upper frequency is set by the perimeter of the inner loop that was formed when shorter slot sections are activated in place of portions of the outer loop. Peroulis et al⁴³ developed a tunable antenna using four PIN diode switches that changed the effective length of the slot so it could operate in one of four different frequency bands between 530 MHz and 890 MHz without the need for changes in the matching network. A coplanar, waveguide-fed slot antenna utilizing similar principles for frequency tuning with PIN diodes is shown in Figure 31-15.⁴⁴ Often, the available switching technology can affect the choice of antenna geometry. For example,⁴⁵ a hybrid coplanar waveguide slot antenna with a 22% effective bandwidth (shown in Figure 31-16)⁴⁵ was designed to directly accommodate a particular RF MEMS switch geometry, making final fabrication and integration more straightforward.

Using tunable reactive loading, rather than switches, can result in continuously tuned slot antennas. In one case,⁴⁶ a one-wavelength slot antenna loaded with two one-port reactive FET components was tuned continuously. By changing the bias voltage, the reactances of the FETs were varied and the effective length of the slot was changed, thereby changing its operating frequency. The range of tuning varied over roughly 1 GHz centered on 10 GHz, producing a 10% tuning band. For this relatively small tuning range, the radiation patterns were essentially unchanged.⁴⁶ Similar tunable slot antennas loaded with varactors^{47–48} take advantage of higher order resonances to create tunable dual-band performance. Using a transmission line model of the loaded slot resonator, the position of the tuning elements can be determined to enable relatively independent tuning of the two bands.⁴⁸

Slot antennas have also been implemented for the purpose of delivering polarization reconfigurability. In one case, the slot-ring antenna⁴⁹ uses PIN diodes to reconfigure between linear and circular polarization or between two circular polarizations. The general topology

FIGURE 31-15 Frequency reconfigurable coplanar waveguide-fed slot antenna with eight diode switches and associated bias lines (after J. M. Laheurte⁴⁴ © IET 2001)

FIGURE 31-16 Reconfigurable hybrid folded slot/slot dipole antenna: antenna geometry including all three switch locations (left) and photograph of the fabricated antenna using only two of the three switches (right) (after G. H. Huff and J. T. Bernhard⁴⁵ © IEEE 2005)

of the antenna is shown in Figure 31-17,⁴⁹ with the specific diode positions, biasing, and ground plane configurations for both designs shown in Figure 31-18.⁴⁹ For the linear-circular design shown in Figure 31-18a, forward-biasing the diodes across the small discontinuities at 45° and -135° (relative to the feed point) produces linear polarization, while reverse biasing the diodes delivers circular polarization.⁴⁹ The design in Figure 31-18b goes one step further and adds additional symmetric discontinuities to support switching between left- and right-handed circular polarizations.⁴⁹ In both designs, care is taken to divide the ground planes carefully to support proper DC biasing for the diodes while providing RF continuity through capacitors connected between ground plane sections. This antenna is a good example of the additional factors that must be taken into account when transitioning from a fixed to a reconfigurable antenna—the fundamental structure may remain the same, but critical adjustments are required to enable proper DC connections and RF performance.

31.7 RECONFIGURABLE MONOPOLE/DIPOLE ANTENNAS

Used in everything from phased arrays to portable communication devices, monopole and dipole antennas are both elemental and ubiquitous. While the theory explaining their operation is well known and based on a simple resonance principle, their application in specific situations typically requires adjustments to their length and packaging in order to deliver operation in one particular band.

Motivation for Reconfigurable Monopole/Dipole Antennas

When multifunctional systems require operation at multiple frequencies, adjustments to the basic monopole/dipole design can be accomplished either by creating a multiband structure, again based on fundamental or higher order resonances, or by making the antenna frequency reconfigurable. In some cases, the multiband approach is the more sensible within cost and complexity constraints, but frequency reconfigurable monopole/dipole antennas have roles to play where size, cost, noise immunity, security, and low observability are important factors. The reconfigurable monopoles and dipoles discussed here change the effective resonant length of the antenna by adding or removing part of the antenna length through electronic, optical, mechanical, or other means.

Examples of Reconfigurable Monopole/Dipole Antennas

Different kinds of switches (for example, PIN diodes, FETs, optical switches, and RF MEMS) have been implemented by several groups in frequency-tunable dipole and monopole antennas for various frequency bands. Roscoe et al implemented four PIN diodes in a printed dipole antenna to deliver three operating bands between 5.2 and 5.8 GHz.⁵⁰ For this specific design, the researchers limited the reconfiguration range so that a single feed network could be used for all of the operating bands. Kiriazi et al. present an example of a frequency reconfigurable antenna using RF MEMS switches.⁵¹ In this work, opening and closing a pair of RF MEMS switches reconfigures a simple dipole antenna printed on a high resistivity silicon substrate, allowing it to operate in one of two frequency bands. Others have applied the same approach to develop frequency reconfigurable Yagi antennas.⁵²

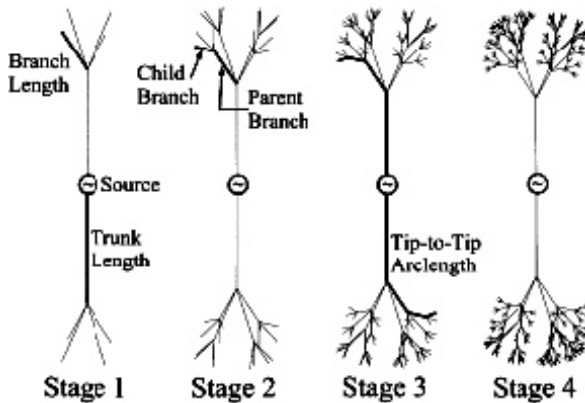

FIGURE 31-19 Reconfigurable three dimensional fractal tree dipole antennas with four branch levels (after J. S. Petko and D. H. Werner⁵³ © IEEE 2004)

More complicated structures based on fractal shapes, but sharing the same underlying principle, have been studied by numerous researchers. For instance, a three-dimensional fractal tree structure is proposed for use with either passive frequency traps or RF MEMS switches to deliver operation over multiple frequency bands.⁵³ An example of the evolution of the structure is shown in Figure 31-19.⁵³ For this antenna, the design methodology can produce operation over multiple contiguous bands, which is only limited by the practicality of implementing the necessary number of switches. Anagnostou et al. propose a reconfigurable monopole based on a Sierpinski gasket, with RF MEMS switches for connecting different sections of the antenna together in order to provide multiple operating bands.⁵⁴ Subsequent work, with the direct integration of RF MEMS switches in a dipole design and shown in Figure 31-20,⁵⁵ provided three separate operating bands with similar omnidirectional radiation characteristics.⁵⁵ Direct fabrication of the RF MEMS switches during the fabrication of the antenna helps to minimize package parasitics that may detune or limit the frequency behavior of the antenna.

FIGURE 31-20 Photograph of a reconfigurable planar Sierpinski dipole antenna with integrated RF MEMS switches (after D. E. Anagnostou et al.⁵⁵ © IEEE 2006)

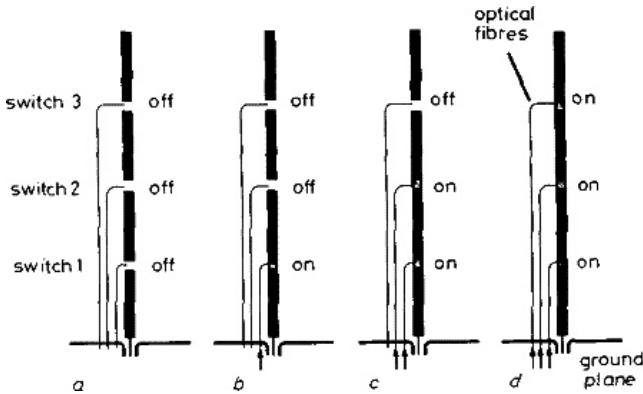

FIGURE 31-21 Diagram of a reconfigurable monopole antenna switchable between four frequency bands with optoelectronic switches (after J. L. Freeman et al⁵⁶ © IET 1992)

Using the same concept but different switch technologies, Freeman et al changed the effective length of a monopole antenna using optical switches. This helped to eliminate many of the switch and bias line effects that can occur with other kinds of switches.⁵⁶ A diagram of this antenna is shown in Figure 31-21.⁵⁶

An excellent example of reconfigurable dipole antennas improving system performance is presented by Piazza and Dandekar.⁵⁷ In this work, reconfigurable printed dipole arrays using PIN diodes have been implemented to enable multiple-input multiple-output (MIMO) orthogonal frequency division multiplexing (OFDM) systems.⁵⁷ For this application, a set of two printed frequency reconfigurable dipoles were spaced a quarter wavelength apart at 2.45 GHz. They were then included at both the transmitter and receiver of a MIMO communication system, shown in Figure 31-22.⁵⁷ In the short configuration of the antennas,

FIGURE 31-22 Diagram of an array of two reconfigurable dipoles used to achieve pattern diversity at a single operating frequency in MIMO systems (after D. Piazza and K. R. Dandekar⁵⁷ © IET 2006)

the elements operated as half-wavelength dipoles. In the long configuration, the antennas were driven in a higher order mode where they were three quarter wavelengths long at the same frequency of 2.45 GHz. By changing the lengths of the antennas but by keeping the operating frequency the same, the researchers were able to achieve four different radiation patterns with each of the arrays, thereby providing a degree of pattern reconfigurability that helped to improve MIMO system capacity.⁵⁷

It is worthwhile to note that implementation of switches, in both monopoles and dipoles, often prevents the antenna from being a self-supporting structure. The need for surfaces for switch and bias line connections usually requires some kind of planar or other dielectric support, which may distort radiation patterns and increase antenna loss and weight slightly.

31.8 CONCLUDING REMARKS

Antenna reconfigurability itself isn't new, but the opportunities for integrating reconfigurable antennas into systems that can fully exploit antenna capabilities are. These opportunities include software defined radio, cognitive radio, MIMO systems, multifunction consumer wireless devices, and high performance phased arrays. As all of the examples discussed in this chapter demonstrate, new antenna designs can be developed to change their frequencies, bandwidths, polarizations, and radiation patterns. They can be designed to solve specific problems now as well as to make systems more flexible and responsive to future operational requirements. However, the challenges for the future of this area of antenna engineering do not lie only in antenna design. Two other significant areas for future work include the development of appropriate control networks and the wide adoption of antenna reconfigurability as an important feature in overall system design. While initial efforts to demonstrate the benefits of reconfigurability in a system-level context have been made by researchers such as Piazza and Dandekar,⁵⁷ a great deal remains to be done. As this work progresses, these new capabilities can be used effectively to deliver high throughput, high reliability, and high security wireless connections in the future.

32.1 INTRODUCTION AND BASIC TERMS

Antennas are used either in transmission, in which case they are fed from the output of some amplifier, or in reception, in which case they provide the RF input to an LNA. Therefore, in some sense, all antennas are active. In the context of this chapter, however, an *active antenna* implies an antenna integrated intimately with an active circuit, including the DC bias circuit, and without an isolator or circulator between them. The absence of isolator/circulator implies that neither the antenna nor the circuit needs to be designed in a 50- Ω environment. Figure 32-1 shows block diagrams of several types of active antennas, classified according to their functionality. Note that this chapter does not discuss in detail phased array antennas. This is a separate and large topic in itself, with excellent overviews given in the literature^{1,2} as well as in papers on T/R modules.³

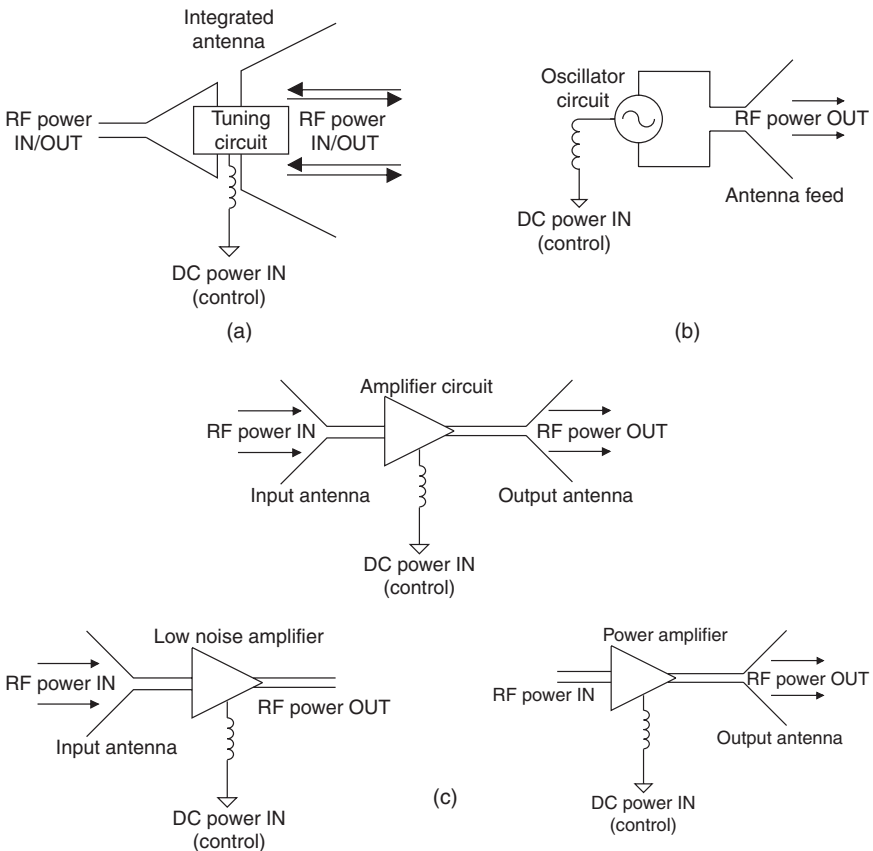

FIGURE 32-1 Schematic diagrams of a few examples of active antennas: (a) actively tuned antenna, (b) oscillator antenna, and (c) amplifier antenna with repeater, receiver, and transmitter subclasses. An *active antenna* implies an antenna integrated intimately with an active circuit.

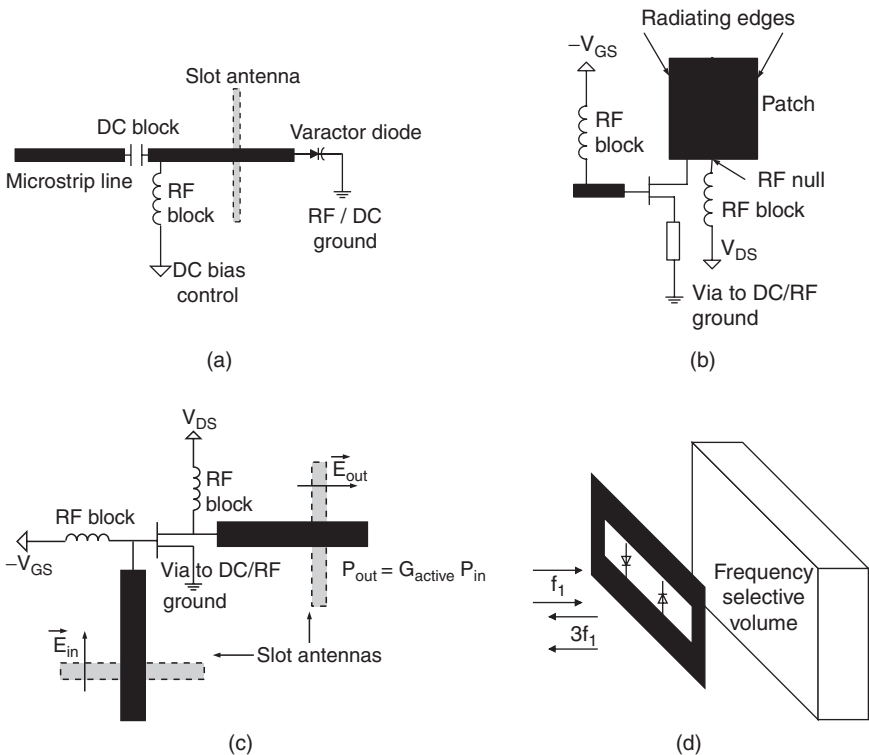

FIGURE 32-2 Illustration of active antennas classified by their functionality: (a) a frequency-agile, in this case continuously tunable, slot antenna with a varactor diode active device; (b) an oscillator patch antenna loaded with a transistor; (c) a dual-slot amplifier repeater antenna; (d) a frequency-doubling slot antenna loaded with a Schottky diode

A Classification of Active Antennas

Antennas are normally classified in terms of operational bandwidth (broadband and narrowband), implementation (e.g. printed, wire, or aperture), etc. In this chapter, it is appropriate to classify active antennas by the function of the active circuit. The following types are discussed at more length throughout this chapter, with an illustration of each type given in Figure 32-2:

- Frequency-agile antennas** A two- or three-terminal active device can be designed into the antenna to enable the antenna impedance to tune with frequency. Figure 32-2a shows an example of this type of active antenna: a slot microstrip feedline contains a varactor diode tuning element, similar to the demonstrations in Forman and Popovic⁴ and Behdad and Sarabandi.⁵ When the capacitance of the diode changes, the electrical length of the antenna, which in turn depends on the antenna reactance, changes and the antenna becomes resonant at a different frequency. In this case, DC power is used to provide increased bandwidth of an antenna element. These antennas find applications in multifunctional systems with multiple nonsimultaneous carriers.

- **Oscillator antennas** A two- or three-terminal negative-resistance device can be connected directly to the terminals of a single antenna element or an array of elements. In this case, DC power is converted to radiated RF power. An example of a patch antenna in the feedback loop of a transistor, similar to the one in Chang et al.,⁶ is shown in Figure 32-2b. Oscillator antennas have been discussed for applications such as low-cost sensors,⁷ power combining,^{8,9,10} and synchronized scanning antenna arrays.¹¹
- **Amplifier antennas** An active device is connected to the terminals of an antenna element to provide amplification in receive mode or transmit mode. In the former case, the matching between the antenna and active element usually optimizes noise, while in the latter case, the matching optimizes power and/or efficiency. Figure 32-2c shows an example of a repeater element with two slot antennas and a prematched amplifier chip, similar to the work in Hollung et al.¹² In this case, increase in gain is enabled by adding DC power to the antenna, and it becomes difficult to separate antenna gain from circuit gain. Amplifier antennas find applications in transmitters where spatial power combining can be achieved with an array, and in receivers where the feedline loss, which contributes to the total noise figure, can be eliminated by directly connecting an LNA to the receiving antenna.
- **Frequency-conversion antennas** A two- or three-terminal active device integrated with an antenna can provide direct down or up conversion of a radiated signal, at frequencies that are direct harmonics or subharmonics of a fundamental frequency (multipliers, dividers), or at frequencies with a given offset from the operating frequency (mixers). Figure 32-2d shows an example of a slot antenna with a Schottky diode, which can be used for frequency doubling since the slot is matched to the diode impedance at both the input frequency and its harmonic.¹³ Such antennas have applications in receivers,¹⁴ mixers with high dynamic range,¹⁵ detectors for millimeter-wave and THz receivers,¹⁶ phase-conjugating RFID type antennas,¹⁷ and high-frequency generation.¹⁸ A special case of frequency-conversion antennas is when a two- or three-terminal rectifying device is connected directly to the terminals of a receiving antenna in such a way that the received RF power is converted with optimal efficiency to DC power, while harmonic production and re-radiation is minimized. This type of active antenna is referred to as a *rectenna*. Such antennas have been applied to RFID tags,¹⁹ sensor powering for cases when there is no solar power and where it is difficult to replace batteries,²⁰ directed narrow-beam array power beaming,²¹ and for energy recycling and/or scavenging.²²
- **Other active antennas** A number of antennas in which the polarization properties (see e.g., Peroulis et al.²³) or radiation pattern can be varied based on control of an active device have been demonstrated. A separate chapter in this book covers reconfigurable antennas, and in this chapter we give a brief description of a few examples of such antennas, including an example of optically controlled antennas and arrays.²⁴

Figures of Merit for Active Antennas

Most standard antenna figures of merit can be applied to active antennas, but care must be taken when defining all properties that include power, since some of the power comes from external DC or RF sources. Properties that do not include power and are defined as in the case of passive antennas are

- Polarization (linear, circular, elliptical; described by an axial ratio)
- Bandwidth (usually defined through return loss, but it is important to also quantify radiation patterns and efficiency, i.e., gain vs. frequency)
- Normalized power radiation pattern

Properties that do include power, for which careful definitions are necessary, defined in the far field are

- Efficiency, defined as

$$\eta = \frac{P_{\text{radiated}}}{P_T + P_{\text{loss}}},$$

where the power loss in the antenna can actually be gain if only RF power is taken into account.

- Gain, defined as

$$G(\theta, \phi) = \eta \frac{S(r, \theta, \phi)}{S_i(r)} = \eta \frac{4\pi r^2 S(r, \theta, \phi)}{P_T}$$

The transmitted power P_T is not easy to determine when the antenna and active circuit are directly integrated. In such cases, the following quantity is relevant:

- Effective radiated power (ERP) with respect to an isotropic source (thus referred to sometimes as EIRP):

$$\text{ERP} = P_T G$$

measured for active transmitting antenna by measuring power density in the far field and assuming it is radiated by an isotropic radiator.

- Effective area, defined as

$$A(\theta, \phi) = \frac{P_R}{S(\theta, \phi)} = \frac{\lambda^2 \cdot G(\theta, \phi)}{4\pi}$$

where G could be the passive or active antenna gain. The passive gain is difficult to access in an integrated antenna, while the active gain yields an effective area that can be larger than the geometric area due to the gain of the active device, and at the expense of DC power.

- Power combining efficiency, relevant in the case of arrays of active transmitting and receiving antennas, and defined as

$$\text{PCE}_{\text{array}} = \frac{\text{ERP}}{G \cdot N \cdot P_i}$$

where the ERP is measured for the entire array, G is found from the geometric area of the array or measured pattern, N is the number of array elements, and P_i is the power of a single isolated element.

- Isotropic conversion loss of a frequency-conversion active antenna has been defined first in Stephan and Itoh²⁵ as

$$L_{\text{iso}} = \frac{P_{\text{IF}}}{P_{\text{RF}} G} = \frac{L}{G_{\text{ant}}}$$

where the measured quantities are the ERP and the down-converted power at the IF frequency, L is the conversion loss of the mixer, and G_{ant} the gain of the antenna. The meaning of this expression is that the same mixer, impedance matched to two different antennas, will have a higher IF output power when connected to an antenna with higher gain.

- Isotropic conversion gain of an oscillator antenna is defined as

$$G_{\text{iso}} = \frac{\text{ERP}}{P_{\text{DC}}} = \frac{P_{\text{RF}} G}{P_{\text{DC}}} = \eta G$$

where the measured quantities are the ERP and the input DC power. The antenna gain can be obtained by simulation or estimated from the measured radiation pattern, which then provides an estimate of the radiated RF power and efficiency of the oscillator circuit.

Modeling of Active Antennas and Limitations of Current CAD Tools

The most efficient way to model an active antenna is to start at the highest level of abstraction, which is a circuit simulator. The antenna can be included as a frequency-variable impedance obtained from a full-wave field simulation. This, however, does not give information about the antenna gain, polarization, or radiation pattern.

The design of an active antenna involves direct matching between the active circuit and antenna. Antennas have a complex impedance with both real and imaginary parts, which vary in frequency. The impedance of active devices is also frequency-dependent. Therefore, matching both the antenna and active device to a common $50\text{-}\Omega$ impedance is not necessarily optimal, although it is common practice due to the fact that the antenna is usually designed separately from the active circuit. An example of an amplifier antenna in which the impedance of the antenna is not $50\text{ }\Omega$, but is designed to have specific complex impedances at both the fundamental and second harmonic frequencies, is given in Weiss and Popovic.²⁶ The impedance of a nonresonant microstrip-circuit-fed antenna is in this case chosen to optimize transistor efficiency by wave-shaping of the voltage and currents.

Consider the Smith chart plots in Figure 32-3. The feedpoint reflection coefficient with respect to $50\text{ }\Omega$ for two antennas is plotted over a broad frequency range. One antenna is a linearly polarized patch centered at 10 GHz and plotted from 8 to 12 GHz in Figure 32-3a. The other is a self-complementary Archimedean spiral antenna that operates above 1.7 GHz and is simulated up to 18 GHz . In an integrated active antenna, the impedance of an antenna needs to be matched to that of the active device. Figure 32-3b shows the input and output reflection coefficients into $50\text{ }\Omega$ for a bipolar and FET transistor from 0.5 to 18 GHz , showing significant variation over frequency. Matching either antenna from Figure 32-3a to a transistor over a range of frequencies can be done in a number of ways.

As an illustration, consider a unit cell, shown in Figure 32-4a, of an amplifier array.²⁷ An off-center-fed $100\text{-}\Omega$ second-resonant slot antenna is the output of a two-stage LNA, while a folded slot receives the input wave in a configuration corresponding to that in Figure 32-1c (top). The off-center-fed second-resonance slot and the folded slot were designed using a method of moments code, where the off-center-fed slot result is shown in Figure 32-4b.

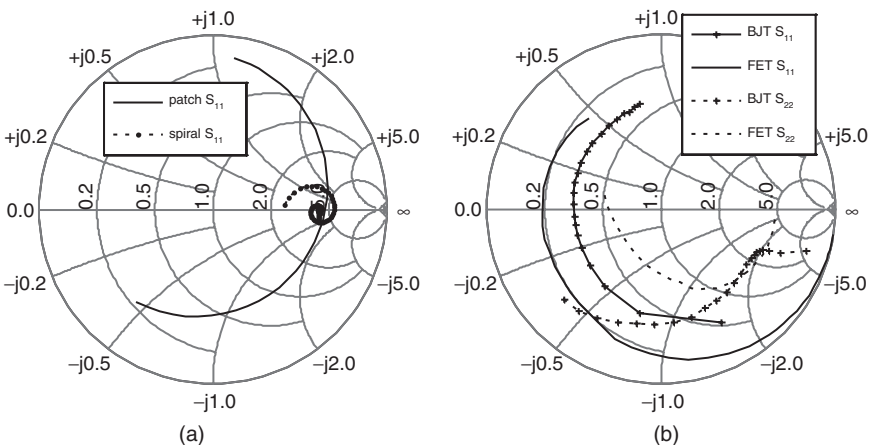

FIGURE 32-3 Smith chart plots of (a) antenna feedpoint reflection coefficient (with respect to $50\text{ }\Omega$) for a narrowband linearly polarized (CP) patch antenna plotted from 8 to 12 GHz , and a broadband CP spiral antenna (0.5 to 18 GHz); and (b) input and output S-parameter variation of a Silicon bipolar transistor (NE6800f) and a GaAs FET (NE7130Na) from 0.5 to 18 GHz . The BJT has gain up to around 10 GHz , while the FET operates to 18 GHz .

FIGURE 32-4 (a) An off-center-fed $100\text{-}\Omega$ second-resonant slot antenna is the output of a two-stage LNA, while a folded slot receives the input wave in a configuration corresponding to that in Figure 32-1c. The printed slot antennas are designed using full-wave analysis. (b) Off-center-fed slot return loss.

The obtained frequency-variable impedances are then inserted into the Agilent ADS circuit simulator to check for stability. It was found that the amplifier was unstable, and a resistively loaded stabilization network that also serves as a bias network was added. Full-wave simulations were used not just for the antenna element design, but also to verify coupling inside a passive unit cell (with a thru-line instead of the transistor). Since the gain of the LNA is around 25 dB in this case, the coupling between the input and output orthogonally polarized antennas needs to be well below this value to ensure stability.

Alternatively, some electromagnetic field simulators have the option of including an S-parameter multiport network in the full-wave simulation. Figure 32-5 shows an example simulation of a transistor with a patch antenna at its output port, with a general connection block between the drain of the FET and the patch antenna. First, the FET from Figure 32-3b is directly connected to the square patch antenna at the radiating edge. Ideally, the

FIGURE 32-5 (a) Patch antenna matched to a transistor input impedance, with added bias line through the patch null. (b) Simulated active antenna gain for transistor directly connected to the patch at the radiating edge, both antenna and transistor matched to $50\text{-}\Omega$, and transistor directly matched to the antenna with a single nonoptimized matching section.

radiating-edge-fed square patch is linearly polarized with symmetric E- and H-plane patterns. The resulting active antenna gain, defined as $G_{AA} = \text{ERP} / P_{\text{RF-in}}$, is shown in Figure 32-5*b*. Then, both antenna and transistor are matched to 50 Ω and the gain of the cascade is shown in the same plot. This is the standard design method and gives improved gain at the expense of space used by two matching networks. Finally, the transistor is directly matched to the antenna with a single matching section, and the gain is shown to change over frequency. For this particular nonoptimal match, the gain is lower than for the 50- Ω case, and is used only as an illustration of the possible different outcomes. For these simulations, a method-of-moments analysis (Ansoft Nexxim) is performed with a two-port *S*-parameter (s2p) transistor “black box” for a specific bias point. A bias line is added to the field simulation through the RF null of the patch antenna, as shown in Figure 32-5*a*. There is no observable change in the active antenna gain, but the radiation pattern loses its symmetry in the H plane due to the addition of the bias line. The amount of pattern distortion depends on the exact position and thickness of the bias line. The E-plane pattern symmetry is affected by the transistor output port, and the polarization is slightly degraded.

This type of analysis gives far-field active antenna parameters, such as gain (defined in Figure 32-5 consistent with the IEEE definition), polarization, radiation pattern, as well as near-field quantities such as current distribution. Because the gain definition only takes into account RF power quantities, the simulated gain for an active antenna is larger than the passive antenna gain as the input DC power is not included. This type of analysis is more computationally intensive than circuit-based analysis.

A reasonable design procedure starts from an EM simulation of the antenna which gives a frequency-dependent impedance for inclusion into a circuit simulation. After the circuit is optimized using linear or nonlinear analysis, an equivalent multiport can be included in a final field simulation in order to validate potential effects of the circuit on radiation pattern.

Active Antenna Measurements

When characterizing the performance of active antennas, it is important to take into account the active circuit properties. An example active antenna measurement for the case of a receiving amplifier antenna of the type given in Figure 32-1*c* (bottom left) is given here. The only quantities that are accessible are the received RF power at the output of the LNA and the DC power input to the LNA. The received RF power is a function of frequency, magnitude, incidence angle, and polarization of the input wave. For an incidence angle (θ, ϕ) and a power P_T transmitted from an antenna in the far field at a distance r away, the power received at the antenna is

$$P_{\text{RF,out}}(\theta, \phi) = \frac{P_T}{4\pi r^2} G_T(\theta, \phi) A_{\text{eff}}(\theta, \phi) [1 - |\Gamma_{\text{in}}|^2] G_{\text{amp}}$$

where generally the transmitted power P_T and transmitter (test) antenna gain G_T are known, while the effective area of the active antenna, match to the amplifier, and gain of the amplifier are not known exactly. By measuring the RF output power over the full sphere for a given polarization at a given frequency, the quantity $A_{\text{eff}}(\theta, \phi) [1 - |\Gamma_{\text{in}}|^2] G_{\text{amp}}$ is determined. Assuming that for the given value of amplifier gain, the antenna is matched to the input of the amplifier, the above can be expressed as

$$P_{\text{RF,out}}(\theta, \phi) = \frac{P_T}{4\pi r^2} G_T(\theta, \phi) \frac{\lambda^2 G_{\text{ant}}(\theta, \phi)}{4\pi} G_{\text{amp}} = \left(\frac{\lambda}{4\pi r} \right)^2 P_T G_T(\theta, \phi) \cdot G_{AA}(\theta, \phi)$$

where G_{AA} is the gain of the active antenna, which will give $A_{\text{eff}} > A_{\text{geom}}$, or an aperture efficiency greater than 100 percent. In this definition, the DC power to the amplifier is not taken into account, and the efficiency of the antenna, which includes aperture and amplifier efficiency, can be found from

$$\eta_{AA} = \eta_{\text{ant}} \eta_{\text{amp}} = \frac{A_{AA}}{A_{\text{geom}}} \frac{P_{\text{RFout}}}{P_{\text{DC}}}$$

where $A_{AA} = G_{AA} \lambda^2 / (4\pi)$ is the effective area of the active antenna.

32.2 FREQUENCY-AGILE ACTIVE ANTENNAS

The feed impedance and radiation pattern of a frequency-agile active antenna is tuned within a frequency range or in multiple bands. If the electrical properties of the antenna are adjusted in a continuous manner, the antenna is said to be *tunable*, and if the variations are in discrete steps, the antenna is said to be *reconfigurable*. Varactor diodes, photo diodes, p-i-n diodes, MEMS switches, and ferrites are examples of active devices that can be integrated with an antenna in such a way that the antenna is impedance matched at different frequencies for different states of the active device. When the impedance changes, it is usually desired that the radiation pattern, polarization, isolation, efficiency, and gain remain the same. However, integration of devices that necessarily have insertion loss results in deterioration in the antenna efficiency.²⁸ This is what makes the design of frequency-agile active antennas challenging. Note that reconfigurability can also be applied to the radiation pattern or polarization of an antenna, as overviewed in more detail in Chapter 31.

Design and Characterization of Frequency-Agile Antennas

The design of a continuously tunable (e.g. Al-Charchafchi and Frances²⁹) or multiple-frequency-band (e.g., Ollikainen et al³⁰) antenna depends on the desired bandwidth for return loss, polarization, radiation pattern, and gain (efficiency). For example, if switching between two or more bands is required to cover an up- and downlink of a half-duplex communication link,³⁰ in addition to requiring the same return loss at the E-GSM band frequencies of 880–915 MHz and 925–960 MHz, the design goals are minimization of losses in the tuning circuit, similar radiation efficiencies, and similar patterns in the two bands. A sketch of the antenna from Ollikainen³⁰ is shown in Figure 32-6a, while the measured dual-band return loss is shown in Figure 32-6b.

The *antenna element design* is based on bandwidth, polarization, available real estate, and preferred circuit architecture. For continuously tunable antennas, a broadband antenna element is desired. For example, a tapered-slot Vivaldi antenna, which can typically achieve octave bandwidth, has been shown to have a 14% varactor-tuned transmit bandwidth,³¹ defined as a 0.8-dB variation in output power. A second-resonant slot antenna with a possible 15–20% bandwidth was tuned over a 10% bandwidth in Forman and Popovic,⁴ as shown in Figure 32-7. Other examples include microstrip antennas and folded-slot antennas, dipoles, etc. For frequency reconfigurability, the antenna itself does not need to be broadband. For example, resonant slots³² and dipoles³³ have been demonstrated with four-band and three-band operation, respectively. Envisioned applications are frequency-hopped spread spectrum systems where a reconfigurable narrowband antenna follows a pseudo-random pattern of the frequency-hopped modulation. Fractal antennas integrated with MEMS switches have been demonstrated as well.³⁴

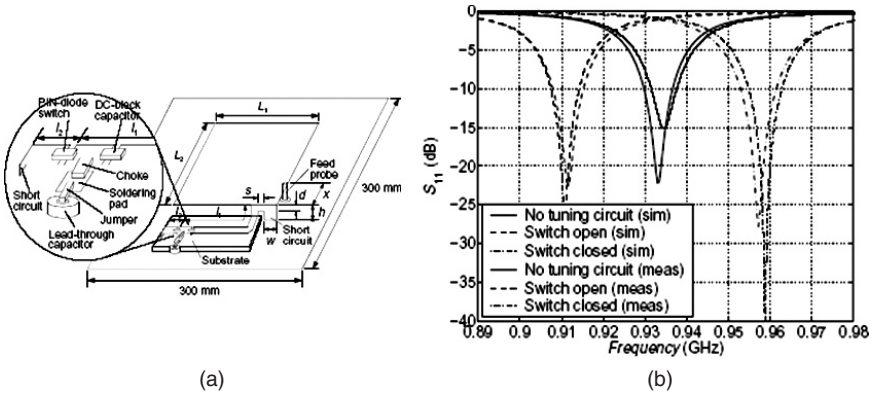

FIGURE 32-6 (a) Schematic of a patch antenna with integrated pin-diode switch and (b) response in the two E-GSM bands. The radiation efficiency was comparable in the two bands, and the radiation patterns remained the same (J. Ollikainen et al.³⁰ © IEEE 2002).

The type of *active element and circuit architecture* are dictated by frequency of operation, and antenna feed. The most commonly used active solid-state devices in frequency-agile antennas are varactor and p-i-n diodes, for continuous and switched operation, respectively. There have also been demonstrations with photo diodes used instead of a varactor, such that the impedance changes as the optical power is varied. In addition, MEMS switches have been proposed as low-loss switching elements. Another possibility is the use of a material with DC bias tuned properties, such as in Castro-Vilaro and Rodriguez-Solis³⁵ where a thin-film ferroelectric material, barium strontium titanate (BST), is used to produce a tunable folded-slot antenna. The DC biasing voltage varies the thin-film dielectric constant, causing a resonant frequency shift. The permittivity of the ferroelectric material can change from 400 to 1200, depending on biasing conditions. In this range the resonant frequency changes from 33.54 GHz to 31.35 GHz, giving an 11% frequency bandwidth with VSWR < 2.

Characterization of frequency-agile antennas should include measurement of return loss, radiation pattern, polarization properties, and efficiency. For example, as can be seen

FIGURE 32-7 Second-resonant slot antenna tuned over a 20% bandwidth with a varactor-loaded microstrip feedline (after M. Forman and Z. Popovic⁴ © IEEE 1997). Measured tuning range and corresponding VSWR (a). The measured radiation patterns change as the bias (frequency) is varied (b).

FIGURE 32-8 An amplifier matched to a tuned antenna with a realistic lossy tuner circuit. The drain efficiency is plotted as a function of the insertion loss in the output network for amplifiers with efficiencies from 20 to 90%. The solid black line indicates how the η_D of a 10-GHz class-E PA with 65% η_D would decrease as loss in the output network increases.

in Figure 32-7b, the radiation pattern of the antenna changes over the tuning bandwidth. In this case, the varactor diode cathode is DC- and RF-shorted to the ground plane, and an extra $\lambda/4$ section is added at the end of the feedline to preserve the RF open. By varying the reverse voltage of the varactor diode from 0 to 30 V, the antenna can be tuned from 7.3 to 8.1 GHz with a VSWR below 1.57, and the peak directivity varies by 2.5 dB over the tuning range. The loss and complexity added by the tuning circuit may not be justifiable. As an example, consider a transmitting active antenna where the goal of the tuning is to provide an impedance match to the amplifier output at several frequencies in a 50- Ω system (see Figure 32-8). Power is lost if either the amplifier is mismatched or there are losses in the circuit/antenna. Assuming a fairly extreme case of a high-efficiency amplifier with 65% efficiency, the question is how much tuning-circuit loss can be tolerated to justify the added complexity. Figure 32-8 shows the calculated efficiency drop as a function of tuner loss. This means that for this high-efficiency case, a tuner/antenna insertion loss of at most 0.3 dB can be tolerated. If the loss is higher, it is more reasonable to tolerate mismatch at the output of the amplifier.

32.3 OSCILLATOR ANTENNAS AND ARRAYS

Antennas integrated with oscillators for power combining and sensors/receivers have been overviewed by a number of authors.³⁶ When an antenna is closely integrated with an oscillator, there is no direct access to the antenna feed or the oscillator output. The design of the active antenna requires both circuit and field modeling. The antenna is part of the feedback loop in an oscillator antenna. It is useful to start the design by considering the antenna to be a simple resonant circuit, as shown in Figure 32-9c,²⁷ although this is a

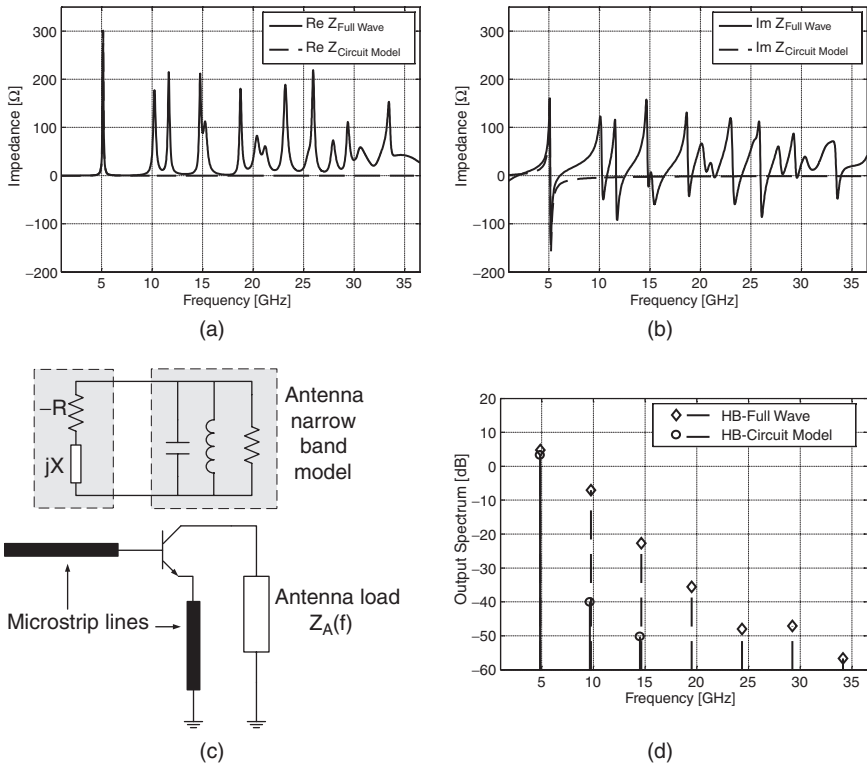

FIGURE 32-9 Example of simulated impedance of a patch antenna over a broad frequency range: (a) real and (b) imaginary part. (c) Simple resonant circuit model of oscillator antenna around first resonance and more realistic model of transistor oscillator antenna. (d) Harmonic balance analysis for the two antenna models, showing the importance of proper broadband modeling.

simplification valid only over a narrow bandwidth. The oscillator circuit is represented as a negative resistance with some equivalent reactance, with bias circuitry omitted. As in standard one-port oscillator models, the negative resistance needs to exceed the radiation resistance of the antenna. In this simple model, the effect of antenna behavior over a broader frequency range is not modeled accurately. Thus, harmonic levels cannot be predicted. An example of the real and imaginary parts of the broadband antenna impedance for the case of an air-patch linearly polarized antenna is shown in Figure 32-9a and b. Both full-wave and circuit models for a patch are included in the plot, showing that the first resonance is correctly modeled by the simple resonant circuit, while the higher harmonics are not. If an active oscillator antenna design is to be correct at the harmonics, the broadband impedance needs to be used in the harmonic-balance nonlinear simulations. A simplified oscillator-antenna circuit is shown in Figure 32-9c. Figure 32-9d compares the harmonic levels obtained with a harmonic balance nonlinear simulation for two circuits which differ only in the way the antenna is included: in one case as the resonant-circuit model and in the other as a set of S -parameters obtained from the full-wave simulation. Power levels at all the harmonics differ considerably in the two cases, including the power at the fundamental. This simple example illustrates the importance of correctly modeling the antenna in circuit design.

FIGURE 32-10 Examples of oscillator antennas: (a) a push-pull oscillator patch; (b) a Vivaldi slot VCO antenna with varactor-tuned Gunn-diode circuit; and (c) a microstrip annular ring is both the radiating element and microstrip feedback circuit for a class-E amplifier.

For a narrowband transmitter, a narrowband antenna is chosen. If radiation in the half plane is desired, a patch antenna is easily integrated with the oscillator circuit, as in the example in Figure 32-10a.¹⁴ The patch antenna has several other properties that can be advantageous for active antennas: the voltage null in the middle is a natural DC bias line, and the phasing of the voltage and current on the two halves of the patch nonradiating edge allows for multitransistor circuit designs, such as in Figure 32-10a where a push-pull FET oscillator loads a 6-GHz patch antenna giving an output ERP of around 18 dBm. Several such elements have been successfully combined in small arrays with increased ERPs.

For a broadband medium-power tunable linearly polarized transmit antenna element, the Gunn-diode varactor-tuned Vivaldi antenna is chosen in Navarro et al.³¹ (see Figure 32-10b). For millimeter-wave (155 and 252 GHz) low-power transmitters, slot antennas with high cutoff frequency transistors (HFETs) are fabricated monolithically. If unidirectional radiation is required, the slot can be backed by a ground plane, polarizer, or substrate lens. Fundamental oscillations from 115-GHz and 215-GHz monolithic oscillator antennas are reported with 10uW and 1uW estimated output powers from the oscillators.³⁷

Classical design of oscillators based on an amplifier with appropriate feedback can also be applied to oscillator antennas. In a high-efficiency 10-GHz integrated transmitting antenna,³⁸ an annular ring is used both as the radiating element and microstrip feedback circuit for a class-E amplifier. A maximum conversion efficiency of the DC power consumption to radiated copolarized power is 55% at 10 GHz with maximum ERP of 23.6 dBm and total radiated power of 15.5 dBm. In this case, the size of the active antenna is minimal, since the antenna is used directly as the feedback circuit, with an amplifier embedded within the antenna footprint. The annular microstrip ring antenna is operated in its TM_{12} mode. The wider bandwidth of the TM_{12} mode compared to the TM_{11} fundamental mode is

useful in the active antenna design, since it enables some tolerances on the active circuit. Nonlinear models of active devices have difficulty predicting behavior in switched mode of operation, which is compensated for in design by increased impedance bandwidth.

Both two-port and three-port active devices have been used in oscillator antennas: Gunn diodes,³¹ IMPATTs,³⁹ various types of transistors, tunnel diodes,³⁶ and Josephson junctions.⁴⁰ Transistor transmitting antennas currently dominate because of the relative ease of integration, the fact that frequency and power are dictated mostly by the circuit/antenna, and availability of devices that cover a broad range of frequencies and powers.

Application Example for a Single Oscillator Element and Small Array

Single oscillating antennas have been developed for compact low-cost RF sensors, while oscillator arrays have been applied to spatial power combining and phase-shifterless beamsteering. Low-cost, low-power manufacturable automotive crash sensors and RFID tag systems⁴¹ have been developed at 24 GHz for use in the ISM unlicensed band. An example of a sensor antenna is shown in Figure 32-11*a*. The active device at 24 GHz is an HEMT or HBT, and the circuit is implemented in microstrip on an Alumina substrate ($\epsilon_r = 9.8$) with gold metalization and is packaged in a standard package. This active antenna is designed as a three-port oscillator, where the gate microstrip resonator is the radiating element.⁴²

In low-power sensor applications, the parameters of interest are the precise oscillation frequency, frequency stability, and phase noise. We first consider design of the oscillator antenna such that for every device, irrespective of device variations, operation within the 200-MHz band around 24 GHz is ensured. The first step is to accurately model the embedding impedances at the active device terminals with full-wave analysis. This is followed by either a linearized or nonlinear circuit analysis. In the former, the oscillator is considered as a combination of an active multiport and a passive multiport which is obtained from field simulations. The oscillation condition can be expressed as

$$|\det(\mathbf{S}_T \cdot \mathbf{S}_p - \mathbf{I})| > 0 \quad \text{and} \quad \text{Arg det}(\mathbf{S}_T \cdot \mathbf{S}_p - \mathbf{I}) = 0$$

where \mathbf{I} is the identity matrix. This condition is plotted as a function of frequency in the complex plane and crossing of the positive real x -axis at the desired oscillation frequency (24 GHz in this case) indicates an oscillation. It is good practice to measure the S -parameters of the device for varying input power levels. The major effect under large signal conditions is the change in $|S_{21}|$, and a reduction in $|S_{21}|$ by a factor between 0.4 and 0.6 is usually appropriate. This type of analysis usually predicts the oscillation frequency within 1% to 5%

FIGURE 32-11 (a) Photograph of the 24-GHz packaged oscillator antenna using an HEMT device; (b) photograph of four-element active array, and (c) measured spectrum of array (black) compared to free-running spectrum of single element (gray)

of the measured value, but does not give any prediction of power or harmonic levels. To obtain the exact oscillation frequency, a varactor diode weakly inductively coupled to the gate resonator can provide 3% tuning.

An important parameter for sensors that rely on small frequency modulations (e.g., Doppler shifts) is the phase noise. The phase noise can be improved by increasing the loaded Q factor of the resonator antenna, by injection locking, or by using mutual locking of a number of active antennas in a small array, and is inversely proportional to the square of the loaded Q factor of the resonator-radiator. When a longer gate resonator-radiator with doubled unloaded Q factor is inserted in the same active antenna, a decrease of 5 dB, compared to the expected 6 dB, in phase noise is measured. The different resonator will, however, affect the radiation pattern and polarization. Injection of a low-phase noise external source can reduce the phase noise further (down to -80 dBc/Hz at 100-kHz offset in this case) but this approach is not practical for low-cost small sensors because it requires a secondary source. In an array of self-locked oscillators, the signal combines coherently and the noise incoherently, resulting in improved phase noise. Mutual locking of a number of nonlinear oscillators cannot be simulated with commercial software tools. However, coupling in the passive part of the circuit can be simulated and used as a useful starting point for mutually locked array design. The coupling for a four-element array shown in Figure 32-11b can be described by a symmetric 4×4 admittance matrix. The oscillation condition can then be calculated by

$$-Y_{\text{osc},i}(\omega_r, A_i) = \sum_{j=1}^N Y_{ij}(\omega_r)$$

where $Y_{\text{osc},i}$ is the frequency and amplitude-dependent transistor admittance, and Y_{ij} are the elements of the coupling matrix. Based on simulation, a four-element array was implemented, with phase noise compared to a single oscillator antenna, as shown in Figure 32-11c. The ERP increased by roughly 10 dB, while the phase noise decreased by 7 dB. Both numbers differ from the theoretical maximum when four identical elements are locked coherently without change in operating conditions. In the array, however, due to the coupling, the individual oscillators operate under different conditions than when alone, and their biases need to be adjusted for locking at 24 GHz. The expected 12-dB increase in ERP (6 dB in power and 6 dB in directivity) and 6-dB decrease in phase noise can only be design guidelines.

Oscillator Antenna Arrays

In addition to phase noise reduction, arrays of oscillator antennas have been implemented for power combining of low-power oscillators. In arrays with standard half-wavelength spacing, the coupling between antenna elements may not be sufficient to enable oscillator synchronization through injection locking, and additional coupling needs to be provided, e.g. through a circuit. This approach lends itself to beam-steering through frequency control. Alternatively, grid arrays with a period on the order of $\lambda/10$ are inherently tightly coupled and provide the highest power densities in power-combining active apertures.²⁷ Quantities that are directly measurable are ERP, radiation pattern, polarization properties, spectral content, and input DC power. From these quantities, the radiated RF power and conversion efficiency can be estimated.

Most standard arrays with half-wavelength spacing between elements have been limited in the number of elements to 16, due to the difficulty in maintaining synchronized oscillations. In tightly coupled grid oscillators, however, the number of elements that can be coherently combined is in the hundreds. The first such planar grid oscillator with 100 MESFET elements at about $\lambda/10$ spacing at 5 GHz is shown in Figure 32-12a,⁸ where λ is the free-space wavelength. The vertical metal lines are connected to the drain and gate leads, and the

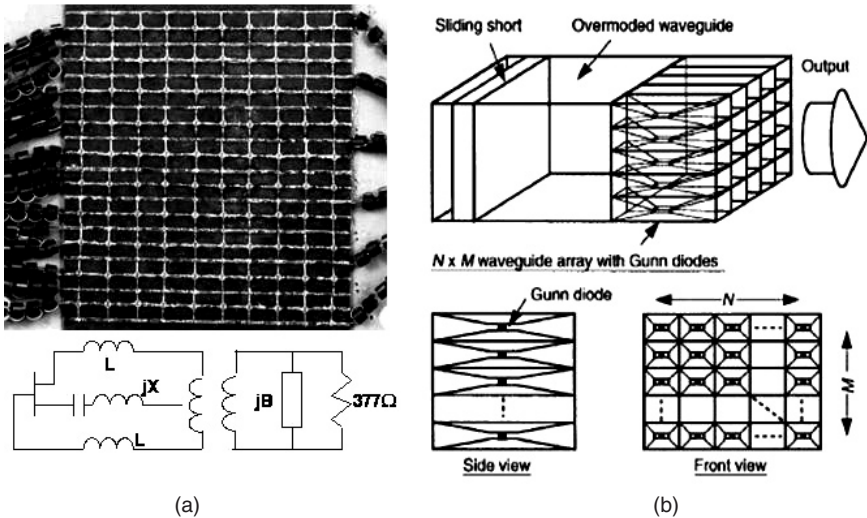

FIGURE 32-12 (a) 100-MESFET grid oscillator with measured ERP = 22W (after Z. Popovic et al⁸ © IEEE 1991). The grid is linearly polarized with a cross-polarization level of -30 dB at broadside. An equivalent circuit convenient for grid-oscillator analysis is shown. (b) Overmoded waveguide resonator coupled to array of waveguides combines a 2D array of Gunn-diode oscillators at millimeter-wave frequencies (after Bae et al⁴⁴ © IEEE 1998).

horizontal metal lines to the source leads and V_{GS} and V_{DS} bias supplies. The grid is a square around λ on the side, backed by a flat reflector of the same size. When the transistors are biased, oscillations start from noise. Power is radiated incoherently from the drain terminals, reflected off the mirror, and received by the gate terminals. For appropriate mirror spacing combined with the phase between gate and drain voltages, steady-state locked oscillation is reached through global coupling after several bounces inside the resonator.

Analysis of this combiner is based on the assumption that the symmetry of the grid reduces it to a unit cell with electric walls on the top and bottom and magnetic walls on the sides. The passive multiport connected to the transistor terminals can be found using the EMF method⁸ or commercial software such as Ansoft's HFSS. An equivalent circuit that describes the physical behavior of the grid is shown in Figure 32-12b, where the vertical leads are represented by inductances, the horizontal leads by a resonant circuit, and the currents on the leads are coupled to the plane wave (a transmission line with a $377\text{-}\Omega$ characteristic impedance) through a center-tapped transformer. The mirror is represented by a short circuit. Circuit simulations using linear parameters give a resonant frequency within 1 to 5% of the measured ones.

Subsequent grid oscillators have demonstrated operation at millimeter-wave frequencies and with up to 660W ERP and 10W of radiated power from 100 devices at X-band.⁴³ Similar arrays at millimeter-wave frequencies where the devices are embedded in one of the mirrors of the resonator are described in, e.g., Bae et al,⁴⁴ where an overmoded-waveguide resonator with an array of TE_{10} -mode waveguides containing Gunn diodes achieved highly efficient spatial power combining at V-band (61.4 GHz). An output power of 1.5W CW was measured with an estimated efficiency of 83% with a 3×3 Gunn-diode array, Figure 32-12c.

Large-scale power combining in a grid oscillator is achieved after radiation in free space. For all elements in phase, the power is combined in the broadside direction and the grid radiates like a continuous active aperture producing a radiation pattern close to $(\sin x/x)^2$. For applications where beam-steering is of interest, antenna arrays with half-wave spacing

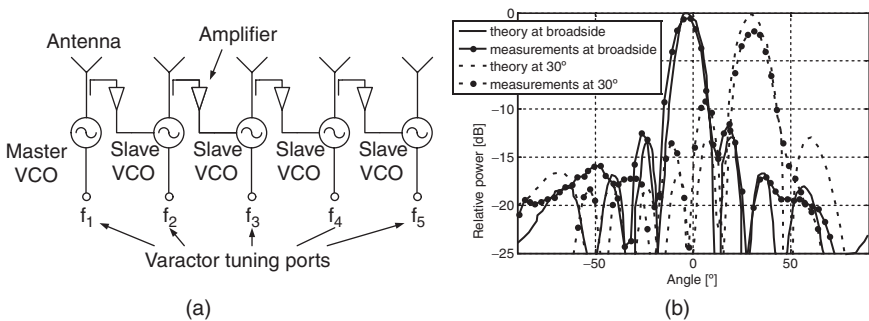

FIGURE 32-13 (a) Principle of beam-steering by frequency detuning. (b) Example measured radiation patterns as the control voltages of the edge VCOs are varied to produce a frequency difference across the array, corresponding to a phase gradient (after R. A. York and T. Itoh⁴⁵ © IEEE 1998).

are more appropriate. A very interesting and elegant approach is described in detail in Popovic and York²⁷ and is illustrated in Figure 32-13. The oscillator antenna elements at the edge of the linear array are detuned in frequency, while the middle elements lock with progressive phase, corresponding to a differential frequency between the end elements. In an X-band prototype ten-element power-combining beam-scanning array of coupled voltage-controlled oscillators (VCOs)⁴⁵ and varactor-tuned patch antennas, a measured ERP of 10.5W at 8.4 GHz is achieved with a maximum scan angle of 30 degrees, corresponding to 500 degrees of phase shift across the array. A theoretical investigation of the phase noise in mutually synchronized oscillator systems indicates the necessity of using external injection locking. The steady-state phases in coupled oscillator arrays are dependent not only on the free-running frequency distribution, but also on the coupling-phase angle, as shown in the insightful theory by York.⁴⁵ Beam-steering arrays with PLLs and multipliers have also been demonstrated. However, extensions to 2D arrays seem unlikely, because it is difficult to independently control and design coupling in two dimensions.

32.4 AMPLIFIER ANTENNAS AND ARRAYS

Amplifier antennas fall into one of the three categories described in Figure 32-1c: receiving antenna integrated with LNA, transmitter PA with antenna load, and amplifier with antenna input and output. While the first two cases are useful both as single elements and arrays, the latter is used mainly in arrays for spatial power combining. The antenna gain is increased compared to a passive antenna at the expense of input DC and RF power. The normalized antenna radiation pattern should remain the same, although addition of circuit and bias can change the antenna far-field properties, especially polarization and sidelobes. The bandwidth of the antenna tends to increase, since effectively loss is added and the Q factor is reduced compared to the passive antenna since the amplifier efficiency is always lower than 100 percent.

Single Amplifier Antenna Elements: Receiving and Transmitting

In a receiver, any loss in the antenna and feedline connected to the LNA contributes to the reduction of noise figure as $F_{\text{tot}} = F_{\text{feed}} + L(F_1 - 1)$, where F_1 is the noise figure of the first amplifier in the receiver chain and L is the loss of the antenna feed connected to the input of the LNA. Usually, the optimal noise match at the input of the amplifier is not 50 Ω ,

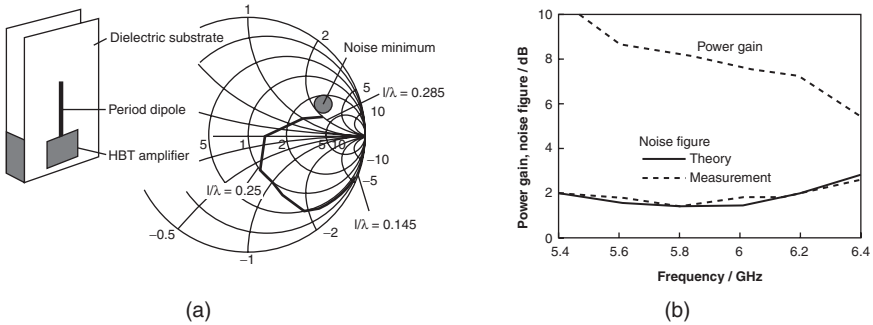

FIGURE 32-14 (a) Input reflection coefficient of printed monopole antenna as a function of length plotted along with the optimal noise match for a SiGe HBT device. (b) Measured and calculated noise figure show increased bandwidth for the integrated amplifier antenna. The power gain is relative to a passive antenna (W. Duerr et al.⁴⁶ © IEEE 1997).

and is also not simultaneously an optimal input reflection coefficient match. In Duerr et al.,⁴⁶ the impedance of a monopole antenna for different dipole lengths was examined as a direct noise match for a SiGe HBT amplifier in the 5.8-GHz WLAN band. Figure 32-14 shows the relevant antenna and device impedances, as well as a plot of the noise figure.

In Radulovic et al.,⁴⁷ a patch antenna is designed to present complex optimal noise figure impedance to a HEMT device at 13 GHz. The patch is fed with an indented microstrip line, which allows for design of complex input impedance by varying two geometric parameters for a given substrate. It is shown that when the patch antenna is designed to provide an optimal noise reflection coefficient of $0.28 \angle 150^\circ$, the radiation pattern of the antenna remains the same, but the gain increases from 7.7 dBi for the passive antenna to 15.1 dBi for the active amplifier antenna. It is interesting to note that there have been demonstrations of broadband electrically short half-loop antenna amplifiers (50–500 MHz),⁴⁸ which are cryogenically cooled and integrated with a SQUID array and buffer amplifier in a portable package. The addition of the inductive SQUID array and buffer amplifier provided the broadband matching for the small inductive antenna.

It is not straightforward to measure the noise figure of the amplifier in an active receiving antenna. If the antenna temperature is T_A , the noise figure of the amplifier can be found from

$$F = 1 + \frac{N}{G_{AA}} - \frac{T_A}{290}$$

where N is the noise spectral power density measured at the output of the LNA referred to input at room temperature of 290K (−174 dBm/Hz), and G_{AA} is the transducer gain of the active antenna, which in turn requires measurements of a reference passive antenna.⁴⁹ The ambient temperature (T_A) needs to be well controlled.

In a transmitter, the antenna is the output load to the amplifier. For a power amplifier, the optimal transistor output impedance is usually not 50 Ω , but is determined by the mode in which the transistor operates. For example, in the case of a class-A saturated power amplifier (PA), the load line and device and packaging parasitics determine the optimal output power impedance. In the case of a high-efficiency switched-mode PA in class-E mode of operation, a specific output impedance forces the time-domain current and voltage waveform product, $i(t)v(t)$, to be zero during most of the period of the carrier frequency, thus minimizing the loss in the transistor. For soft switching, it can be shown that this complex impedance is, e.g., Weiss and Popovic,²⁶

$$Z_E = \frac{0.28015}{\omega C_{out}} e^{j49.052^\circ}$$

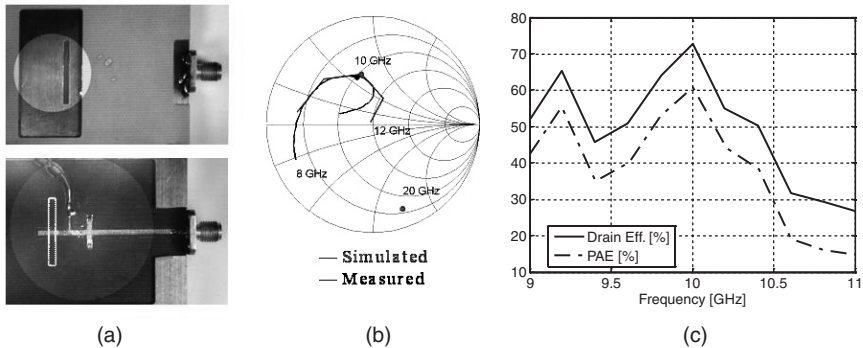

FIGURE 32-15 (a) Circuit side and antenna side of active class-E amplifier antenna at 10 GHz. (b) Simulated and measured nonresonant slot antenna impedance, along with optimal class-E impedances for transistor at fundamental (10 GHz) and second harmonic (20 GHz). (c) Measured efficiency of active antenna as a function of frequency.

where $\omega = 2\pi f$ is the fundamental operating angular frequency, and C_{out} is the output capacitance of the transistor. The higher harmonics are assumed to be terminated with high impedances (ideally open circuits). In Weiss and Popovic,²⁶ a 10-GHz active class-E antenna is demonstrated with a MESFET device and a slot antenna (see Figure 32-15a). The output capacitance of the transistor is 0.107pF, resulting in an optimal output impedance of $41.7\Omega \angle 49.05^\circ$ with a resulting reflection coefficient with respect to 50Ω equal to $-6.67\text{dB} \angle 104^\circ$. Thus, a nonresonant antenna with this impedance at the fundamental 10-GHz frequency and a high impedance at the higher harmonic frequencies can be directly connected to the transistor and thus reduce the footprint of the active antenna. A slot antenna is designed using a full-wave simulator, with impedance at the fundamental and second harmonic as shown in Figure 32-15b. A passive slot was also fabricated and the measured reflection coefficient at 10 GHz, with a TRL calibration, was measured to be $-6.8\text{dB} \angle 106^\circ$. The efficiency and power of the antenna are estimated from measured copolar and cross-polar radiation patterns. The radiated power of around 100 mW with 75% drain efficiency was achieved. This is higher or comparable to an amplifier designed with the same device in a microstrip circuit, since some circuit losses are avoided. Due to the direct circuit-antenna integration, the total active antenna footprint is $0.4\lambda^2$.

Receiving Amplifier Antenna Arrays

Figure 32-16 shows an active receiving antenna array where antennas are directly connected to LNAs in each element with no lossy isolators or circulators. Such antenna arrays are used in radioastronomy, either as large-area arrays or reflector feeds. The transistor amplifier produces noise waves at both of its ports, and the noise at the input will radiate, potentially coupling into the neighboring antenna elements and amplified by their LNAs thus degrading the system noise performance.⁵⁰ As the phases of the phase shifters are varied and the beam is scanned, the amount of coupling between the antennas varies and this affects the reflection coefficient at the input of each of the LNAs, as well as the amount of noise coupled to neighboring elements.

Referring to Figure 32-16a, it can be shown that the coupled noise at the output of all the phase shifters is

$$c_{\text{tot}}(\theta, \phi) = c_2 + Gc_1S_i(\theta, \phi)$$

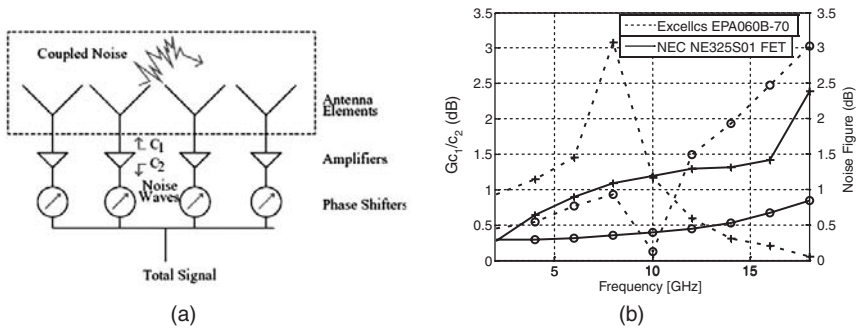

FIGURE 32-16 (a) Receiving LNA active array with noise coupling. (b) Plot of transistor characteristics relevant to noise coupling. The best noise figure of a transistor does not correspond to a minimal noise coupling coefficient for a given antenna array.

where c_2, c_1 are the noise waves at the input and output of all (identical) LNAs, G is the gain of each LNA, and $S_i(\theta, \phi)$ is the active scan reflection coefficient of element i for a scan angle (θ, ϕ) . The noise coupling for a given scan angle can therefore be found from measured or simulated active scan reflection coefficient, amplifier gain, and amplifier input and output noise waves. The latter can be determined using standard techniques from minimal noise figure F_{\min} , optimal reflection coefficient Γ_{opt} , and noise resistance R_n , parameters given in specification sheets for most transistors. If a blind (noisy) scan angle appears for a certain element type or element coupling, the noise coupling can be modified by changing the antenna type, as well as the transistor.

As an example, consider a 7×7 half-wave dipole array above a ground plane with a half-wave spacing. The 49×49 full scattering matrix of the array can be found using a full-wave simulator, and the scan reflection coefficient can be found for each element. The noise coupling ratio, defined as the ratio of the uncoupled noise to the coupled noise, can be written as $\text{NCR} = (Gc_1 S_i) / c_2$ and is a function of antenna array properties and amplifier properties. The amplifier quantity Gc_1 / c_2 is plotted for three different transistors in Figure 32-16b, while the noise figures for these amplifiers from their data sheets are shown in Figure 32-16c. A lower noise figure can un-intuitively result in higher noise coupling, reflecting the fact that minimal noise figure implies low noise power at the output, but not necessarily at the input of an LNA.

An interesting figure of merit is the amount of coupling that produces 50 percent more noise power at the array output at certain scan angles, as compared to that expected without noise coupling. To find the minimal amount of inter-element antenna coupling that would give the noise ratio of -3 dB, we set

$$10 \log \frac{|Gc_1 S_i(\theta, \phi)|^2}{|c_2|^2} = -3 \text{ dB}$$

and solve for the allowable active scan coefficient for each array element, given the amplifier properties. For reasonable LNA gain, the practical scan angle for low coupled noise will be limited: low noise coupling requires low values of active scan coefficient, i.e., larger element spacing; but larger element spacing limits the scan angle due to sidelobe appearance. The design of a low-noise scanning array therefore involves choice of transistor, design of LNA and match to antennas, choice of antenna element, and design of array for minimal coupling for desired scan range.

Transmitting Amplifier Antenna Arrays

A power amplifier integrated in each antenna element provides distributed amplification, resulting in higher achievable efficiency and improved degradation properties for a given ERP. Spatial power combining upon radiation results in an ERP that is proportional to N^2 , where N is the number of amplifier antenna elements. Spatially fed combiners are fed in two ways: using a guided-wave feed network and a spatial feed. For a given combiner network loss per stage, there is a minimal number of elements N for which spatial power combining has a larger power-combining efficiency.²⁷

An example of a circuit-fed array is shown in Figure 32-17a where 16 high-efficiency 10-GHz amplifiers are spatially combined using stacked patch antennas spaced a half wavelength apart.⁵¹ In this case, the antennas and feeds are designed to present a specific complex impedance to the output of the transistors.²⁶ A corporate four-level Wilkinson divider feed network is used at the input of the array with a measured loss of 1.4 dB. The output powers are spatially combined through an array of multilayer patch antennas with 2:1 VSWR bandwidth of 11.6%. An average drain efficiency of 70% at 162W EIRP, or approximately 1.5W of transmitted power, is measured for an array of 16 amplifiers at 10.2 GHz. The estimated power-combining efficiency is 75%.

Spatially fed, spatially combined arrays have also been demonstrated, e.g. using slot antennas at Ka-band as shown in Figure 32-18a. Input and output antennas are anti-resonant cross-polarized slots fabricated on alumina⁵² or aluminum-nitride⁵³ substrates with MMIC amplifiers providing power gain between the input and output slots. Polarizers ensure unidirectional slot radiation. Several such arrays with watt-level power at Ka-band have been demonstrated, e.g. a 6×6 array gave an output power of 4W and power gain of 6 dB at 29 GHz, where a liquid-cooling test fixture removed excess heat. Aluminum nitride proved to be an adequate heat conductor for a 1W 6×6 33-GHz array. In this case, all input slot antennas are spatially fed with a dielectric-loaded (“hard”) horn antenna in the near field of the array. The amplitude and phase profile of the horn loaded with the array is not uniform and degrades the power-combining efficiency. Figure 32-18b shows the measured H-plane copolarized radiation patterns of two arrays that differed only in bias line configurations: the bias lines of Array B have extra air bridges and capacitors that short slot-mode radiating RF currents on the bias lines, which results in an improved pattern.

A compact approach for combining a smaller number of elements was done in N-S. Cheng et al.^{54,55} where tapered-slot antennas connected to both ends of 50-Ω monolithic amplifier chips are inserted in a waveguide, achieving broadband combining from 8 to 11 GHz with over 120W of output power. In the array shown in Figure 32-19a, a total of $N = 24$ amplifiers is combined, with six cards inserted in the waveguide, containing four MMIC amplifiers each. This approach provides large bandwidth, good heat-sinking, and space

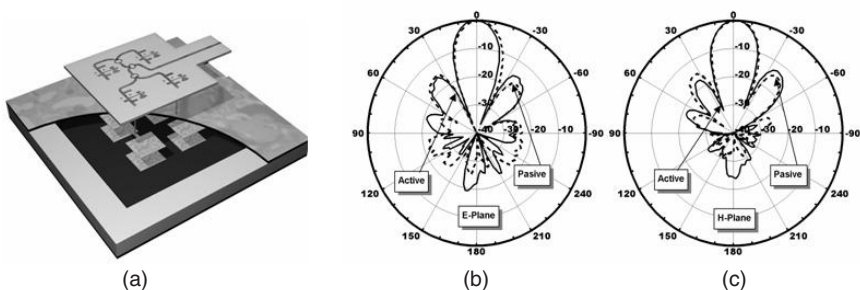

FIGURE 32-17 (a) Schematic of the four-element active subarray showing multiple layers. (b) Radiation patterns of the passive and active 16-element antenna arrays (S. Pajic and Z. Popovic⁵¹ © IEEE 2003).

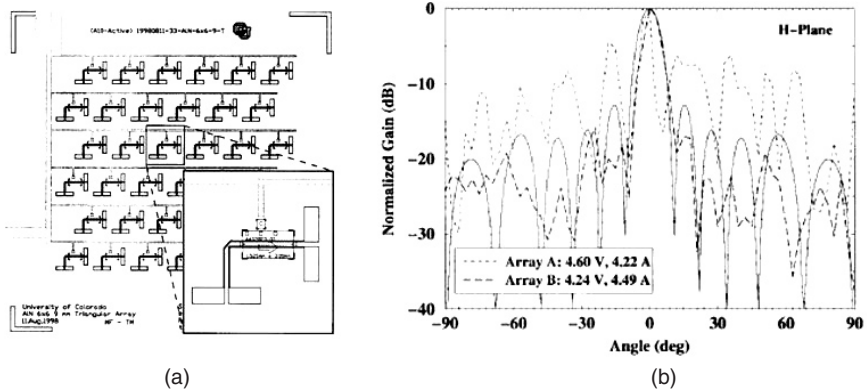

FIGURE 32-18 (a) Layout of a Ka-band slot antenna amplifier array with prematched 50- Ω MMIC amplifiers. Polarizers are used externally to the array for unidirectional slot radiation. in the z -direction to add gain, and has graceful degradation as shown in Figure 32-19b. However, the architecture accommodates a limited number of cards, and the waveguide mode has a nonuniform input field profile, thus the edge amplifiers contribute less to the total output power.

Another approach for large-scale combining is a grid amplifier.⁵⁶ The radiating portion of a grid amplifier is similar to that of a grid oscillator (see Figure 32-12), except in this case, the input and output radiating elements are orthogonally polarized to reduce feedback between input and output waves. A differential transistor pair provides amplification in each unit cell. Figure 32-20 shows a photograph of a portion of a monolithic 37-GHz grid amplifier, with measured 5W of output power.⁵⁷ Grid amplifiers have been realized as both transmission and reflection type. In DeLisio et al,⁵⁸ a 31-GHz two-stage transmission

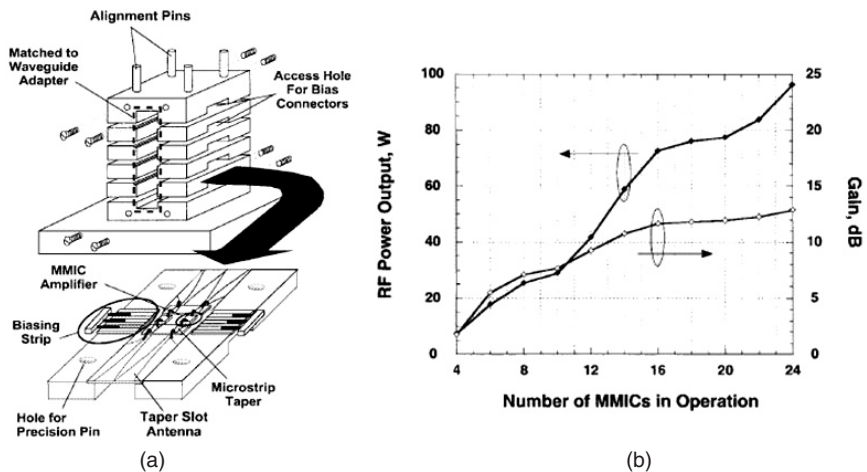

FIGURE 32-19 (a) Architecture of a broadband finline waveguide amplifier array, delivering over 120W over the entire waveguide X-band. (b) Measured gain and output power vs. number of operating amplifiers. The inset shows one card with two tapered slot antennas connected with MMIC amplifiers (N-S. Chang et al⁵⁵ © IEEE 1992).

grid amplifier module with over 10W output power and 12-dB gain is described. An 82-GHz reflection grid amplifier with 5.5-dB gain, 400-MHz 3-dB bandwidth, and 110-mW saturated output power is presented in Cheung.⁵⁹ Commercially available grid amplifiers are not plane-wave fed from the far field, but placed in an overmoded waveguide with excellent feed efficiency, in which case they arguably are no longer active antennas.

Practical issues in active antenna amplifier arrays include feeding, heat management, impedance matching, and stability. Several types of spatial feeds have been demonstrated: plane-wave feeding is inefficient and practical only for characterization; Gaussian-beam feeds are low-loss but large⁵⁸; dielectric-loaded horn antennas do not produce uniform amplitude and phase illumination, thus reducing power-combining efficiency⁶⁰; and discrete lens antenna arrays, e.g. Hollung et al,¹² are large in volume but provide additional functionality. An especially difficult problem is stability in active antennas and arrays—electromagnetic coupling is present due to radiation. Bias-line oscillations are easily excited in amplifiers where one of the loads radiates, and this can limit the gain of the active antenna. Shunt capacitors of different values placed along the bias lines to short the bias-line oscillation currents to ground can eliminate instabilities.

32.5 FREQUENCY-CONVERTING ANTENNAS

The two extreme cases of frequency-converting antennas are oscillator antennas (Section 32.2) that convert DC power to power at a single RF frequency and its harmonics, and rectifier antennas that convert incident RF waves into DC power (Section 32.6). In this section, multiplier and mixer active antennas are briefly overviewed.

Multiplier Antennas and Arrays

Although there have been a number of active antenna frequency multipliers demonstrated in the literature, it is easy to conclude that at microwave frequencies, fundamental-frequency oscillators will give more power and lower phase noise, which grows at best as

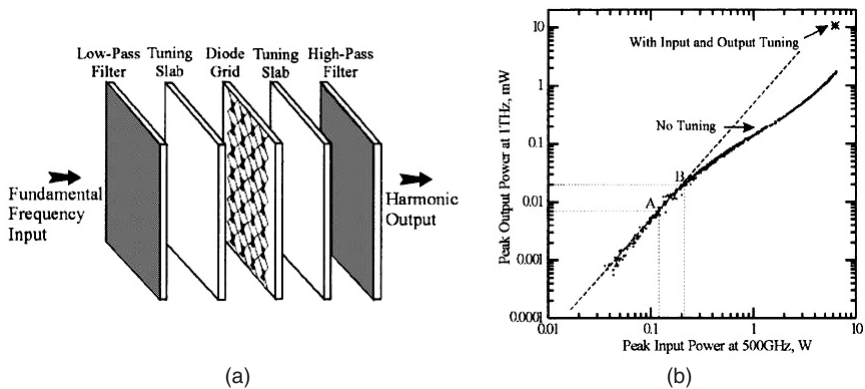

FIGURE 32-21 (a) A millimeter-wave active antenna quasi-optical grid multiplier; (b) measured output power at 1 THz with and without input and output tuning slabs (A. Moussessian et al⁶² © IEEE 1998)

$20 \log N$, where N is the multiplication factor. At millimeter-wave frequencies, however, transistors are either not available or have low output powers, and multiplication becomes more relevant. Frequency doubler and tripler antenna arrays for millimeter-wave generation with Schottky and varactor diodes have the advantage of input power division between a large number of elements, allowing high-power generation. For example, 0.5W was generated at 66 GHz in Jou et al⁶¹ in a monolithic 760-diode grid array with around 10% conversion efficiency from a pulsed source. A similar approach was used by Moussessian et al⁶² where 144 diodes generated 24 mW at 1 THz from a 47W peak pulsed source with an efficiency below 1%. As shown in Figure 32-21, the input plane wave is incident on an array of antennas loaded with a nonlinear harmonic-generating element (diodes). The output wave is filtered so that only the higher harmonic is radiating in transmission. For tripler antennas, the diodes are connected in anti-parallel, eliminating the even harmonics for perfectly matched diode pairs.

Mixer Antennas and Arrays

Among the many interesting up/down-conversion active antennas, reviewed nicely in Mortazawi et al,³⁶ we choose a few examples as illustrations in this chapter. Self-oscillating mixer antennas with fundamental and subharmonic oscillations have been demonstrated, and an example of a 60-GHz balanced integrated-antenna self-oscillating mixer is shown in Figure 32-22.⁶³ This mixer employs the modal radiation characteristics of a dual-feed planar quasi-Yagi antenna to achieve RF-local oscillator (RF-LO) isolation between closely spaced frequencies. The balanced mixer is symmetric, inherently broadband, and does not need an RF balun. A 30-GHz push-pull circuit is used to generate the second harmonic, and a 30-GHz dielectric resonator is used to stabilize the fundamental oscillation frequency. This allows the possibility of building a balanced, low-cost self-contained antenna integrated receiver with low LO leakage for short-range narrowband communication. Figure 32-23b shows the measured conversion efficiency of this mixer antenna at the sum and difference IF ports.

A grid mixer, similar to grid oscillators and amplifiers and attractive for millimeter-wave frequencies, is demonstrated in Hacker et al⁶⁴ at X-band. A planar bow-tie grid periodically loaded with 100 Schottky diodes showed an improvement in dynamic range of 3.5 dB over an equivalent single-diode mixer with the same conversion loss and noise figure. The advantage of a mixer array is that power handling and dynamic range scale as the number of the devices.

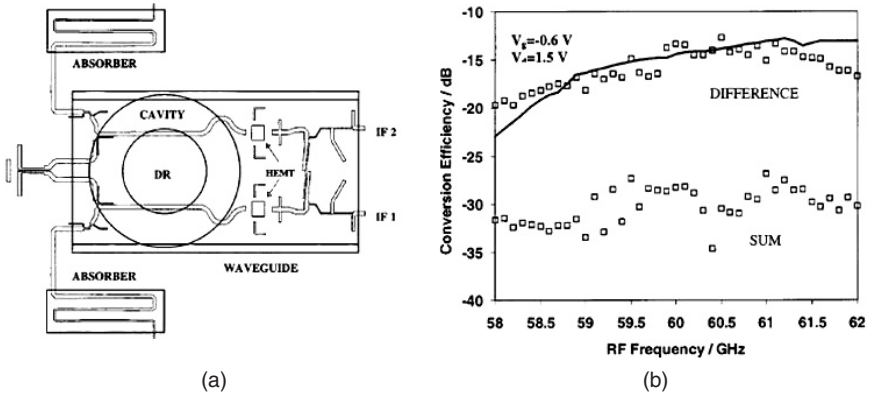

FIGURE 32-22 (a) Layout of a subharmonic mixer active antenna; (b) measured conversion efficiency for sum and difference IF ports as a function of the V-band RF frequency for a 30-GHz push-pull self-oscillating mixer (M. Sironen et al.⁶³ © IEEE 2001)

Different nonlinear functions can be performed by active mixer antennas. An example is four-wave mixing, or phase conjugation, as shown in Pobanz and Itoh,⁶⁵ with the application to saving power in back-scatter mode communication and radar systems. A phase-conjugating active antenna is shown in Figure 32-23a. The circuit is similar to a standard single-balanced mixer with a rat-race hybrid, but with the LO and IF interchanged, so that isolation between RF and IF is accomplished via hybrid balance rather than the usual filter. In this case, the LO frequency is chosen to be twice the RF, and a dual-frequency ring hybrid is implemented. The LO is coupled into the ring through a 12-GHz bandpass filter. The filter is an open circuit at the ring port at 6 GHz, with sum

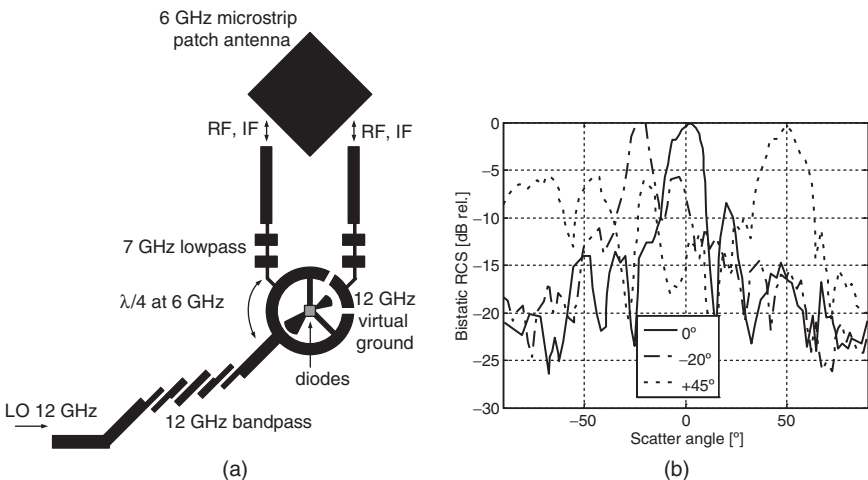

FIGURE 32-23 (a) Layout of a phase-conjugating four-wave mixing active antenna element; (b) measured radiation patterns of an eight-element array for waves incident from broadside, -20° , and 45° (after Pobanz and Itoh⁶⁵ © IEEE 1995)

and difference inputs feeding the mixer diodes at the remaining ports. Low-pass filters (LPFs) are used on the RF/IF ports, which appear as open circuits to the ring at 12 GHz. Since the LO wavelength is half that of the ring design wavelength, only a sum port can be formed to feed the diodes with equal power. By placing the LO port in the longer section of the ring at a 6-GHz quarter-wave from either port 1 or 4, two virtual ground points can be created in the matched ring. The mixer is coupled to an antenna with two orthogonal feeds, allowing this phase-conjugate scattering element to operate for any polarization of the incident wave. Measured radiation patterns for an eight-element array with a 0.8λ spacing with different incidence angles of the incoming wave are shown in Figure 32-23b. In the phase-conjugating process, the spacing between the elements is effectively doubled, resulting in grating lobes even for half-wavelength spacing, which is traded off with mutual coupling between elements.

32.6 RECTENNAS

An integrated antenna and rectifier is usually referred to as a *rectenna*, as shown in Figure 32-24a. The incident waves within a certain spectral range are received by the antenna and coupled to the rectifying device (diode in this case), and the LPF ensures that no RF is input to the power management circuit. A controller provides input to the power management circuit, which enables storage of the received energy over time, and delivery of DC power at the level and time when it is needed. Such active antennas have been primarily proposed for wireless power transmission, which dates back to Nikola Tesla's U.S. Patent No. 685,954 (1901),⁶⁶ which describes wireless transmission of energy, storage of the energy in a capacitor, and energy management in time. Rectification of microwave signals for supplying DC power by high-power beaming has been researched for several decades, and a good review of earlier work is given in Brown.⁶⁷ In power beaming, the antennas have well-defined polarization, and high rectification efficiency is enabled by single-frequency high microwave power densities incident on an array of antennas and rectifying circuits. Applications for this type of power transfer have been proposed for helicopter powering, solar-powered satellite-to-ground power transmission, inter-satellite power transmission including utility power satellites, mechanical actuators for space-based telescopes, small DC motor driving, and short-range wireless power transfer.⁶⁷⁻⁷³ Linear, dual-linear, and circular polarization of the receiving antennas were used for demonstrations of efficiencies ranging from around 85–90% at lower microwave frequencies to around 60% at X-band and around 40% at Ka-band.

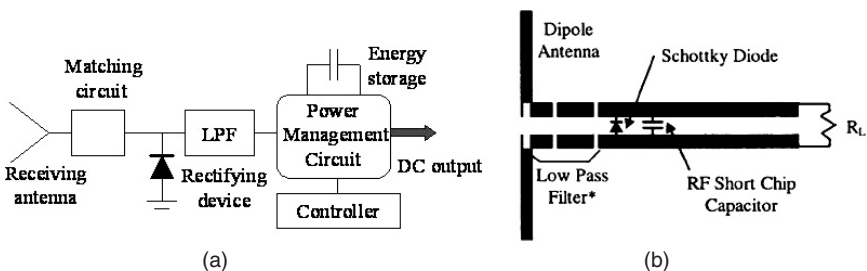

FIGURE 32-24 (a) Schematic of a rectenna and associated power management circuit; (b) an example of a dipole rectenna for 5.8-GHz narrowband operation (after J. O. McSpadden⁷² © IEEE 1998)

There are several distinct scenarios for wireless powering, which influence the rectenna design:

- One or more high-directivity narrowband (single frequency) line-of-sight transmitters with well-known and fixed polarization and well-known power levels. In this approach, used for power beaming, the efficiency of the rectenna can be very high.
- One or more medium-power semidirectional transmitters that illuminate a range in space, with multipath present. In this case, the incident power density is known approximately, but there are multipath effects that change polarization and spatial distribution of power density. The transmitters can be single-frequency, multiple-frequency, or broadband. An application of this scenario is for powering multiple sensors whose location is not precisely known.
- Unknown transmitters over a range of frequencies, power levels, generally unpolarized, with varying low-level spatial power densities, such as in energy harvesting or energy scavenging.

The incident power density on the rectenna, $S(\theta, \phi, f, t)$, is a function of incident angles, and can vary over the spectrum and in time. The effective area of the antenna, $A_{\text{eff}}(\theta, \phi, f)$, will be different at different frequencies, for different incident polarizations and incidence angles. The average RF power over a range of frequencies at any instant in time is given by

$$P_{\text{RF}}(t) = \frac{1}{f_{\text{high}} - f_{\text{low}}} \int_{f_{\text{low}}}^{f_{\text{high}}} \int_0^{4\pi} S(\theta, \phi, f, t) A_{\text{eff}}(\theta, \phi, f) d\Omega df$$

The DC power for a single-frequency (f_i) input RF power is given by

$$P_{\text{DC}}(f_i) = P_{\text{RF}}(f_i, t) \cdot \eta(P_{\text{RF}}(f_i, t), \rho, Z_{\text{DC}})$$

where η is the conversion efficiency, and depends on the impedance match $\rho(P_{\text{RF}}, f)$ between the antenna and the rectifier circuit, as well as the DC load impedance. The reflection coefficient in turn is a nonlinear function of power and frequency. Therefore, to find the efficiency of the rectenna, the following measurements can be performed:

- Illuminate the rectenna from a known distance and incidence angle with a known frequency and power; thus $S(\theta, \phi, f, t)$ is known.
- For each frequency of interest, determine the geometrical electrical area of the antenna. This is generally larger than the effective area and therefore overestimates the received RF power.
- Measure the DC power as a function of the DC load impedance (resistance).
- Calculate the estimated conversion efficiency as $P_{\text{RF}}/P_{\text{DC}}$. Since the DC power is measured directly, and the RF power is overestimated, the resulting efficiency will be an underestimate.

This process should be done at each frequency in the range of interest. However, the process is not linear and DC powers obtained in that way cannot be simply added in order to find a multifrequency efficiency.

Narrowband Rectenna Design

For most rectennas and arrays reported to date, the antenna is matched to the diode around one frequency at a well-defined polarization and assuming relatively high incident power levels, e.g. in Brown.⁷⁴ For example, the rectenna shown in Figure 32-24*b* is linearly polarized and designed to operate at 5.8 GHz with an incident power of 50mW corresponding to an incident power density of around 3.2 mW/cm², assuming a dipole effective area of $\lambda^2/8$. In this case, the incident wave carries enough power to turn on the diode, and rectification efficiency can be very high (>80%). A different design is required for low incident power levels. For example, the unlicensed ISM band around 2.4 GHz is an appropriate frequency range for low-power wireless sensor powering. In this scenario, the sensor is mobile and therefore the polarization changes. Thus, the rectenna is designed to be dual-polarized with two rectifier diodes. Each diode rectifies one of the two received polarizations, and the DC signals add. The rectenna is a 19×19-mm square patch, with a 6×6-cm square ground plane on a Rogers Duroid 6010 substrate ($\epsilon_r = 10.2$, thickness = 50 mil) chosen to reduce the antenna size. A Schottky diode is connected at each of the two centers of the two orthogonally polarized patch radiating edges (see Figure 32-25*a*). A via isolated from the patch ground plane terminates each diode to RF/DC ground, and the DC output is taken from the RF short in the center of the patch. Figure 32-25*b* shows a histogram of measured power levels for an incident power level of 170 $\mu\text{W}/\text{cm}^2$ for different incident polarization combinations, which will all be present in the multipath environment envisioned in this application. This rectenna operates with incident power levels as low as 10 $\mu\text{W}/\text{cm}^2$ and is capable of powering a low-power wireless sensor.

Broadband Rectenna Design

For low-power applications, as is the case for collected ambient energy, there is generally not enough power to drive the diode in a high-efficiency mode. Furthermore, rectification over multiple octaves requires a different approach from standard matching techniques. In a rectenna application, the antenna itself can be used as the matching mechanism instead of using a transmission-line or lumped-element matching circuit. The antenna design is therefore heavily dependent on the diode characteristics. A source-pull of the diode is performed over a given area of the Smith chart for different input powers, and the resulting DC voltage and

FIGURE 32-25 (a) Measured rectified DC power as a function of the DC load for different incident power levels. A photograph of dual-polarized 2.4-GHz patch rectenna is shown in the inset. (b) Histogram of measured DC power for 170 $\mu\text{W}/\text{cm}^2$ incident power density and different polarizations of the patch.

is quantified for each source impedance. The region of optimal source impedance is used for optimizing the antenna design. Since the harmonic balance technique calculates the response at all harmonics of the excitation frequency, in the simulation an assumption must be made for the impedance seen by the reflected harmonics, and in the presented case this impedance was set to the impedance of a broadband, self-complementary antenna, $189\ \Omega$. Usually, the optimal source impedance moves counter-clockwise along a constant admittance circle with increasing frequency due to the junction capacitance.

For maximal power transfer, the antenna impedance would match the optimal diode impedance for all frequencies. Since this is difficult to accomplish, a possible suboptimal approach is to present a constant impedance to the diode by using a frequency-independent antenna element. An equiangular spiral was chosen as the array element since it is uniplanar with convenient feedpoint for diode connection, and can be left- or right-hand circularly polarized. A single element was simulated with full-wave CAD tools (Ansoft's Ensemble and Zeland's IE3D) resulting in a one-port frequency-dependent impedance that becomes the diode load in the rectenna. A diode is connected at the antenna feed and the resulting rectenna element performance is shown in Figure 32-26a. The disagreement around 4 GHz is believed to be caused by the 1-cm-long unbalanced coaxial feed, which is not part of the active antenna.

A 64-element array of left- and right-hand circularly polarized spiral elements, each with a rectifier diode, is shown in Figure 32-26b, as described in Hagerty et al.²² The RF powers received independently by each element are summed upon rectification as DC currents and/or voltages. The array was characterized for incident power densities ranging from tens of nW/cm^2 to $0.1\ \text{mW}/\text{cm}^2$. The rectenna array receives radiation from all directions (there is no ground plane), and to measure the re-radiated power at the harmonics, the array was placed halfway between a transmit and receive test antenna, perpendicular to the line-of-sight axis. The DC voltage is measured across a $100\text{-}\Omega$ load. The rectification efficiency reaches the 20% range for an incident power density of $0.1\ \text{mW}/\text{cm}^2$ and arbitrary polarization. The array scaling in size is trivial, since there is no RF feed network, and only the DC output network is required. If space allows, this type of array can be made in the form of wallpaper for collecting as much power as possible. The DC collecting lines can be made to be reconfigurable, so that either current or voltage is summed, depending on the DC load.

FIGURE 32-26 (a) Nonlinear harmonic-balance simulation and measurements of the DC rectified voltage response across $60\ \Omega$ for the spiral antenna in the inset, over a 4:1 bandwidth (after J. A. Hagerty et al.²² © IEEE 2004); (b) photograph of 64-element dual-circularly polarized 2- to 18-GHz spiral rectenna array

(b) Photograph of a switchless simplex T/R series-fed amplifier patch array at 24 GHz. (c) A 4- μm -long infrared imaging antenna and detector.

32.7 OTHER ACTIVE ANTENNAS

The goal of this section is to briefly overview some interesting active antennas that do not fit any of the categories discussed in Sections 2 to 6, but have found useful applications or have promise for future front ends. Other design methodologies⁷⁵ for antenna-circuit modules are not discussed here. Figure 32-27a shows a unit cell of a 10-GHz optically switched transmit-receive (T/R) multibeam antenna array.⁷⁶ Two pairs of multimode optical fibers are held by an FR4 mount and the light from a laser diode is coupled to off-the-shelf photodetectors, which control the bias of pin-diode SPDT switches. The signal between two patch antennas in each unit cell of the amplifier array is routed either through an LNA or PA at nsec speed with only pJ of optical energy, and the optical fibers are transparent at 10 GHz and do not affect the radiation pattern. Figure 32-27b shows a single T/R series-fed 24-GHz patch array fed by a bi-directional (PALNA) chip amplifier, where the T/R path is controlled by bias, eliminating switch loss.⁷⁷ Figure 32-27c shows an infrared antenna with a tunnel-diode detector, and other similar extremely high-frequency antennas have been demonstrated for millimeter-wave and THz imaging applications.^{78,79}

33.1 INTRODUCTION

The term *nature-based antenna design* was recently coined in Neiss et al¹ to describe the process of designing complex antenna systems based on concepts inspired by nature. Examples of nature-based techniques that have been recently applied to solve advanced antenna engineering design problems include fractal geometry, neural networks, fuzzy logic, genetic algorithms, particle swarm optimization, and ant colony optimization. In some cases, even two or more of these nature-based design techniques have been combined together to effectively solve a specific antenna design problem. An example of this can be found in Petko and Werner,² where a powerful nature-based antenna array synthesis technique was introduced that incorporates aspects of both fractal geometry and genetic algorithms.

Traditional approaches to the analysis and design of antenna systems have their foundation in Euclidean geometry. In this chapter, however, we focus on nature-based antenna design concepts that employ fractal geometry. The term *fractal*, meaning broken or irregular fragments, was originally used by Mandelbrot³ to describe a family of complex shapes that possess an inherent self-similarity or self-affinity in their geometrical structure. The original inspiration for the development of fractal geometry came largely from an in-depth study of the patterns of nature. Fractals are abundant in nature, with a few examples of natural fractals being snowflakes, ferns, trees, coastlines, mountain ranges and even galaxies.⁴

Several book chapters and review articles have been published that provide a comprehensive overview of research in the area of fractal antenna engineering.⁵⁻⁹ This research can be divided into two categories, the first of which deals with the study of fractal-shaped antenna elements, and the second of which concerns the use of fractals in the design of antenna arrays. The next section presents a brief summary of some of the most popular types of fractal geometries found to be useful in antenna engineering applications. Section 33.3 then provides an introduction to the theory of iterated function systems (IFSs) along with a discussion of the important role they play in the mathematical description of fractals. Sections 33.4 and 33.5 summarize approaches that employ fractal concepts in the design of antenna elements and arrays, respectively. Finally, Section 33.6 is devoted to design methodologies for antenna arrays that are based on fractal and aperiodic tilings.

33.2 USEFUL FRACTAL ANTENNA GEOMETRIES

This section presents a brief introduction to some of the more common fractal geometries that have been found to be useful in antenna engineering applications. This includes applications involving fractal-shaped antenna elements as well as conventional Euclidean antenna elements placed in fractal array configurations. The first and perhaps the most recognizable fractal geometry that will be considered is known as the Sierpinski gasket.⁴ Figure 33-1 illustrates the first few stages in the construction of the Sierpinski gasket fractal. The procedure for geometrically constructing this fractal begins with an equilateral triangle contained in the plane, shown in black as stage 1 of Figure 33-1. The next step in the construction process is to remove the central triangle whose vertices are located at the midpoints of the sides of the original stage 1 triangle, which leads to the geometry shown in stage 2 of Figure 33-1. This process is then repeated for the three remaining black triangles, with the result shown in stage 3 of Figure 33-1. The next stage (stage 4) in the construction of the Sierpinski gasket is also shown in Figure 33-1. The Sierpinski gasket fractal is

FIGURE 33-1 The first four stages in the generation of a Sierpinski gasket fractal

generated by carrying out this iterative process an infinite number of times. It follows from this definition that the Sierpinski gasket is an example of a self-similar fractal; i.e., it is composed from small but exact copies of itself. This self-similar property of the Sierpinski gasket fractal is illustrated in Figure 33-2.

Another useful fractal is commonly referred to as the Koch snowflake.⁴ This fractal also starts out as an equilateral triangle in the plane, as depicted by the solid black triangle in stage 1 of Figure 33-3. However, unlike the Sierpinski gasket, which was formed by systematically removing smaller and smaller triangles from the original structure, the Koch snowflake is constructed by adding smaller and smaller triangles to the structure in an iterative fashion. The first four stages in the iterative process of constructing the Koch snowflake are illustrated in Figure 33-3.

A number of structures based on purely deterministic or random fractal trees have also proven to be extremely useful in developing new design methodologies for antenna elements and array configurations. An example of a deterministic fractal tree is shown in Figure 33-4a. A ternary (three-branch) generator is used for the first three stages of growth. A fractal-random tree, on the other hand, is a type of fractal tree which uses multiple generators selected in random order to form the tree structure. Figure 33-4b shows the first three stages of growth of a random fractal tree. In this case the tree is grown by randomly selecting between two generators, one with three branches and the other with two branches. Fractal-random trees are more representative of natural trees or plants than deterministic fractal trees, which appear too ordered. The examples presented in Figure 33-4 are of two-dimensional fractal trees. However, the concept of a fractal tree can be easily generalized to three-dimensions. Figure 33-5 shows the first four stages in the growth of a three-dimensional deterministic fractal tree.^{8,10}

FIGURE 33-6 The first four stages of growth for a space-filling Hilbert curve

The space-filling properties of the Hilbert curve and related curves make them attractive candidates for use in the design of fractal antennas. The first four stages in the construction of the Hilbert curve are shown in Figure 33-6.^{4,11} The Hilbert curve is an example of a space-filling fractal curve that is self-avoiding (i.e., has no intersection points). Another important example of a space-filling curve with applications in antenna engineering is the Peano-Gosper curve.^{3,11} Figure 33-7 illustrates the first three stages in the construction of the Peano-Gosper curve. The initiator is shown in Figure 33-7a as the dashed-line segment superimposed on the stage 1 generator. A copy of the stage 1 generator is shown again in Figure 33-7b as the dashed curve. Also shown in Figure 33-7b is the stage 2 Peano-Gosper curve, which is obtained by replacing each of the seven segments in the stage 1 generator by an appropriately scaled copy of itself. The next iteration (stage 3) of the Peano-Gosper curve is shown in Figure 33-7c. At this stage, the space-filling property of the curve starts to become more apparent.

Fractal tiles, or fractiles, represent another important category of fractal objects that has found application in antenna theory and design.^{3,12} Fractiles are tiles or islands that possess fractal boundaries. They are a unique subset of all possible tile geometries that can be used to cover the plane without overlapping or leaving any gaps in between the tiles. We consider here two specific types of fractiles, known as fudgeflakes and Gosper islands. Both fudgeflakes and Gosper islands can be used to cover the plane via a tiling.^{3,12} The first through sixth iterations of the fudgeflake are shown in Figure 33-8, while the first through

FIGURE 33-7 The first three stages of the space-filling Peano-Gosper curve. The initiator is shown as the dashed-line segment superimposed on the stage 1 generator, which is shown as the dashed curve superimposed on the stage 2 generator.

FIGURE 33-8 Geometry of the first through sixth iterations of the fudgeflake fractile

fifth iterations of the Gosper island are shown in Figure 33-9. Finally, Figure 33-10 demonstrates how fudgeflake and Gosper island fractiles can be used to provide a perfect covering of the plane (i.e. no gaps or overlaps between tiles).

33.3 ITERATED FUNCTION SYSTEMS

Iterated function systems (IFSs) are the mathematical language of fractals. They provide a unified approach to the theory of fractal geometry and represent an extremely versatile tool for conveniently generating a wide variety of useful fractal structures.^{4,13} These IFSs are based on a collection of contractions achieved through the application of a series of affine transformations w defined as

$$w \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} e \\ f \end{pmatrix} \quad (33-1)$$

or equivalently as

$$w(x, y) = (ax + by + e, cx + dy + f) \quad (33-2)$$

where a, b, c, d, e , and f are real numbers. Hence, the affine transformation w is represented by six parameters, which may be expressed using the compact notation

$$\begin{pmatrix} a & b & e \\ c & d & f \end{pmatrix} \quad (33-3)$$

such that a, b, c , and d control rotation and scaling, while e and f govern linear translation.

Now if we let w_1, w_2, \dots, w_N be a set of affine linear transformations and A be the initial geometry, then a new geometry can be formed by applying the set of transformations to

FIGURE 33-9 Geometry of the first through fifth iterations of the Gosper island fractile

FIGURE 33-10 A covering of the plane by (a) fudgeflake fractiles and (b) Gosper island fractiles

the original geometry A and collecting together the results from $w_1(A)$, $w_2(A)$, ..., $w_N(A)$ in the following way:

$$W(A) = \bigcup_{n=1}^N w_n(A) \quad (33-4)$$

where W is known as the Hutchinson operator.⁴ A fractal geometry can be obtained by repeatedly applying W to the previous geometry in an iterative fashion. For example, if the set A_0 represents the initial geometry, then this iterative process would yield a sequence of Hutchinson operators given by

$$A_1 = W(A_0), A_2 = W(A_1), \dots, A_{k+1} = W(A_k) \quad (33-5)$$

An IFS generates a sequence that converges to a final image A_∞ in such a way that

$$W(A_\infty) = A_\infty \quad (33-6)$$

This image is called the attractor of the IFS and represents a “fixed point” of W , where the “points” in this case are actually defined as sets.

The IFS procedure for generating the well-known Koch fractal curve is demonstrated in Figure 33-11. In this case, the initial set A_0 is the line interval of unit length such that $A_0 = \{x: x \in [0,1]\}$. Four affine linear transformations (i.e., $N=4$) are then applied to A_0 as depicted in Figure 33-11. Next, the results of these four linear transformations are combined together using Eq. 33-4 to form the first iteration of the Koch curve denoted by A_1 . The second iteration of the Koch curve A_2 may then be obtained by applying the same four affine transformations to A_1 and again using Eq. 33-4 to combine the results. Higher-order versions of the Koch curve are generated by simply repeating the iterative process until the desired resolution is achieved. The first four iterations of the Koch curve are shown in Figure 33-12. This sequence of curves eventually converges to the actual Koch fractal (represented by A_∞) as the number of iterations approaches infinity.

IFSs have proven to be a very powerful tool in the analysis and design of fractal antennas. This is primarily because they provide a general framework for the description, classification, and manipulation of fractals.¹³ To further illustrate this important point, an IFS approach was used to produce the Sierpinski gasket shown in Figure 33-13a and the tree-like structure shown in Figure 33-13b, two very different fractal objects. The IFS codes for generating these two objects have also been provided in the figure.⁴

33.4 FRACTAL ANTENNA ELEMENTS

Some of the more common fractal geometries that have found applications in antenna engineering are depicted in Figure 33-14. The Koch snowflakes and islands have been primarily used to develop new designs for miniaturized loop as well as microstrip patch antennas.^{8,9,14,15} Moreover, fractile concepts have also been employed in the design of fudgeflake and Gosper island microstrip antennas.¹⁶ The self-similar structure of Sierpinski gaskets and carpets has been exploited to develop multiband and broadband antenna elements.^{7,9,17,18,19,20} Finally, novel designs for miniaturized dipole and monopole antennas have been developed based on a variety of Koch curves and fractal trees.^{7,8,9,10,21,22,23}

The self-similar properties of fractal trees have been utilized to create antenna elements with multiband characteristics.²⁴⁻²⁷ In addition, fractal tree geometries have been used as an effective means to miniaturize antenna designs. A set of dipole antennas has been studied that utilizes three-dimensional fractal tree structures as end-loads in Gianvittorio and Rahmat-Samii.⁸ This set of antennas, illustrated in Figure 33-5, has been shown to exhibit lower resonant frequencies than standard dipole antennas of comparable length while not significantly affecting the bandwidth or the gain. An investigation of performance trends of various three-dimensional end-loaded fractal tree dipoles has also been carried out in Petko and Werner.¹⁰ It has been shown that denser fractal tree end-loads exhibit greater reduction in resonant frequency than less dense structures. The influence of branch elevation angles of the fractal tree generator was also studied in Petko and Werner.¹⁰ Figure 33-15 plots the value of the VSWR that corresponds to the resonant frequency of various four-branch fractal tree antenna designs with different branch elevation angles. The results show that fractal tree antennas with small branch elevation angles have a lower VSWR but a higher

FIGURE 33-14 Some fractal geometries commonly used in antenna applications: (a) Koch curves and fractal trees have been used to create miniaturized dipole and monopole antenna elements. (b) Koch snowflakes and islands have been used to create loop and patch antennas. (c) Sierpinski gaskets and carpets have been used to create multiband antenna elements.

FIGURE 33-15 VSWR vs. elevation angle resonant frequency for a set of stage 3, four-branch fractal tree antennas with elevation angles ranging from 10° to 90°. The VSWR was calculated with respect to a 50- Ω line (after Petko and Werner¹⁰ © IEEE 2004).

resonant frequency than those with large elevation angles. This trend continues until the resonant frequency reaches a minimum for designs with elevation angles of approximately 50°. Designs with elevation angles beyond 50° are not optimal because both the resonant frequency and VSWR increase with the increase in elevation angle.

These trends have been used to design more effective miniature fractal tree dipoles, such as one created from a six-branch generator with branch elevation angles alternating between 30° and 50°. Figure 33-16 illustrates the geometry of the end-loads for the first three iterations of this dense fractal tree antenna. In Figure 33-17, the reflection properties (i.e., S_{11} and VSWR) of these dense fractal tree antennas are compared with the reflection properties of the four-branch fractal trees illustrated in Figure 33-5. The second-stage, six-branch 50°–30° antenna is shown to have a resonant frequency of 920 MHz, which is identical to the resonant frequency of the third iteration for the four-branch fractal tree antenna. The resonant frequency for the third-iteration, six-branch 50°–30° antenna is shown to be 790 MHz. This resonance occurs at a frequency 57 percent lower than the 1820-MHz resonance of an equivalently sized conventional Euclidian dipole antenna, and is 70 MHz lower than the fourth iteration of the four-branch fractal tree antenna.

One of the key advantages of end-loading a dipole antenna with a fractal-tree geometry is evident when LC resonators or RF switches are incorporated throughout the end-load structure. Resonators and switches are often used to make conventional antennas either multiband or reconfigurable; however, in conventional structures, it is difficult to create

FIGURE 33-16 Fractal tree end-loads for the three-dimensional six-branch 30°–50° fractal tree dipole antenna (after Petko and Werner¹⁰ © IEEE 2004)

FIGURE 33-17 S_{11} versus frequency for a stage 1, stage 2, and stage 3 three-dimensional, six-branch 50° – 30° fractal tree antenna. Also shown for comparison is the S_{11} for the first four stages of a standard four-branch fractal tree antenna and an equivalently sized conventional dipole. The S_{11} was calculated with respect to a $50\text{-}\Omega$ line (after Petko and Werner¹⁰ © IEEE 2004).

resonances that are close to each other in frequency. This difficulty arises primarily because in order to achieve this type of behavior, the reactive loads and switches would have to be placed in close physical proximity to each other on the antenna. Moreover, the reactive loads or switches are usually distributed in a series fashion along the antenna, which can compound the losses associated with the use of these devices. In a fractal tree end-load, however, these problems do not exist because reactive loads and switches can be spread throughout the fractal structure, placing the loads into a parallel configuration and separating the required physical distance between them. These reactive loads and switches essentially change the configuration, and hence the size, of the fractal tree end-load for specific frequencies.

In one study, RF switches are strategically placed throughout the end-load of a third-stage, six-branch 50° – 30° fractal tree dipole antenna (see Figure 33-16) to make it reconfigurable (i.e., tunable) over a bandwidth of 68 percent. The design uses 102 individual switches placed in each end-load of the antenna, as shown in Figure 33-18, to produce 20 reconfigurable states. The resulting dipole antenna was found to be reconfigurable from 770 MHz to 1570 MHz for a bandwidth of 800 MHz with a VSWR under 3:1 and reconfigurable from 970 MHz to 1570 MHz for a bandwidth of 560 MHz with a VSWR below 2:1. Also, since the design uses the fractal tree end-loads, the lowest resonance of this antenna occurs at a frequency 57 percent below that of a conventional linear dipole of equivalent length.

In Figure 33-19 each of the 20 reconfigurable states is represented by a separate S_{11} curve (indicated by light-gray lines) with the lowest resonant frequency representing the state with all the switches closed and the highest resonant frequency representing the state

FIGURE 33-18 Switch layout for the reconfigurable six-branch, 50° – 30° fractal tree dipole antenna (after Petko and Werner¹⁰ © IEEE 2004)

with all the switches open. The remaining states are achieved by opening the switches progressively from the top to the bottom. In addition, for three of the reconfigurable states the antenna effectively operates as a 50° – 30° fractal tree dipole with fractal stages 3, 2, or 1. The S_{11} curves for these three special cases are indicated on the graph by thick dark-gray lines. Finally, the solid-black line represents the overall minimum S_{11} the antenna can be configured to for a particular frequency over the entire operating range of the antenna.

FIGURE 33-19 S_{11} versus frequency for the reconfigurable six-branch, 50° – 30° fractal tree antenna. The light-gray curves represent each of the 20 states the antenna can be configured to operate. The dark-gray curves represent reconfigured states that operate as stage 1, stage 2, and stage 3 fractal tree antennas. The black line represents the overall minimum S_{11} the antenna can operate over the entire band. The S_{11} was calculated with respect to a $50\text{-}\Omega$ line (after Petko and Werner¹⁰ © IEEE 2004)

33.5 FRACTAL ANTENNA ARRAYS

The advantages of fractal geometries are most evident when applied to antenna arrays. Their nature-based structure provides interesting radiation properties that are not found in conventional arrays. The radiation characteristics of deterministic fractal array configurations, such as Cantor linear arrays, Cantor ring arrays, and Sierpinski carpet planar arrays, have been considered in the literature.^{6,7,9,28,29} In some cases, these arrays were found to possess lower sidelobe levels than their conventional Euclidean counterparts. In addition, the fact that these fractal-based array geometries can be generated in an iterative fashion (i.e., via successive stages of growth starting from a simple generating array) has been exploited in order to develop rapid algorithms for use in efficient radiation pattern computations.^{6,7,9} Fractal concepts were also employed in Puente and Pous²⁸ to design linear arrays that exhibit multiband radiation characteristics. Moreover, a fractal radiation pattern synthesis technique has been developed in Werner et al³⁰ for the design of reconfigurable multiband linear and planar arrays.

In addition to deterministic fractal arrays, properties of random fractals have been used to develop a design methodology for quasi-random arrays, called fractal-random arrays.^{7,9,31} Inspiration for fractal-random geometries are found in the natural world, where many objects closely resemble fractals but are also not completely deterministic. Figure 33-4 illustrates the process of introducing randomness into a fractal-random object. Each time a generator is applied to construct a fractal structure, it is randomly selected from a set of multiple generators. In this manner, random fractals are used to generate array configurations that are somewhere between completely ordered (i.e., periodic) and completely disordered (i.e., random). An example of a fractal-random array layout is shown in Figure 33-20a. The main advantage of this technique is that it yields sparse arrays that possess relatively low sidelobe levels, which is a property indicative of periodic arrays, but over a range of bandwidths that are comparable to random arrays.

More recently, a robust and versatile design methodology for large size arrays has been developed that is based in part on the concept of an “optimal” fractal-random array.² This technique incorporates a genetic algorithm with a specialized subset of fractal-random arrays called polyfractal arrays. A genetic algorithm is a nature-based design tool that optimizes a problem globally using the Darwinian notions of natural selection and survival

FIGURE 33-20 Fractal-random tree analogy for the construction of linear fractal-random and polyfractal arrays. The connection factors in (b) are illustrated by the numbers above the branches of the four-branch and the three-branch generators. Antenna elements are positioned at the ends of the topmost branches (after Petko and Werner² © IEEE 2005)

of the fittest. Useful overviews on the topic of genetic algorithms can be found in the literature.^{32,33,34} Although easily visualized, fractal-random geometries cannot exactly be reproduced from a small set of parameters and are not truly recursive when applied in an IFS. The subset of polyfractal arrays overcomes these limitations while retaining many of the desirable properties of fractal-random arrays.

To construct a polyfractal array, the IFS technique introduced in Section 33.3 must first be modified to handle multiple generators. Polyfractal arrays are constructed from multiple generators, $1, 2, \dots, M$, each of which has a corresponding Hutchinson operator W_1, W_2, \dots, W_M . Each Hutchinson operator W_m in turn contains N_m affine linear transformations, $\omega_{m,1}, \omega_{m,2}, \dots, \omega_{m,N_m}$. These affine linear transformations, $\omega_{m,n}$, are simplified from the more general six-parameter affine linear transformations introduced in Section 33.3 to a similitude approach consisting of three local parameters, $r_{m,n}$, $\varphi_{m,n}$, $\psi_{m,n}$, and one global-scale parameter s_f that is applied throughout the polyfractal structure. This affine linear transformation can be represented by

$$\omega_{m,n} \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} s_f \cos(\varphi_{m,n} + \psi_{m,n}) & -s_f \sin(\varphi_{m,n} + \psi_{m,n}) \\ s_f \sin(\varphi_{m,n} + \psi_{m,n}) & s_f \cos(\varphi_{m,n} + \psi_{m,n}) \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} + \begin{pmatrix} r_{m,n} \cos \varphi_{m,n} \\ r_{m,n} \sin \varphi_{m,n} \end{pmatrix} \quad (33-7)$$

In addition to these three local parameters, a fourth local parameter, $\kappa_{m,n}$, is associated with each affine linear transformation. This parameter, referred to as the connection factor, is an integer value ranging from 1 to M , the number of generators used to construct the polyfractal array. In this generalized iterated function system approach, a Hutchinson operator, W_m , is used to construct a stage $\ell + 1$ polyfractal array from the set of possible stage ℓ polyfractal arrays, F_ℓ . Each affine linear transformation, $\omega_{m,n}$, can only be performed on stage ℓ polyfractal arrays where the generator applied at stage ℓ matches the connection factor, $\kappa_{m,n}$. Because the connection factors dictate how the affine linear transformations are applied, only one unique polyfractal array geometry can be associated with each Hutchinson operator. Therefore, the set of stage ℓ polyfractal arrays, F_ℓ , can be expressed by the notation

$$F_\ell = \{F_{\ell,1}, F_{\ell,2}, \dots, F_{\ell,M}\} \quad (33-8)$$

where the first subscript defines the level of the polyfractal array and the second subscript defines the generator employed at that level. Therefore, a polyfractal array of stage $\ell + 1$ constructed by generator m can be represented by

$$F_{\ell+1,m} = W_m(\{F_{\ell,1}, F_{\ell,2}, \dots, F_{\ell,M}\}) = \bigcup_{n=1}^{N_m} \omega_{m,n}(F_{\ell,\kappa_{m,n}}) \quad (33-9)$$

After the polyfractal structure is formed, the overall structure is adjusted by another global-scale parameter s_g . The global-scale factor s_f can be factored out of the Hutchinson operators to create the final normalized IFS construction procedure for a stage L polyfractal array:

$$F_{\ell,m}^L = s_g (s_f)^{L-\ell} \overline{W_m}(\{F_{\ell-1,1}^L, F_{\ell-1,2}^L, \dots, F_{\ell-1,M}^L\}) = s_g (s_f)^{L-\ell} \bigcup_{n=1}^{N_m} \overline{\omega_{m,n}}(F_{\ell-1,\kappa_{m,n}}^L) \quad (33-10)$$

This process is illustrated for a linear polyfractal array in Figure 33-20b using the fractal-tree analogy. In this figure, numbers representing the connection factors are attached to the ends of the generator branches. The branches ending with number 1 have generator 1 connected to their ends. Likewise, the branches ending with number 2 have generator 2 connected to their ends. The ends of the topmost branches represent the positions of the antenna elements.

Recursive beamforming algorithms can be created for both fractal and polyfractal arrays. Many fractal array recursive beamforming algorithms are based on the pattern multiplication approach. The radiation pattern of a stage ℓ fractal array is equal to the product of the radiation pattern of a stage $\ell-1$ fractal subarray and the array factor of the appropriately scaled fractal generator. In other words, the stage ℓ fractal array can be thought of as an array of stage $\ell-1$ fractal subarrays. An equation expressing the stage ℓ fractal subarray radiation pattern, FR_{ℓ}^L , is derived using the fractal similitude ω_n . The similitude is based on Eq. 33-7, using the local parameters, r_n , ϕ_n , and ψ_n and scale parameters s_g and s_f (the m is omitted because there is only one generator). To perform pattern multiplication, all subarray radiation patterns must be identical and oriented in the same direction. Therefore, the sum of ϕ_n and ψ_n is required to be equal to a multiple of 2π , making the axes of symmetry of the subarrays parallel. The equation for a recursive beamforming algorithm based on pattern multiplication can be written as

$$FR_{\ell}^L(\theta, \phi) = FR_{\ell-1}^L(\theta, \phi) \sum_{n=1}^N \exp j \left[k \left(s_g (s_f)^{L-\ell} r_n \right) \sin \theta \cos(\phi - \phi_n) \right] \quad (33-11)$$

Using isotropic sources as the initial subarray radiation pattern, the final stage L fractal array factor can be written in a similar manner as has been done in Werner et al⁶:

$$AF_L^L(\theta, \phi) = \prod_{\ell=1}^L \sum_{n=1}^N \exp j \left[k S \delta^{\ell-1} r_n \sin \theta \cos(\phi - \phi_n) \right] \quad (33-12)$$

where $\delta = 1/s_f$ and $S = s_g (s_f)^{L-1}$. Typically, the values of r_n are scaled such that S can be set equal to one.

The unique scaling procedure and connection factor-based construction allow the rapid recursive beamforming algorithms associated with fractal arrays to be generalized to handle polyfractal arrays. The fractal array recursive beamforming operation discussed above requires all subarrays to have the same radiation pattern and be oriented in the same direction. In that way, pattern multiplication can be employed. In the more general polyfractal array, there are multiple types of subarrays that do not necessarily point in the same direction. Therefore, these subarray patterns cannot be factored out of the sum and the resulting expression for the stage ℓ , generator m subarray pattern is given by

$$FR_{\ell,m}^L(\theta, \phi) = \sum_{n=1}^{N_m} \left(FR_{\ell-1,k_{m,n}}^L(\theta, \phi - \phi_{m,n} - \psi_{m,n}) \right) \exp j \left[k \left(s_g (s_f)^{L-\ell} r_{m,n} \right) \sin \theta \cos(\phi - \phi_{m,n}) \right] \quad (33-13)$$

This subarray radiation pattern is based on the set of stage $\ell-1$ fractal subarray patterns. The final radiation pattern can be determined by using isotropic sources for the initial subarray radiation patterns and recursively applying the expression until the stage L radiation pattern is obtained. Figure 33-21 illustrates this process for the example array shown in Figure 33-20b. One of the main advantages of the recursive beamforming approaches associated with fractal and polyfractal arrays is that they can be exploited to considerably speed up the convergence of the genetic algorithm (GA). This allows the possibility of optimizing much larger size arrays than has previously been possible using other approaches.

While conventional genetic algorithm techniques can be applied to polyfractal arrays of the same size, it is advantageous to generalize the optimization process to include polyfractal arrays of varying sizes. To accomplish this, the genetic algorithm crossover routine, where parameters of two parent arrays are combined to create new offspring, must be modified so that the parent chromosomes of the polyfractal arrays are broken apart into simpler pieces. This process, discussed in more detail in Petko and Werner,² essentially combines

FIGURE 33-21 Rapid recursive beamforming algorithm for a two-generator polyfractal array (after Petko and Werner² © IEEE 2005)

various affine linear transformations from each parent array and performs crossover at that level. The resulting transformations are then combined into the offspring arrays. The genetic algorithm mutation routine can also be generalized for polyfractal arrays of varying sizes. Genetic mutation typically consists of changing a single parameter; however, polyfractal arrays offer a wide range of flexibility. Mutations can be performed on any of the global parameters as well as on any transformation. In addition, mutation can also remove or add a gene to a generator. Mutation can also be used to switch the order of the generators. This process is also discussed in more detail in Petko and Werner.² By allowing the algorithm to handle more general polyfractal array geometries, an added degree of flexibility is incorporated into the optimization process.

When the optimization appears to reach premature convergence for a population of polyfractal arrays, a unique mutation process, called *generator autopolyploidization*, can be used to stimulate the evolution process.³⁵ The generator autopolyploidization process divides each fractal-random generator into two identical parts. The connection factors that were used to select the previous generator are uniformly divided to choose between the two new generators. In this way the arrays are exactly the same; however, they are described using twice the number of local parameters, adding new flexibility for genetic evolution. After the generator duplication, each chromosome parameter is mutated a small amount through a perturbation process. This perturbation adds a degree of genetic diversity to the population that can aid in the overall evolution procedure. Finally, the population is ready for another period, or epoch, of genetic evolution. An example of this generator autopolyploidy process is illustrated in Figure 33-22 for the transformation of a one-generator fractal array into a two-generator polyfractal array.

It is important to note how generator autopolyploidization can benefit the optimization process. Initially, the genetic algorithm is used to evolve simple solutions consisting of a small number of generators. The limited number of generators restricts the initial antenna

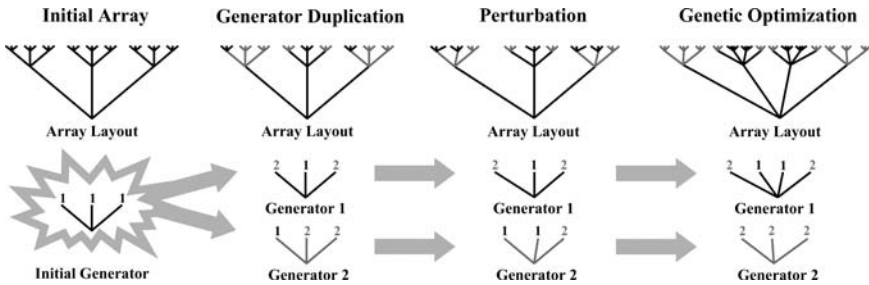

FIGURE 33-22 Generator autopolyloidization process for the conversion of a one-generator fractal array to a two-generator polyfractal array (after Petko and Werner³⁵ © IEEE 2007)

geometries to a small area of the search space; however, the time required to evaluate the performance of each antenna is very small. The optimization takes advantage of this short evaluation time until convergence is reached. At this point the algorithm can get no further using this limited set of generators; therefore, the generator autopolyloidization process is applied to expand the number of generators, which in turn expands the search space. This expansion comes at the cost of increasing the evaluation time; however, the optimization now has a good idea of where to search for more complex solutions based on the simpler designs found during the previous epoch. On the contrary, if the genetic algorithm began by optimizing the more complex solutions, not only would it initially take much longer to evaluate each array, the large number of unfocused input parameters could overwhelm the optimization process. This cycle of autopolyloidization can be repeated numerous times, producing more and more complex solutions with each optimization epoch. If the evolutionary progress is summarized for each generation, the resulting diagram would exhibit a staircase pattern. Thus, generator autopolyloidization offers polyfractal-based genetic algorithms an efficient “path” to complex design solutions, first optimizing simple designs very quickly and then only adding the increasing levels of complexity when they are finally needed.

Next, an example is presented to illustrate the GA design methodology for evolving an optimal uniformly excited linear polyfractal array. The design considered here is an example of a large- N array, i.e., an array that has a relatively large number of elements. In this case, an initial population of arrays is optimized to minimize the peak sidelobe level and maintain a narrow beamwidth for a polyfractal array with a 0.5λ minimum interelement spacing. The initial population was based on 500, 2401-element periodic arrays with 0.5λ spacing. These initial arrays were created using a polyfractal structure consisting of one generator. Three generator autopolyloidy operations were performed: one initially and two triggered after the population did not improve over 30 generations. Therefore the optimization process is divided into three epochs of evolution. The evolutionary diagram, shown in Figure 33-23, exhibits the characteristic staircase pattern resulting from the three generator autopolyloidy operations. During the first epoch, the polyfractal arrays had two generators. This epoch ended at generation 217, where the number of generators was doubled to four for the second epoch. Two hundred generations later, the third epoch began with each polyfractal array now having eight generators. The final 1616-element design was found after 700 generations and had a sidelobe level of -24.30 dB and a beamwidth of 0.056° . The recursive beamforming algorithm on average calculated radiation patterns 20 times faster for arrays with two generators, 15 times faster for arrays with four generators, and 10 times faster for arrays with eight generators when compared to a conventional discrete Fourier transform (DFT) approach. Table 33-1 summarizes these speed increases for each epoch. The array factor and geometrical layout of this antenna array are shown in Figure 33-24 with the corresponding performance properties of the antenna listed in Table 33-2.

TABLE 33-1 Number of Generators and Radiation Pattern Evaluation Speed Increase per Epoch for the 1616-element Polyfractal Array Using the Recursive Beamforming Algorithm vs. a Conventional DFT Approach (Radiation patterns have been sampled at 72,000 points.)

	Epoch 1	Epoch 2	Epoch 3
Number of Generators	2	4	8
Evaluation Speed Increase	1937%	1431%	892%

FIGURE 33-25 Layout for a 1230-element, uniformly excited, Pareto optimized polyfractal array.

More complex design problems can have multiple criteria that must be optimized. In these cases, it is desirable to compare the solutions that lie upon the Pareto front (i.e., the set of all nondominated solutions). Several different types of genetic algorithms have been developed to search for this Pareto front.^{36–43} An example of a uniformly excited polyfractal array evolved from one of these Pareto genetic algorithm optimization techniques^{39,40} is discussed here. The goal of the optimization is to minimize the peak sidelobe level at two frequencies: one in which the minimum spacing is 0.75λ and another where the minimum spacing is 2.0λ . The optimization evolved arrays from an initial population of fractal arrays based on a 1296-element periodic array. Three generator autopolyploidy processes were performed: one initially, one at generation 150, and one at generation 300. The optimization was terminated after 450 generations and the resulting Pareto front consists of arrays with between 1186 and 1230 elements. One solution with 1230 elements was chosen from the Pareto front for discussion. This example has a -19.3 -dB sidelobe level at both the 0.75λ and at the 2.0λ minimum spacings when the mainbeam is pointed at broadside. The layout of this design is shown in Figure 33-25, while Table 33-3 summarizes the properties of this array at the two different design frequencies.

While the array was optimized only at these two frequencies, the fractal-random properties of polyfractal arrays allow for low sidelobe levels over fairly wide ranges of bandwidth without the appearance of grating lobes. Figure 33-26 plots the sidelobe level performance of the polyfractal array shown in Figure 33-25 as a function of the minimum separation between elements in wavelengths and compares them to a 1296-element periodic array. When steered to broadside, the sidelobe level of the periodic array is -13.26 dB until the electrical spacing between elements increases to about 1λ , when grating lobes first appear. In contrast, the polyfractal array maintains sidelobe levels less than -14 dB even up to 20λ minimum spacings. This array was not optimized at a 20λ minimum spacing; nevertheless, the robust physical properties of the polyfractal arrays in combination with the optimization goals at 0.75λ and 2.0λ minimum spacings have allowed the low sidelobe performance to be maintained far beyond the specified separation distance of 2.0λ . This array also has a sidelobe level under -16 dB for up to 16λ minimum spacing, and a sidelobe level under -17 dB up to 7λ minimum spacing when the mainbeam is directed to broadside. In addition, one can see how the goals of the optimizer at the 0.75λ and 2.0λ minimum spacings have evolved an array with sidelobe levels under -19 dB for these lower frequencies.

TABLE 33-3 Performance at the Two Optimization Target Frequencies for the 1230-element Polyfractal Array

Number of Elements	0.75 λ Minimum Spacing			2.0 λ Minimum Spacing		
	<i>SLL</i>	<i>HPBW</i>	<i>Average Spacing</i>	<i>SLL</i>	<i>HPBW</i>	<i>Average Spacing</i>
1230	-19.31 dB	0.0078°	5.60λ	-19.31 dB	0.0029°	14.96λ

FIGURE 33-26 Sidelobe level performance of a uniformly excited, 1230-element, Pareto optimized polyfractal array over a range of bandwidth compared to the performance of a conventional uniformly excited periodic linear array. The polyfractal array was optimized at broadside for simultaneous minimum element spacings of 0.75λ and 2.0λ .

Finally, these arrays also exhibit their wideband properties when they are steered away from broadside. Figure 33-26 also plots the peak sidelobe level vs. minimum spacing when the mainbeam is steered 60 degrees from broadside. The grating lobes for the periodic array when steered to 60 degrees from broadside first appear at interelement spacings of 0.56λ . On the other hand, the peak sidelobe level performance of the polyfractal array is still less than -14 dB even up to 20λ minimum spacing. Figure 33-27 shows the radiation pattern for this optimized polyfractal array when the minimum spacing between elements is 8λ and the beam is steered 60 degrees from broadside.

FIGURE 33-27 Radiation pattern for a uniformly excited, 1230-element, Pareto optimized polyfractal array with its mainbeam steered 60 degrees from broadside and an 8λ minimum spacing between elements

33.6 ANTENNA ARRAYS BASED ON FRACTAL AND APERIODIC TILINGS

This section is devoted to design methodologies for antenna arrays that are based on fractal and aperiodic tilings. Although a wide variety of tilings ranging from simple to complex patterns have been known since early civilizations (an example of an early tiling is shown in Figure 33-28), the formal mathematical theory of tilings has only been in existence for about a century.⁴⁴ Tiling theory has found applications in many fields, such as crystallography, biology, and communication theory. More recently, tiling theory has been successfully applied to the field of electromagnetics, in particular, antenna array design using fractal tilings^{45,46,47} and aperiodic tilings.⁴⁸ The unique geometry of these tilings can be exploited to generate antenna arrays that exhibit low sidelobe levels and suppressed grating lobes for minimum element spacings of at least one-wavelength. Moreover, it has been shown that robust element perturbation schemes based on the GA can be used to greatly improve the performance of these arrays.^{49,50,51}

A modular design approach based on the theory of fractile geometry has been introduced in Werner et al.⁴⁵ for designing low-sidelobe arrays with suppressed grating lobes. A fractile array is defined as an array composed of a tiling of self-similar subarrays with fractal boundaries that covers the plane or a portion of the plane without any overlaps or gaps. A variety of different fractile array configurations have been investigated including Peano-Gosper, terdragon, six-terdragon, and fudgeflakes.⁴⁵ Another important property of fractile arrays is that their self-similar tile geometry can be exploited to develop a rapid iterative procedure for calculating far-field radiation patterns that, for sufficiently large arrays, can be considerably faster than using a conventional DFT.

One specific type of fractile array that has been reported on extensively in the literature is based on the Peano-Gosper family of space-filling curves (see Figure 33-7) and is therefore known as the Peano-Gosper fractile array (PGFA).^{45,46,47,49,50} The elements of the array are uniformly distributed along a Peano-Gosper curve as shown in Figure 33-29, which leads to a planar array configuration with an equilateral triangular (i.e., hexagonal) lattice on the interior that is bounded by an irregular closed Koch fractal curve around its perimeter. The Koch fractal boundary plus its interior form a Gosper island that can be used to cover the plane

FIGURE 33-28 Photograph of a tiling from the Alhambra in Granada, Spain (Courtesy of Douglas H. Werner)

FIGURE 33-29 Element distribution along stage 1 and stage 2 of the Peano-Gosper curve. The initial uniformly spaced element locations are denoted by a +. Examples of GA perturbed element locations are denoted by an o.

via a tiling.^{45,46} Furthermore, Gosper island tiles as illustrated in Figure 33-9 are self-similar and can be divided into seven smaller tiles, each representing a scaled copy of the original. Finally, the PGFA may be iteratively constructed to any arbitrary stage of growth based on a set formula for shifting, scaling, and rotating the generating array defined at stage 1. These unique properties were exploited in Werner et al⁴⁵ and Bogard et al⁴⁷ to develop a design methodology for deterministic arrays that possess several desirable properties, including a uniform current distribution, low sidelobe levels, relatively broad bandwidth, modular architecture, and the ability to perform rapid beamforming. Moreover, due to its equilateral triangular lattice, the PGFA will have no grating lobes for broadside operation even when the minimum spacing between elements is increased to one wavelength.

Because the PGFA possesses a fractal boundary contour, its sidelobe levels are lower than an equivalent size rectangular array with an equilateral triangular (i.e., hexagonal) grid of elements on its interior. Figure 33-30 shows a comparison of the array factor for a 352-element rectangular-hexagonal array, a 344-element stage 3 PGFA, and a 361-element (19×19) square periodic array.⁴⁷ All of the arrays have uniform element excitation and a minimum element spacing of one-wavelength. At this spacing the PGFA exhibits lower overall sidelobes than either its conventional square periodic or rectangular-hexagonal array counterparts.

In the design of phased arrays (especially broadband phased arrays), care must be taken to ensure that grating lobes do not appear when the main beam is to be steered away from broadside. For example, when the element spacing of a PGFA is increased to one wavelength, no grating lobes occur in the entire visible region for broadside operation. However, when the minimum element spacing is one wavelength or greater and the main beam is scanned away from broadside, grating lobes occur in the far-field radiation pattern of the array. It has been shown in Bogard and Werner⁴⁹ and in Bogard et al⁵⁰ that a GA technique can be used to perturb the element locations in an optimal way on the interior of the PGFA to eliminate the grating lobes and provide acceptable sidelobe levels during scanning. This procedure results in a modular or tiled phased-array architecture that has an irregular fractal distribution of elements around its periphery together with an aperiodic arrangement of elements on its interior. During the design process, the element locations of the stage 1 generator are varied and subsequently used to generate higher-order stages of the PGFA through an efficient iterative procedure while, at each stage, the array maintains its broadband

FIGURE 33-30 Comparison of the normalized array factor versus θ for a 361-element (19×19) square periodic array, a 352-element rectangular-hexagonal array, and a 344-element stage 3 PGFA at $\phi = 0$. In all three cases the array elements are uniformly excited and they have a minimum element spacing of one wavelength.

characteristics within a specified scan volume. Examples of GA perturbed element locations along the Peano-Gosper curve are shown in Figure 33-29.

In Bogard and Werner⁴⁹ and in Bogard et al.,⁵⁰ a stage 3 PGFA was optimized and its performance was compared with that of a uniform PGFA. The array had an initial element spacing of 2λ and was optimized for scanning up to $\theta = 30^\circ$. During scanning, grating lobes are suppressed over the entire visible region of the GA optimized design. Figure 33-31

FIGURE 33-31 Normalized array factor cut for the stage 3 PGFA with an initial element spacing of 2λ . The main beam of the array was steered to $\theta = 30^\circ$, $\phi = 180^\circ$.

shows a $\theta = 30^\circ$ cut of the array factor for the optimized PGFA and the uniform PGFA when the main beam is steered to $\theta = 30^\circ$ and $\varphi = 180^\circ$. In this plane cut, a grating lobe is present in the array factor of the original uniform PGFA, whereas the optimized PGFA has complete grating lobe suppression over the same scanning range.

Analogous to fractal-based tilings, aperiodic tilings can be used to generate antenna arrays that exhibit properties that are not typically associated with conventional periodic arrays. Unlike fractile arrays, which consist of a collection of elements that are placed a uniform distance apart along a space-filling curve (e.g. a Peano-Gosper curve), aperiodic tiling-based arrays consist of elements that are located at the vertices of an aperiodic tiling lattice.⁴⁸ Arrays that are generated in this manner tend to have geometrical structures that contain local order and rotational symmetry, but are devoid of any translational symmetries. A common method that is employed to generate these tilings is based on a decomposition process,⁴⁴ which is similar in some ways to the IFS techniques used to generate fractal geometries. In the process, tiles are decomposed into a collection of smaller tiles, which are either scaled copies of the original tiles or other tiles. This iterative process is continued until a large tiling is created.

The Danzer tiling is an example of an aperiodic tiling that can be used to generate broadband low-sidelobe planar antenna arrays that are naturally thinned.^{48,51} Moreover, the Danzer tiling is a type of aperiodic tiling that comprises a collection of three specific triangular-shaped prototiles. The tiling is formed by covering the plane with the triangles while maintaining specific matching rules throughout. A portion of a Danzer tiling is shown in Figure 33-32 along with its three prototiles.⁴⁴ An example of a Danzer tiling-based array is shown in Figure 33-33. The peak sidelobe level versus the minimum element spacing in terms of wavelengths for the array is shown in Figure 33-34. The tiling for the array has been scaled such that its physical dimensions correspond to a minimum element spacing, d , of $\lambda/2$ at the lowest intended operating frequency, and it has been truncated to have a circular aperture with a 12λ radius. In Figure 33-34, the performance of the Danzer array is compared with a conventional periodic array that has the same circular aperture and minimum element spacing. It is clear that the Danzer array outperforms the periodic array in terms of grating lobe suppression for large element spacings. Additionally, to fit within the same aperture size, the conventional periodic array requires approximately 1793 elements, while the naturally thinned (i.e., its mean interelement spacing is greater than $\lambda/2$) Danzer array only requires 811 elements.

Given the intrinsic properties of this class of arrays, they are attractive candidates for use as the baseline in various antenna designs, such as generating very sparse arrays⁵¹ and arrays with very wide bandwidth. One design methodology that is capable of producing

FIGURE 33-32 Truncated region of a Danzer tiling and its three prototiles

FIGURE 33-33 Geometry of the initial Danzer array and the GA optimized Danzer array

wideband planar arrays is based on a simple perturbation of the basic aperiodic array generation process. In this technique, an additional point (or points) is placed within the boundary of the prototiles that are used to generate the aperiodic tiling. The locations of these points are preserved within the prototiles as the overall aperiodic tiling is generated via the decomposition process. The result of this process is the formation of an aperiodic tiling that contains an additional point within each of its constituent tiles. Converting this to an antenna array yields fundamental elements at the vertices of the tiling along with elements at each of the additional points. The array can be scaled to have a specific minimum element spacing and then truncated to fit within a desired aperture. By adjusting the position of the point within each base tile, it is possible to greatly vary the radiation properties of the modified aperiodic tile-based array.

FIGURE 33-34 Sidelobe level performance of the initial Danzer array, GA optimized Danzer array, and periodic array. All of the arrays have a circular aperture with a radius of 12λ and a minimum element spacing of $d = 0.5\lambda$ at the lowest operating frequency.

FIGURE 33-35 (a) Perturbation points of the Danzer prototiles and (b) an example of a truncated Danzer tiling with its corresponding perturbed array element locations

A GA-based optimizer was combined with the perturbation technique with the objective of designing a Danzer array that has the lowest possible sidelobe levels at $d/\lambda = 5$. Since the Danzer array comprises a collection of three prototiles, the GA was only required to optimize the planar coordinates of the three additional perturbation points, as illustrated in Figure 33-35. During the optimization, all of the generated arrays were scaled to have a minimum element spacing of $\lambda/2$ and were truncated to have a circular aperture with a radius of 12λ at the lowest operating frequency. The base tiling for the optimization was the same one that was used in the formation of the array shown in Figure 33-33. The design that results from this optimization process is shown in Figure 33-33 and has a normalized radiation pattern with a maximum sidelobe level of -10.05 dB at a frequency corresponding to $d/\lambda = 5$. The peak sidelobe level versus frequency for the array is shown in Figure 33-34. For this particular example, the simple perturbation scheme is capable of greatly extending the bandwidth (peak sidelobe level ≤ -10 dB with no grating lobes) of the basic Danzer array.

34.1 INTRODUCTION

The growing number of wireless communication systems continuously challenges antenna engineers to create novel antenna structures and improve existing antenna designs. Due to the advancements in computational electromagnetics and fabrication technologies, antenna engineers nowadays are capable of exploiting complex engineered electromagnetic materials in antenna designs.¹⁻⁴

Surveying the literature, one observes that various engineered materials have been investigated and numerous antenna applications have been proposed. For example, Figure 34-1 illustrates some representative engineered electromagnetic materials with unique electromagnetic properties.⁵ Frequency selective surfaces (FSS) are widely used in radome and reflector antenna designs as wave filters.^{6,7} Double negative (DNG) material refers to those materials with effective negative permittivity and permeability, which results in properties such as left-handed (LH) wave propagation and negative index of refraction (NIR).⁸⁻¹⁰ Periodic structures that prohibit the propagation of electromagnetic waves in a certain frequency band for certain arrival angles and polarization senses are classified as electromagnetic band gap (EBG) structures.¹¹⁻¹³ Another important category consists of ground planes that exhibit unique reflection characteristics other than conventional PEC, known as complex artificial ground planes.^{14,15}

This chapter summarizes several typical engineered electromagnetic materials and illustrates their applications in antenna engineering. It is demonstrated that they not only improve the performance of conventional antennas such as gain, bandwidth, and efficiency, but also lead to novel radiator concepts and structures like surface wave antennas and reconfigurable antennas.

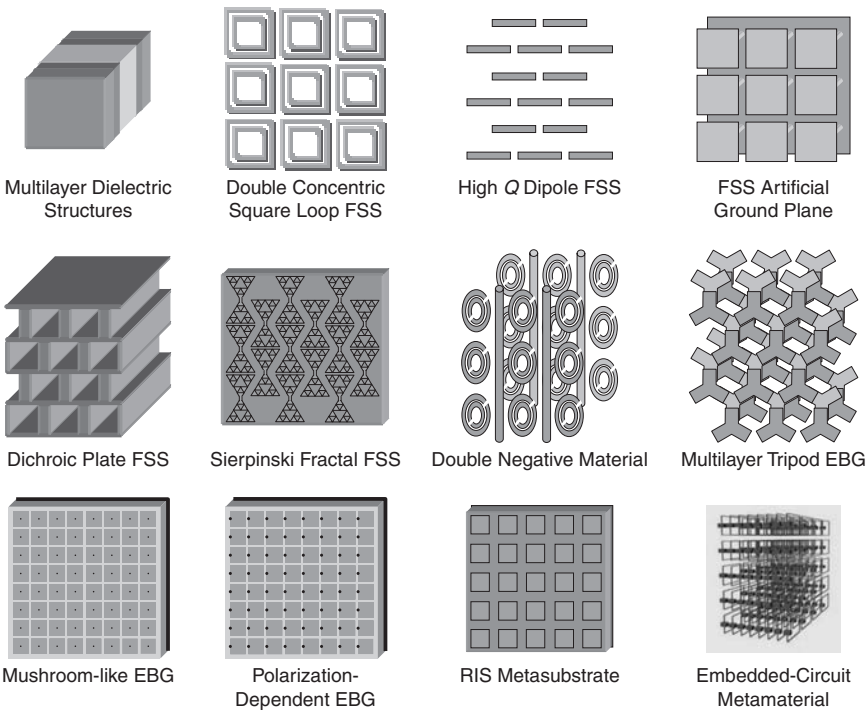

FIGURE 34-1 Different classes of engineered electromagnetic materials

34.2 CHARACTERIZATIONS AND DESIGNS OF ELECTROMAGNETIC BAND GAP (EBG) STRUCTURES

Among various engineered electromagnetic materials, mushroom-like EBG structure has attracted increasing attention.¹² It consists of four parts: a ground plane, a dielectric substrate, periodic metal patches, and connecting vias, as shown in Figure 34-2. This structure is easy to fabricate using the printed circuit board (PCB) technique.

Frequency Band Gap and In-phase Reflection Coefficient

The mushroom-like EBG structure exhibits distinctive electromagnetic properties with respect to incident electromagnetic waves:

- When the incident wave is a surface wave ($k_x^2 + k_y^2 \geq k_0^2$), the EBG structure shows a *frequency band gap* through which the surface wave cannot propagate for any incident angles and any polarization states, resulting in an ideal isolator for electromagnetic waves.
- When the incident wave is a plane wave ($k_x^2 + k_y^2 < k_0^2$), the EBG structure has an *in-phase reflection coefficient* of +1 at a certain frequency, which resembles an ideal perfect magnetic conductor (PMC) that does not exist in nature.

FIGURE 34-2 Geometry of a mushroom-like electromagnetic band gap (EBG) structure (after Yang et al.⁶² © *Microwave Optical and Technology Letters* 2005)

In the above equations, k_x and k_y denote the wave numbers in the horizontal directions, while k_0 is the free-space wave number. The operation mechanism of this EBG structure can be explained by an *LC* filter array: the inductor L results from the current flowing through the vias, and the capacitor C is due to the gap effect between the adjacent patches. Some empirical formulas for the inductor L and the capacitor C are presented in Rahman and Stuchly.¹⁶

To accurately characterize the frequency band gap property and the in-phase reflection coefficient, the finite difference time domain (FDTD) method^{17–20} is used to analyze the EBG structure. A single unit of the EBG structure is simulated with periodic boundary conditions (PBC) incorporated on four sides to model an infinite periodic structure. The dimensions of the analyzed EBG structure are

$$W = 0.10\lambda, g = 0.02\lambda, h = 0.04\lambda, \epsilon_r = 2.94 \quad (34-1)$$

where W is the width of the square patch, g is the gap width, h is the substrate thickness, and ϵ_r is the dielectric constant of the substrate. The vias' radius in the EBG structure is 0.005λ . The free-space wavelength at 4 GHz, $\lambda = 75$ mm, is used as a reference length to define the physical dimensions of the EBG structure. It is worthwhile to point out that the periodicity of the EBG structure (0.12λ) is much smaller than the wavelength. In addition, these dimensions are readily scaled to other frequencies of interest for different applications.

Figure 34-3a shows the ω - β diagram of the EBG structure, where the vertical axis is the frequency and the horizontal axis represents the values of the horizontal wave numbers (k_x, k_y) in the Brillion zone. Each point in the dispersion diagram represents a certain surface wave mode. It is observed that in the frequency range from 3.5 GHz to 5.9 GHz,

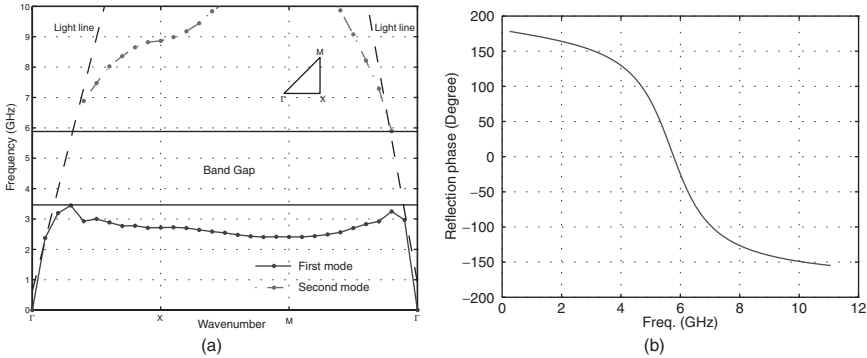

FIGURE 34-3 Electromagnetic properties of an EBG structure characterized using FDTD method with periodic boundary conditions (PBC): (a) the ω - β diagram and (after Yang et al⁶² *Microwave Optical and Technology Letters* 2005) (b) the reflection phase. The EBG structure exhibits a frequency band gap for surface waves and an in-phase reflection coefficient for plane-wave incidence.

no surface waves can exist regardless of propagation angles or polarization states. Thus, this frequency region is defined as a surface wave band gap of the EBG structure.

Figure 34-3b shows the reflection phase curve for a normally incident plane wave. The reflection phase of a surface is defined as the phase of the reflected E field normalized to the phase of the incident E field at the reflecting surface. It is known that a perfect electric conductor (PEC) has an 180° reflection phase and a perfect magnetic conductor (PMC) has a 0° reflection phase. In contrast, the reflection phase of the EBG surface decreases continuously from 180° to -180° as frequency increases. For example, the EBG surface exhibits a 90° reflection phase around 4.6 GHz and a 0° reflection phase around 5.8 GHz. It is important to note that the reflection phase varies with incident angles and polarization states.

Parametric Studies

The electromagnetic properties of the EBG structure are determined by its physical dimensions, namely, patch width W , gap width g , substrate permittivity ϵ_r , and substrate thickness h . Hence, in-depth studies on these parameters are required to develop engineering design guidelines for the EBG structure.²¹

The reference EBG parameters are listed below:

$$W = 0.12\lambda_{12 \text{ GHz}}, g = 0.02\lambda_{12 \text{ GHz}}, h = 0.04\lambda_{12 \text{ GHz}}, \epsilon_r = 2.20 \quad (34-2)$$

The vias' radius is $0.005\lambda_{12 \text{ GHz}}$. Figure 34-4 presents the effects of the preceding four parameters on the reflection phase of the EBG structure. During each study, only the parameter of interest changes, while the other three parameters remain the same as Eq. 34-2. Two important properties on the reflection phase curve are concerned: the resonant frequency where the reflection phase equals to zero and the slope of the curve that corresponds to the frequency bandwidth of the EBG structure. Following are observations that can be obtained from Figure 34-4:

- When the patch width W increases, the resonant frequency decreases and the slope of the curve becomes steep.
- When the gap width g increases, the resonant frequency increases and the slope of the curve becomes flat.

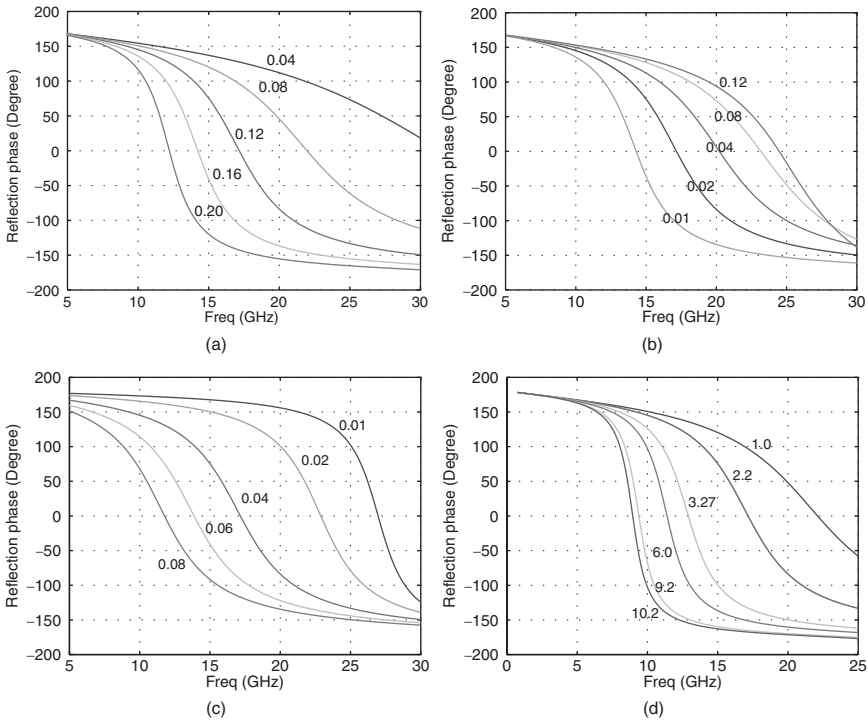

FIGURE 34-4 Parametric studies on the EBG dimensions: (a) patch width W effect, (b) gap width g effect, (c) substrate thickness h effect, and (d) substrate permittivity ϵ_r effect

- When the substrate thickness h increases, the resonant frequency decreases but the slope of the curve becomes flat.
- When the dielectric constant ϵ_r increases, the resonant frequency decreases and the slope of the curve becomes steep.

Although the preceding observations focus on the reflection phase feature of the EBG structure, it is noticed that similar parameter effects also apply in the surface wave band gap property.

Polarization-Dependent EBG Designs

The aforementioned mushroom-like EBG structure has a symmetric square unit cell so that its reflection phase for the normal incidence is independent of the polarization states. When the unit geometry is modified, EBG structures with polarization-dependent reflection phases can be obtained.²²⁻²⁴

Figure 34-5a shows a polarization-dependent EBG design using rectangular patch units. The patch length L is $0.24\lambda_{3\text{ GHz}}$ and the width W is $0.16\lambda_{3\text{ GHz}}$. The gap width is $0.02\lambda_{3\text{ GHz}}$ and the vias' radius is $0.0025\lambda_{3\text{ GHz}}$. The substrate thickness is $0.04\lambda_{3\text{ GHz}}$ and the dielectric constant is 2.20. As a reference, a square patch EBG surface ($0.16\lambda_{3\text{ GHz}} \times 0.16\lambda_{3\text{ GHz}}$) is also studied. Due to different values of L and W , the reflection phase of the EBG surface

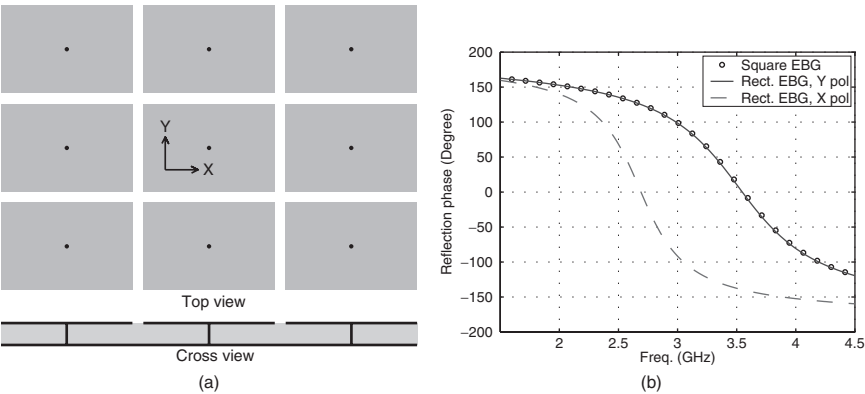

FIGURE 34-5 (a) A rectangular-patch EBG surface and (b) the reflection phases of the EBG structure with respect to different polarizations of the incident wave (after Yang and Rahmat-Samii²³ © *Microwave Opt. Technol. Lett.* 2004)

becomes dependent on the x - or y -polarization state of the incident plane wave, as depicted in Figure 34-5b. When the incident plane wave is y -polarized, the rectangular patch EBG surface has the same reflection phase as the square patch EBG surface because the patch widths are the same. For the x -polarized incident plane wave, the patch length L plays a dominant role in determining the reflection phase. Since the length L is longer than the width W , the reflection phase curve shifts down to lower frequencies. It is noticed that near 3 GHz, the EBG surface shows a -90° reflection phase for the x -polarized wave and a $+90^\circ$ reflection phase for the y -polarized wave.

Besides the rectangular patch unit, various other approaches have also been used to realize the polarization-dependent feature. For example, Figure 34-6 shows two alternative designs:

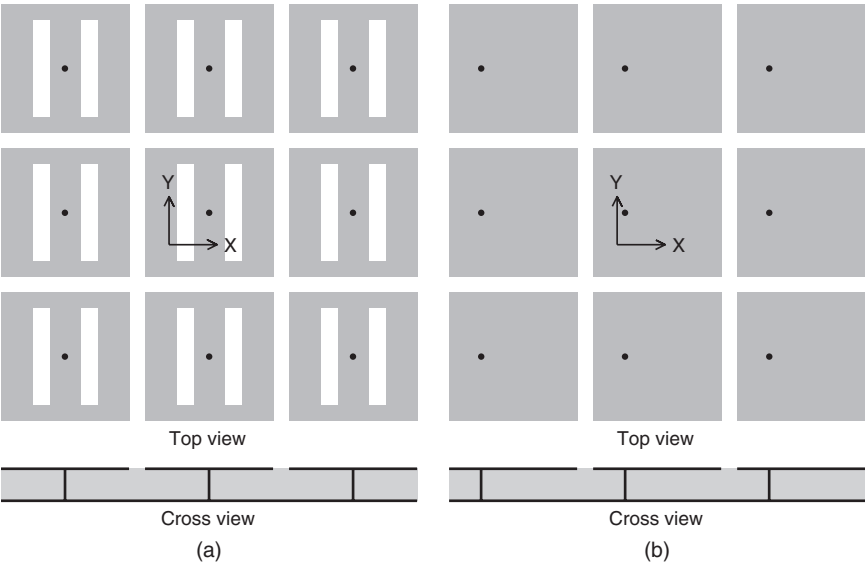

FIGURE 34-6 Polarization-dependent EBG structures: (a) slot-loaded design and (b) offset vias design (after Yang and Rahmat-Samii²³ © *Microwave Opt. Technol. Lett.* 2004)

a slot-loaded EBG and an EBG with offset vias. In Figure 34-6*a*, a pair of y -oriented slots are symmetrically incorporated into the patch of a square EBG surface. The slots affect electric currents flowing along the x direction, resulting in a longer current path. Thus, the reflection phase of the x -polarized wave decreases to a lower frequency. In contrast, the reflection phase of the y -polarized wave remains the same as the square patch EBG surface because the slots have little effect on the electric currents flowing along the y direction.

In Figure 34-6*b* the vias are offset along the x direction while they are still centered along the y direction. Therefore, the reflection phase for the y -polarized wave remains unchanged whereas the reflection phase for the x -polarized wave varies with the vias' position. When the vias are located in the center of the patch, only one resonant frequency is observed. When the vias are offset, dual resonance behaviors are observed with one resonant frequency higher than the original frequency and the other lower. The different frequencies correspond to the different widths of the left and right regions of the patch with respect to the vias. The left part is narrower and thus corresponds to the higher resonant frequency. The right part is wider and is related to the lower resonant frequency.

34.3 LOW PROFILE WIRE ANTENNAS ON EBG GROUND PLANE

Because of the attractive electromagnetic properties, the EBG structure has been applied in various antenna applications. In this section, the in-phase reflection coefficient feature is exploited to increase the radiation efficiency of low profile wire antennas.^{21,25-27} The low profile design usually refers to an antenna structure whose overall height is less than one-tenth of the operating wavelength, which is desirable in many mobile communication systems.

Dipole Antenna on an EBG Ground Plane

To appreciate the advantages of using an EBG ground plane, we start with a dipole antenna, the simplest radiating structure. As shown in Figure 34-7*a*, a dipole antenna is horizontally positioned above an EBG ground plane to obtain a low profile configuration.²⁸ The dipole length is $0.40\lambda_{12\text{ GHz}}$ and its radius is $0.005\lambda_{12\text{ GHz}}$. The height of the dipole over the top surface of the EBG ground plane is only $0.02\lambda_{12\text{ GHz}}$. A finite EBG ground plane with a $1\lambda_{12\text{ GHz}} \times 1\lambda_{12\text{ GHz}}$ size is used in the analysis, and the dimensions of the EBG structure are the same as those given in Eq. 34-2.

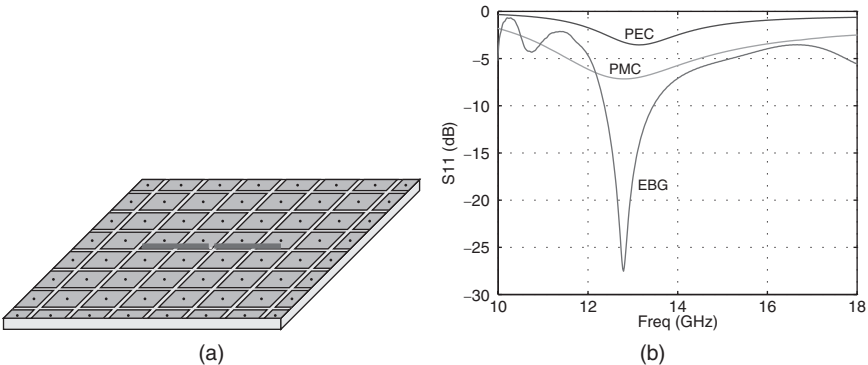

FIGURE 34-7 Dipole antenna near an EBG ground plane: (a) geometry and (b) FDTD simulated return loss (after Yang and Rahmat-Samii²¹ © IEEE 2003)

Figure 34-7*b* shows the FDTD simulated return loss of the dipole antenna. For comparison purposes, the performances of dipole antennas on PEC and PMC ground planes are also simulated and plotted. When the dipole is located above the PEC ground plane, the return loss is only -3.5 dB. The PEC surface has a 180° reflection phase so that the direction of the image current is opposite to that of the original dipole. The radiations from the image current and the original dipole cancel each other, resulting in a very poor return loss. When the PMC surface, which has a reflection phase of 0° , is used as the ground plane, the dipole has a return loss of -7.2 dB. The return loss is improved; however, it suffers from a strong mutual coupling between the image current and the dipole due to their close proximity.^{21,29} The best return loss of -27 dB is achieved by the dipole antenna over the EBG ground plane. The reflection phase of the EBG varies with frequency from 180° to -180° . In a certain frequency range, the EBG surface successfully serves as the ground plane for a low profile dipole, resulting in a high radiation efficiency. It is clear from this comparison that the EBG surface is a good ground plane candidate for low profile wire antenna designs.

A further question is how to identify the operational frequency band of an EBG ground plane. To this end, the parameters of the EBG surface are fixed and the length of the dipole is varied to resonate at different frequencies. By observing the return loss value and radiation patterns of the dipole at different frequencies, one can find a useful operational frequency band of the EBG ground plane for low profile wire antenna designs. Figure 34-8*a* shows the return loss results of a dipole with its length varying from $0.26 \lambda_{12 \text{ GHz}}$ to $0.60 \lambda_{12 \text{ GHz}}$. It is observed that the dipole shows a return loss better than -10 dB in a frequency range from 11.5 to 16.6 GHz.

From a computational efficiency viewpoint, it would be interesting to know if one could directly use the reflection phase curve of the EBG structure to identify the operational frequency band. Thus, the reflection phase of the EBG surface is evaluated, and the result is presented in Figure 34-8*b*. In contrast to the 180° reflection phase of a PEC surface or the 0° reflection phase of a PMC surface, if one chooses the $90^\circ \pm 45^\circ$ reflection phases as the criterion for the EBG ground plane, a frequency region from 11.3 to 16 GHz is identified, which is close to the frequency region obtained in the dipole model. It is revealed from this comparison that the operational frequency band of an EBG ground plane is the frequency region inside which the EBG surface shows a quadratic reflection phase ($90^\circ \pm 45^\circ$). This quadratic reflection phase criterion has been further demonstrated by various numerical and experimental results.²¹

FIGURE 34-8 Identification of the operational frequency band of an EBG ground plane: (a) return loss of a nearby dipole with length varying from 0.26 to $0.60 \lambda_{12 \text{ GHz}}$ and (b) reflection phase of the EBG surface (after Yang and Rahmat-Samii²¹ © IEEE 2003)

FIGURE 34-9 Radiation patterns of three dipoles at their resonant frequencies: (a) *E*-plane patterns and (b) *H*-plane patterns (after Yang and Rahmat-Samii²¹ © IEEE 2003)

The radiation patterns of dipole antennas above the EBG ground plane are also calculated to verify the radiation efficiency. Figure 34-9 displays both the *E*- and *H*-plane patterns of three dipole antennas at their resonant frequencies: (1) $0.48 \lambda_{12 \text{ GHz}}$ dipole resonating at 12 GHz, (2) $0.36 \lambda_{13.6 \text{ GHz}}$ dipole resonating at 13.6 GHz, and (3) $0.32 \lambda_{15.3 \text{ GHz}}$ dipole resonating at 15.3 GHz. It is observed that all three dipoles radiate efficiently with directivities around 8 dB.

Circularly Polarized Designs

Circularly polarized (CP) antennas are desired in many communication systems such as the Global Positioning System (GPS) and satellite links. The EBG ground plane is also implemented in low profile CP wire antenna designs. The first approach is to replace the traditional PEC ground plane of a curl antenna with an EBG ground plane, as shown in Figure 34-10a. The circular polarization is generated by the traveling current along the curl and the EBG ground plane helps to improve the radiation efficiency of the curl in a low profile configuration.^{31,32} It is noticed that the overall antenna height (0.07λ)

FIGURE 34-10 Photographs of low profile CP wire antennas on EBG ground plane: (a) a curl on a square patch EBG ground plane (after Yang and Rahmat-Samii³¹ © *Microwave Opt. Technol. Lett.* 2001) and (b) a dipole on a rectangular patch EBG ground plane (after Yang and Rahmat-Samii³³ © IEEE 2005)

is much smaller than that of a conventional curl design on a PEC ground plane (0.25λ). Figure 34-10*b* presents the second approach for low profile CP wire antenna design where a linearly polarized dipole is used instead of the CP curl.³³ The circular polarization pattern of the overall antenna is realized by the superposition of the directly radiating wave from the dipole and the reflected wave from the EBG ground plane. A polarization-dependent EBG ground plane is carefully designed and implemented here so that the reflected wave has a perpendicular polarization direction to the directly radiating wave as well as a 90° phase shift.²³ The function of the polarization-dependent EBG ground plane is similar to a meandering line polarizer.⁶

Reconfigurable Antenna with Pattern Diversity

Another interesting application of the EBG ground plane is to build a low profile reconfigurable wire antenna with radiation pattern diversity.³⁴ Reconfigurable antennas are desirable in modern wireless communication systems³⁵⁻³⁷ because they can provide more functionalities than ordinary antennas by reconfiguring their radiation performance, such as the operating frequencies,^{38,39} polarizations,⁴⁰⁻⁴² and radiation patterns.⁴³⁻⁴⁷ Figure 34-11*a* shows the geometry of a reconfigurable wire antenna design, where a feeding probe is connected to two metal strips through two switches. When the left switch is ON and the right switch is OFF, the probe has an electrical connection to the left strip, resulting in a bent monopole oriented along the $-x$ direction. When the left switch is OFF and the right switch is ON, the probe has an electrical connection to the right strip, resulting in a bent monopole oriented along the $+x$ direction. As a consequence, the direction of the antenna beam can be switched in space and the diversity in the radiation pattern is realized. A reconfigurable antenna prototype is built to demonstrate the operational mechanism, and the measured diversity patterns are shown in Figure 34-11*b*. It is observed that the antenna beam is switched between $\pm 26^\circ$.

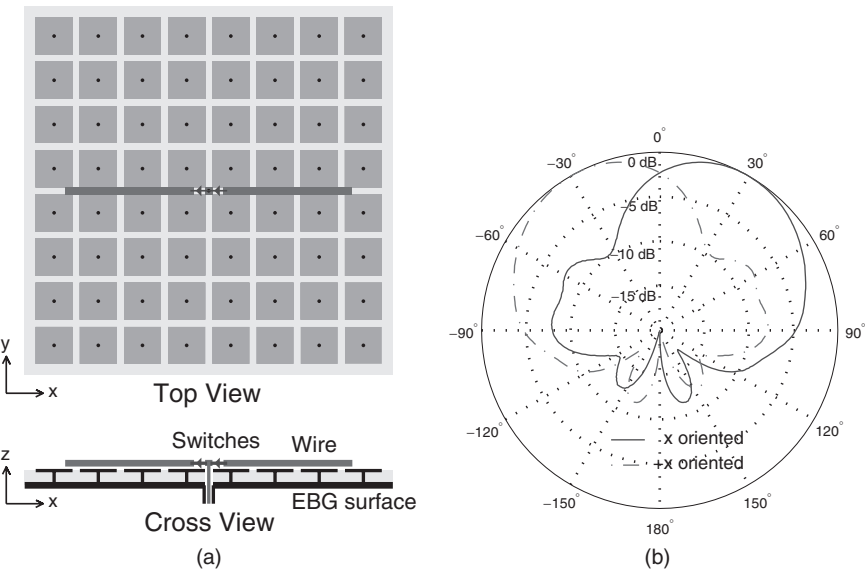

FIGURE 34-11 A low profile reconfigurable wire antenna on the EBG ground plane with radiation pattern diversity: (a) antenna geometry and (b) measured radiation patterns

34.4 PATCH ANTENNAS WITH ENHANCED PERFORMANCE USING EBG STRUCTURES

The EBG structure has two main features, and the in-phase reflection coefficient feature is used in the preceding section to improve the radiation efficiency of low profile wire antennas. This section discusses how the surface wave band gap feature is used to enhance the performance of microstrip antennas and arrays. Microstrip antennas are widely used in wireless communications due to their numerous advantages, including low profile configuration, light weight, low fabrication cost, and conformability with RF circuitry. In typical microstrip antenna designs, unwanted surface waves are excited in the substrate. These surface waves degrade the antenna performance, such as decreasing the antenna gain, increasing the back lobe, and increasing the mutual coupling. This problem becomes more severe when high dielectric constant substrates are used to design miniaturized microstrip antennas. Various methods have been proposed to solve this problem,^{48–51} and the EBG structures demonstrate excellent capability in reducing the surface waves.^{52–61} In this section, the mushroom-like EBG structure is integrated into microstrip antennas and arrays, and the applications of metasubstrate in microstrip antennas will be discussed in Section 34.6.

Patch Antenna Element

The EBG structure is first integrated with a microstrip patch antenna element to increase the antenna gain and suppress the back radiation.⁵⁴ The basic idea is to properly design the EBG structure such that the resonant frequency of the patch antenna falls inside the band gap of the EBG structure, hence inhibiting the surface waves. Figure 34-12*a* shows a patch antenna surrounded by four rows of EBG cells. The patch antenna is designed to resonant at 5.8 GHz and is fabricated on a 2.54-mm-thick RT/duriod 6010 ($\epsilon_r = 10.2$) substrate with a finite ground plane of 52×52 mm ($1\lambda \times 1\lambda$ at 5.8 GHz). The EBG patch size is 2.5×2.5 mm and the gap width between adjacent patches is 0.5 mm. It is noticed that the EBG structure is compact in this design because a thick substrate with a high dielectric constant is used. For comparison purposes, a conventional patch antenna on the same substrate but without EBG cells is built as a reference. It is noticed that both antennas have similar return loss,

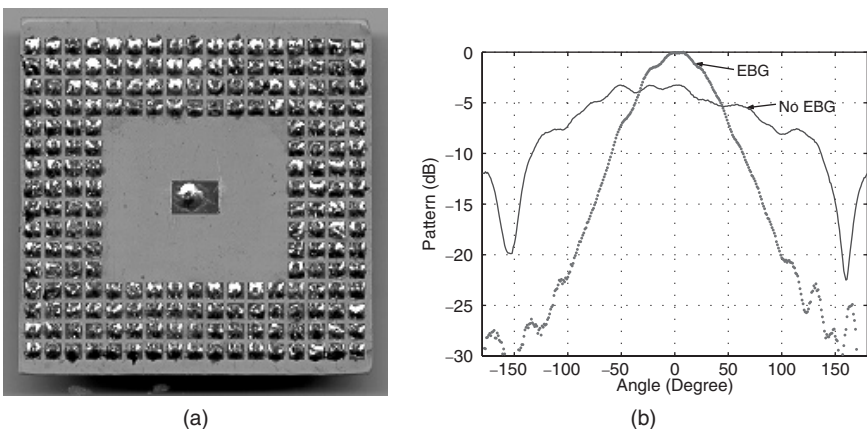

FIGURE 34-12 (a) Photo of a microstrip patch antenna surrounded by an EBG structure and (b) measured *E*-plane radiation patterns for patch antennas with and without EBG structure

FIGURE 34-13 (a) Photos of a normal microstrip antenna array (above) and a design that integrates the EBG structure into the array (below); (b) measured scattering coefficients of the microstrip antenna arrays (after Yang and Rahmat-Samii⁵⁵ © IEEE 2003)

but the EBG case shows an improved radiation pattern, as plotted in Figure 34-12b. With the surrounding EBG cells, the antenna gain is successfully increased by 3.2 dB while the back lobe is effectively reduced by more than 15 dB.

Patch Antenna Array

The EBG structure also can be integrated with a microstrip antenna array to reduce the mutual coupling between antenna elements.⁵⁵ As shown in Figure 34-13a, two pairs of microstrip antennas with and without the EBG structure are fabricated on 1.92-mm-thick Roger RT/duroid 6010 substrates. The antenna's size is 6.8×5 mm, and they are fabricated on a finite ground plane of 100×50 mm with the patch distance of 38.5 mm ($0.75 \lambda_{5.8 \text{ GHz}}$). The EBG patch width is 3 mm and the gap width is 0.5 mm.

The measured results are shown in Figure 34-13b, where both antennas resonate at 5.86 GHz with a return loss better than -10 dB. For the antenna array without the EBG structure, the mutual coupling at 5.86 GHz is as high as -16.8 dB. In contrast, the mutual coupling of the antennas with the EBG structure is only -24.6 dB. An 8-dB reduction of mutual coupling is achieved at the resonant frequency because of the effective suppression of surface waves by the EBG structure. This low mutual coupling design is potentially useful for various phase array applications, such as eliminating blind angles in radar systems.

34.5 SURFACE WAVE ANTENNAS WITH A MONOPOLE-LIKE RADIATION PATTERN

The mushroom-like EBG structure exhibits both a surface wave band gap feature and an in-phase reflection coefficient. However, these two characteristics are not necessarily associated with each other.⁶² For example, this section discusses another engineered electromagnetic material that only has an in-phase reflection coefficient but has no band gap for surface waves. This new engineered material is used to design surface wave antennas that realize a monopole-like radiation pattern with a low profile configuration.

Dipole-Fed Surface Wave Antenna

Figure 34-14a shows the geometry of a horizontal dipole antenna above a patch-loaded grounded slab. The dipole is simply fed by a 50-Ω coaxial cable: one arm of the dipole is connected to the center probe of the cable, and the other arm is connected to the outside conductor of the cable, which is soldered to the lower PEC of the artificial surface. Compared to Figure 34-7a, this design uses a patch-loaded grounded slab as the ground plane, which is similar to a mushroom-like EBG structure except that the vertical vias are all removed. It is revealed that removing the vertical vias has little effect on the in-phase reflection feature for a normally incident plane wave; however, it completely changes the surface wave characteristic of the engineered ground plane. Figure 34-14b presents the dispersion diagram of the patch-loaded grounded slab. The dimensions of this artificial ground plane are the same as those given in Eq. 34-1. It is clear that when the vertical vias are removed, the surface wave band gap disappears. Therefore, the surface waves can exist over the entire frequency band.

Due to the different properties of the engineered ground plane, the radiation performance of the antenna is vastly different from the ones discussed in Section 34.3. The return loss of the antenna with various dipole lengths is shown in Figure 34-15a. It is noticed that the low profile antenna also obtains a good return loss in a frequency region where the artificial surface exhibits a quadratic reflection phase. When the dipole length is $0.26\lambda_{4\text{ GHz}}$, the antenna achieves a good return loss of -30 dB at 4.05 GHz with a 7.1 percent impedance bandwidth. It is worthwhile to point out that the length of the dipole is much smaller than the half wavelength at the operating frequency. In contrast, if a dipole is located near an EBG ground plane and resonates at the same frequency, the length of the dipole is close to a half wavelength.

Figure 34-15b shows the radiation patterns of the antenna at the resonant frequency of 4.05 GHz. Several interesting observations can be made from this figure. First, the antenna shows a small radiation power in the broadside direction ($\theta = 0^\circ$). The main beam of this antenna points to the $\theta = 50^\circ$ direction with a directivity of 5 dBi. This is different from the

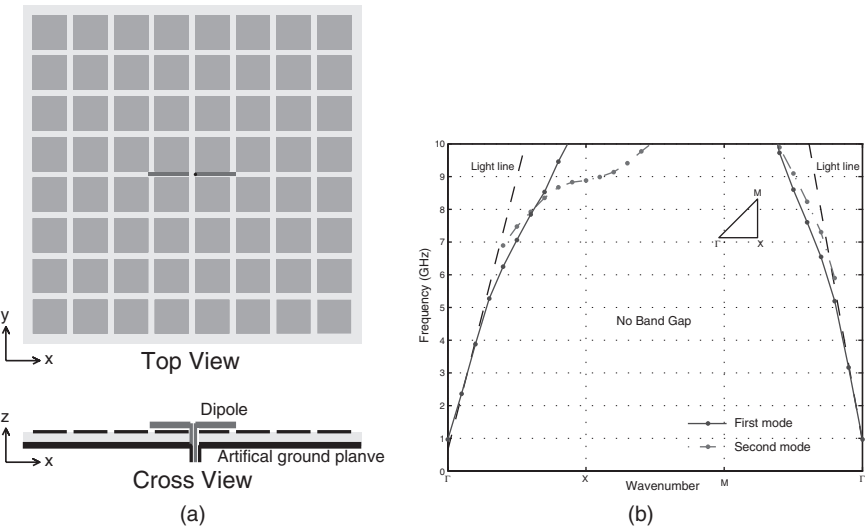

FIGURE 34-14 (a) A dipole antenna near a patch-loaded grounded slab and (b) the dispersion diagram of the patch-loaded grounded slab. No surface wave band gap exists for this engineered structure (after Yang et al.⁶² © *Microwave Optical and Technology Letters* 2005).

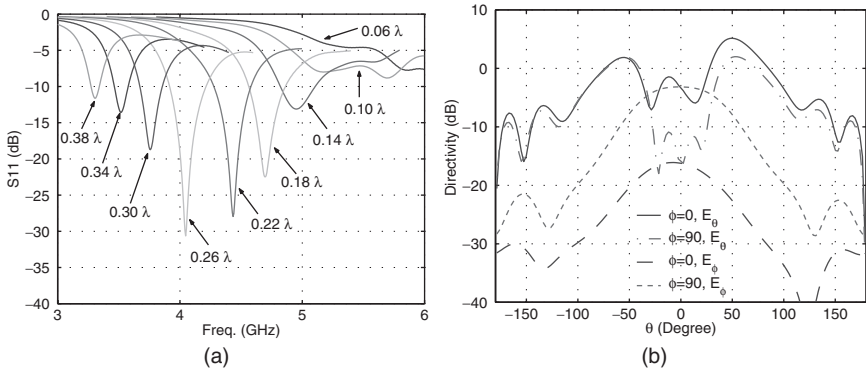

FIGURE 34-15 Radiation characteristics of the dipole-fed surface wave antenna: (a) FDTD simulated return loss of the antenna with different dipole lengths (after Yang et al.⁶² © *Microwave Optical and Technology Letters* 2005) and (b) radiation patterns of the antenna at 4.05 GHz with a dipole length of 0.26λ

dipole antenna on an EBG ground plane whose main beam points to the broadside direction, as shown in Figure 34-9. Second, E_θ is the copolarized field in both the xz ($\phi = 0^\circ$) and yz planes ($\phi = 90^\circ$). Thus, both the xz and yz planes are E planes. In contrast, if the dipole is near an EBG ground plane, the xz plane is the E plane but the yz plane is the H plane. In summary, this antenna has entirely different radiation characteristics compared to a horizontal dipole on an EBG ground plane.

The radiation characteristics in Figure 34-15 can be explained by the propagation and diffraction of surface waves in the engineered ground plane. When a dipole is positioned near a patch-loaded grounded slab, strong surface waves are excited to propagate along the ground plane. The dipole works more like a transducer than a radiator. Therefore, the optimal length of the dipole is not necessarily equal to a half wavelength. It is also noticed that the surface waves are dominated by the TM_z mode and the electric field is vertically polarized. When the surface waves diffract at the edge of the ground plane, a monopole-like radiation pattern is generated. For example, since the diffraction at the edge is hard boundary diffraction, two diffracted rays from opposite edges will cancel in the broadside direction, resulting in a radiation null. The hard diffraction also determines the polarization of the radiating field along the θ direction. Therefore, this antenna is properly identified as a surface wave antenna (SWA)⁶³⁻⁶⁷ because of this operational mechanism.

The attractive feature of this SWA design is the low profile configuration. The height of the horizontal dipole over the artificial ground plane is only $0.02\lambda_{4\text{ GHz}}$, whereas the height of a typical monopole antenna is $0.22\lambda_{4\text{ GHz}}$. The dipole height is less than 10 percent of the conventional monopole antenna. Therefore, this low profile SWA design has a promising potential in mobile communication systems such as vehicle radio systems.

Patch-Fed Surface Wave Antenna

A deficiency in the previous design is the relatively high cross-polarization attributed to the direct radiating field from the dipole. To solve this problem and obtain a better monopole-like radiation pattern, a patch-fed surface wave antenna (PFSWA) is sketched in Figure 34-16a. The same patch-loaded grounded slab is used in the antenna design while a circular patch is inserted in the middle of the substrate to excite surface waves.⁶⁸ Investigation shows that the energy can be effectively coupled from the cavity fields underneath the circular patch to the surface waves propagating along the engineered ground plane. Hence, good radiation

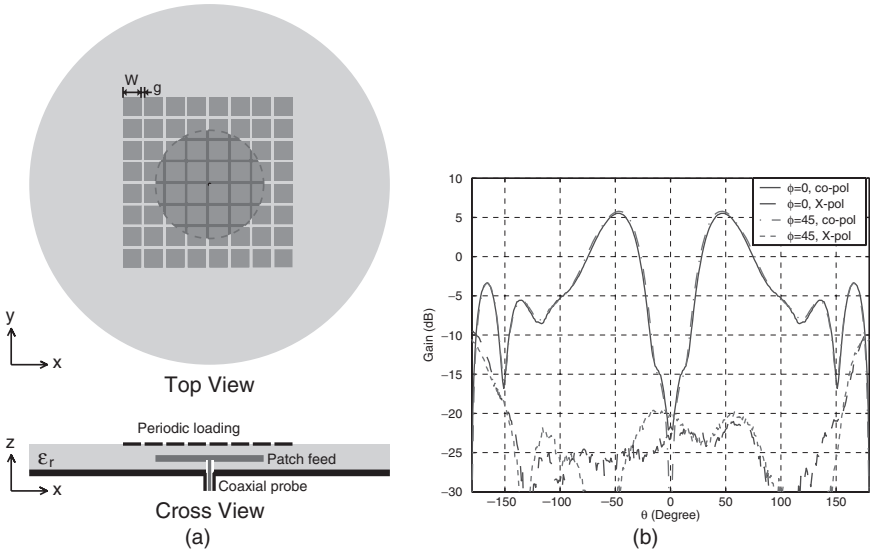

FIGURE 34-16 A low profile patch-fed SWA with a monopole-like radiation pattern: (a) antenna geometry and (b) measured radiation patterns

efficiency can be obtained. Parametric studies reveal that 8×8 periodic patches are enough to launch the surface waves. In order to get a symmetric diffraction pattern, the ground plane is truncated into a circular shape. Figure 34-16b shows measured radiation patterns of a PFSWA prototype, which is very similar to a typical monopole pattern. Both the xz plane ($\phi = 0^\circ$) and diagonal plane ($\phi = 45^\circ$) patterns are presented, which are almost identical to each other. It has a deep null in the broadside direction and the antenna beam is at $\theta = 47^\circ$ direction with a gain of 5.6 dBi. The co-polarization is along the θ direction, and the cross-polarization is -25 dB lower than the co-polarization in the front side. A noticeable cross-polarization is observed in the backside of the antenna due to diffractions from the supporting posts and feeding cable.

34.6 IMPEDANCE AND MAGNETO-DIELECTRIC SUBSTRATES FOR SMALL ANTENNA DESIGNS

The growing number of wireless applications has presented RF engineers with a continuing demand for low-cost, power-efficient, and small-size system designs. Depending on the application at hand and required system characteristics, such as data rate, environment, range, etc., the system parameters, such as operating frequency, transmitter power, and modulation scheme, may vary widely. However, independent of the application, compactness, wide bandwidth, high efficiency, ease of fabrication and integration, and low cost are always sought in wireless systems. One of the most important components of wireless systems is their antenna. The substrate of the antenna has a significant role in successfully providing the above engineering requirements. In this section, three novel substrates—namely, reactive impedance, layered magneto-dielectric, and embedded-circuit metasubstrates—are presented, and their advantages and challenges in the design of small antennas with improved bandwidth performance are addressed.

Reactive Impedance Surface

Design of antenna elements with significant front-to-back radiation ratio is usually accomplished through the use of metal-backed substrates.⁶⁹ However, printed antennas on metal-backed substrates have limited bandwidth and efficiency. As demonstrated earlier, this problem stems from the fact that the radiated field from the image of the antenna's electric current, which is placed in close proximity and parallel to a PEC, tends to cancel out the radiated field from the antenna current itself. In this case, matching the antenna input impedance is rather difficult, and if a matching condition can be achieved, it would be over a relatively narrow bandwidth. To circumvent this difficulty, a reactive impedance surface (RIS), as proposed in Mosallaei and Sarabandi,²⁹ can be used for the antenna substrate. The RIS has three major features:

- It provides a total reflection power that enhances the antenna front-to-back ratio.
- The image of a point source located above the RIS is a spatially distributed current element that has the minimum interaction with the point source. This has the significant advantage of reducing the mutual coupling between the antenna and its substrate, resulting in the impedance bandwidth enhancement. Mutual coupling F between an infinitesimal dipole located at $0.02\lambda_0$ above the RIS and its image as a function of the normalized impedance ν/η_0 is demonstrated in Figure 34-17. It shows the minimum coupling occurs for a surface impedance of $\nu = 0.33\eta_0$, an impedance between the PEC and PMC behaviors, as pointed out before.
- RIS has the ability to store magnetic (or electric) energy that can be properly used to compensate for the near-field electric (or magnetic) energy of the radiating structure resulting in the antenna size reduction.

To realize an RIS with surface impedance $\eta = j\nu$, a periodic configuration of small-size patch elements printed on a dielectric material backed by a PEC can be used (see Figure 34-18a). The gap capacitances between the patches provide an equivalent capacitor that is in parallel with an inductor obtained from the PEC after the distance d through the dielectric material. A parallel LC circuit offers a reactive impedance behavior satisfying the required condition. The FDTD is applied to demonstrate the surface impedance property of the RIS and the results for normal and oblique incident waves are plotted in Figure 34-18b. Since the dielectric constant of substrate is relatively large,

FIGURE 34-17 Mutual coupling between an infinitesimal dipole, located above the RIS, and its image: (a) amplitude and (b) phase (after Mosallaei and Sarabandi²⁹ © IEEE 2004)

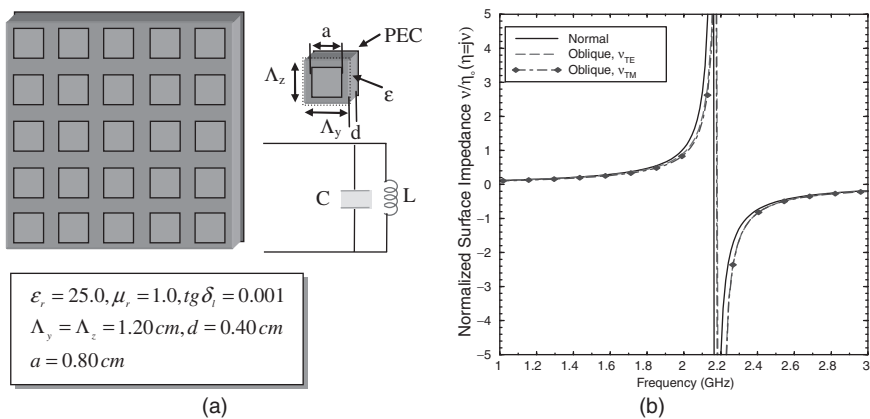

FIGURE 34-18 An RIS constructed from the periodic array of patches printed on a dielectric material backed by PEC: (a) the geometry and its equivalent circuit model and (b) normalized surface impedance (after Mosallaei and Sarabandi²⁹ © IEEE 2004)

according to Snell's law, the transmission angle is almost independent of the incident angle. As a result, the surface performance is almost insensitive to the incident angle (see Figure 34-18b).

It must be mentioned that in the proposed design, no connecting vias between the patch elements and ground plane are constructed. In fact, the vias have nothing to do with the reflection phase and impedance performance of the structure. The major application of vias is when undesirable surface waves can propagate through the substrate, where in this case the vias can be used to successfully forbid the propagation of these waves. This has been clearly demonstrated in Section 34.4.

Figure 34-19a shows the geometry of a patch antenna printed on a relatively low dielectric material with $\epsilon_r = 6$ and located above the RIS substrate. The FDTD is applied to characterize the structure, and the return loss is determined in Figure 34-19b, where a resonant frequency of $f_0 = 1.86 \text{ GHz}$ is obtained. The inductive property of RIS below the resonant frequency is properly combined with the capacitive behavior of patch in this spectral range and successfully shifts down the resonance frequency of antenna, resulting in the antenna

FIGURE 34-19 (a) Patch antenna printed on RIS and (b) its return loss (after Mosallaei and Sarabandi²⁹ © IEEE 2004)

miniaturization by a factor of about $5(\lambda_0/10)$ antenna size). In addition, since the RIS has a very small coupling with the antenna, a relatively wide bandwidth of about $BW = 5.0\%$ is achieved. For comparison, the performance of the patch printed on a dielectric material with $\epsilon_r = 21.0$ (providing the same resonant frequency) and thickness $t = 0.2$ cm is also plotted in Figure 34-19b. Patch radiator printed on the conventional substrate provides a very narrow bandwidth of about $BW = 0.63\%$. A thicker conventional dielectric substrate may provide a wider bandwidth; however, the impedance matching is more difficult.

Fabrication of the patch antenna printed over the RIS substrate is illustrated in Figure 34-20. Two independent layers are fabricated separately on high-quality ceramic substrates. The dielectric material used for the patch antenna substrate is Trans-Tech D-6 magnesium silicate ($\epsilon_r = 6$), commonly known as Forsterite. The RIS substrate is made using Trans-Tech MCT-25 magnesium calcium titanate composition ($\epsilon_r = 25$). Using a thick film silver paste and Trans-Tech's screen printing process, the array of square patches, corresponding metal backing, and patch are generated. Both substrates are heat treated to form an intimate bond of the silver to the dielectric material. This intermediary stage is diagrammed in Figure 34-20a. Using a two-part, low-loss dielectric adhesive, the substrates are assembled in a fixture to ensure alignment. The return loss of the fabricated patch antenna is measured and plotted in Figure 34-21a. The antenna resonance is found to be at $f_0 = 1.92$ GHz and it exhibits an impedance match with better than -25 -dB return loss. The measured relative bandwidth is $BW = 6.71\%$. The radiation patterns are measured in the anechoic chamber of the University of Michigan Radiation Laboratory and are shown in Figure 34-21b. The gain and front-to-back ratio are, respectively, measured to be $G = 4.5$ dBi and 5.6 dB. This measured gain corresponds to an excellent radiation efficiency of $\epsilon_r = 90\%$. To our knowledge, this is the highest reported gain and bandwidth for such a small planar antenna.

Magneto-Dielectric Substrate

In this section, the design of a layered magneto-dielectric substrate for antenna miniaturization and bandwidth enhancement is presented. A common approach for antenna miniaturizing is to print the radiator on a high-permittivity substrate. However, the strong electric energy stored inside the high dielectric substrate beneath the patch increases the radiation quality factor of antenna (Q) resulting in a narrow impedance bandwidth. To overcome this problem, one can use a magneto-dielectric material with moderate values of μ_r and ϵ_r .

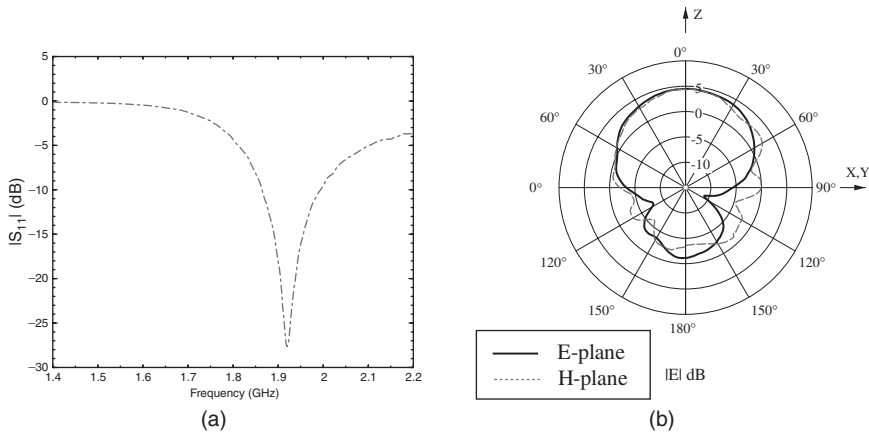

FIGURE 34-21 (a) Measured return loss and (b) radiation patterns of the patch antenna fabricated over the RIS substrate (after Mosallaei and Sarabandi²⁹ © IEEE 2004)

that provides the same miniaturization factor $n = \sqrt{\mu_r \epsilon_r}$, while a wider bandwidth can be achieved.⁷⁰ It has been shown by Hansen and Burke⁷¹ that the zero-order bandwidth for an antenna over a magneto-dielectric substrate with thickness t can be approximated by

$$BW \approx \frac{96\sqrt{\mu_r/\epsilon_r} t/\lambda_0}{\sqrt{2} [4 + 17\sqrt{\mu_r \epsilon_r}]} \tag{34-3}$$

Thus for a given miniaturization factor (constant $\sqrt{\mu_r \epsilon_r}$), the antenna bandwidth can be enhanced by increasing μ_r/ϵ_r ($\mu_r > \epsilon_r$). Figure 34-22a shows a patch antenna with size 10×8 cm printed on a four-layer dielectric and hexaferrite materials with thickness 2 cm. The size of the ground plane is 20×20 cm. The hexaferrite is a Z-type hexagonal material fabricated in Trans-Tech. It has the permeability shown in Figure 34-22b. The dielectric material has permittivity $\epsilon_r = 2.2$ and loss tangent $tg\delta_l = 0.001$. Notice that to offer a low-loss radiation performance, the antenna must operate away from the material resonant frequency.

FIGURE 34-22 Patch antenna printed on four-layer dielectric and hexaferrite substrate: (a) the geometry and (b) hexaferrite performance (after Mosallaei and Sarabandi⁷⁰ © IEEE 2004)

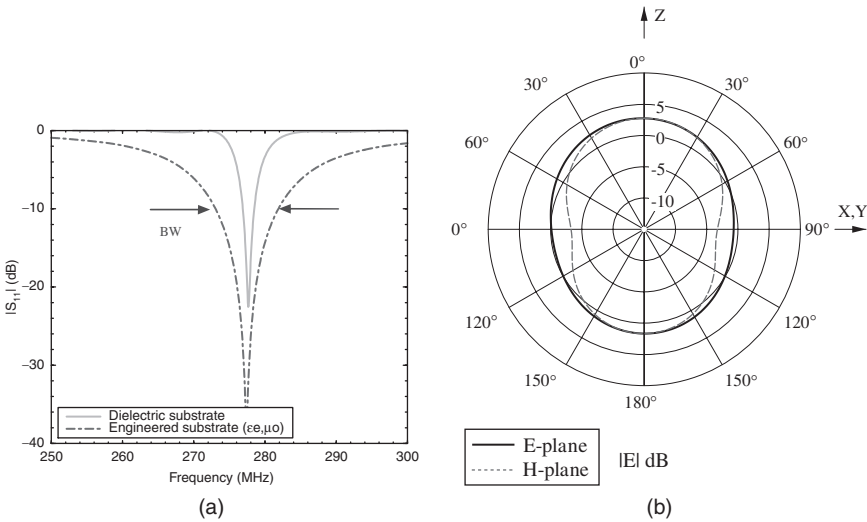

FIGURE 34-23 The performance of patch antenna printed on the magneto-dielectric substrate: (a) return loss and (b) radiation patterns (after Mosallaei and Sarabandi⁷⁰ © IEEE 2004)

As discussed above, the larger μ_r/ϵ_r provides the larger bandwidth. The layered design allows us to effectively accomplish a large μ_r/ϵ_{er} , although the hexaferrite itself has almost the same permittivity and permeability below the resonance. Since the patch antenna supports a dominant TEM wave with electric and magnetic fields polarized vertically and horizontally, respectively, they experience the effective dielectric and magnetic materials of $\epsilon_{er} = 3.84 - j0.004$ and $\mu_{er} = 8.61 - j0.16$.⁷⁰ This provides a miniaturization factor greater than 5 with considerably enhanced antenna bandwidth. The FDTD is applied to obtain the return loss and radiation patterns of antenna, as shown in Figure 34-23. The antenna resonance is at $f_0 = 277$ MHz and it provides a wide bandwidth of about $BW = 3.2\%$. The size of the antenna is around $0.09\lambda_0$ with a miniaturization factor of 5.4. The directivity of the antenna is $D_0 = 2.9$ dB and it has a front-to-back ratio 1.3 dB (ground plane size is $0.18\lambda_0 \times 0.18\lambda_0$). The calculated antenna efficiency is about $e_r = 67\%$. Notice that to achieve the same miniaturization factor utilizing only a dielectric material ($\mu_r = 1$) one must use $\epsilon_r = 23.7$. This reduces the bandwidth to about $BW = 0.5\%$ as shown in Figure 34-23a. The efficiency in this case for a dielectric loss tangent of 0.001 is about $e_r = 64\%$. Therefore, utilizing the magneto-dielectric substrate, one can offer a miniaturized wideband planar antenna with relatively high efficiency. The antenna bandwidth for the proposed magneto-dielectric substrate is about six times higher than that of the dielectric substrate. However, the major challenge is to practically achieve a low-loss magnetic material at any frequency of interest (e.g., GHz range).

Embedded-Circuit Metasubstrate

A metasubstrate constructed from loop circuits embedded in a low dielectric host medium can realize a magneto-dielectric substrate at any frequency of interest.⁷²⁻⁷⁵ Figure 34-24a shows the geometry of a periodic configuration of loop circuits. The building block unit cell of the structure is constructed from a metallic loop terminated to a large capacitor, modeling a resonant LC circuit. The loops are very small in size realizing artificial material molecules. They are oriented along the y-direction to offer the desired effective permeability

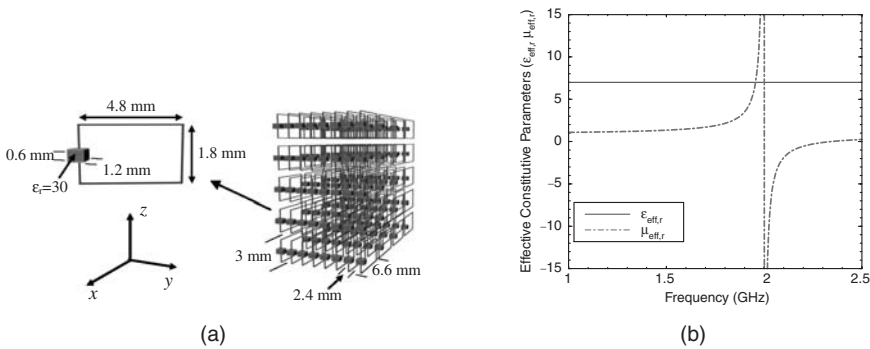

FIGURE 34-24 An embedded-circuit metamaterial with ϵ - μ parameters: (a) the geometry and (b) permeability performance (after H. Mosallaei and K. Sarabandi⁷⁵ © IEEE 2007)

in this direction. The gap coupling between the loops provides the required effective permittivity. The designed embedded-circuit medium has constant effective permittivity of $\epsilon_{\text{eff}} = 7.0\epsilon_0$, and the effective resonant permeability given by Mosallaei and Sarabandi⁷⁵ of

$$\mu_{\text{eff}} = \mu_0 \left(1 - (0.52)^2 \frac{1}{1 - (2.0)^2 / f^2 (\text{GHz})} \right) \quad (34-4)$$

These parameters are plotted in Figure 34-24b. Note that the resonant frequency of permeability, and thus the μ , can be properly tuned at any frequency of interest by simply changing the loop capacitors.

A metasubstrate is made from the embedded-circuit inclusions, as shown in Figure 34-25a. The operating mode of the patch antenna is a TM wave with electric and magnetic fields polarized along the z - and x -directions, respectively. Hence, the fields experience the effective parameters of the designed metamaterial. The FDTD is applied to characterize the antenna printed on the embedded-circuit metasubstrate, and the result for return loss is shown in Figure 34-25b. A resonant frequency of $f_0 = 1.74$ GHz (miniaturization factor of about 4) and bandwidth of about $BW = 1\%$ are determined. The patch antenna printed on a dielectric substrate with $\epsilon_r = 13.92$ (keeping the same resonant frequency) has bandwidth of about $BW = 0.6\%$. The metasubstrate offers a relatively wider bandwidth. It must be highlighted that the dispersion behavior of the permeability function plays an important role in degrading the impedance bandwidth performance. Both the dielectric and embedded-circuit substrates provide similar radiation patterns, as shown in Figure 34-26.

FIGURE 34-25 Patch antenna printed on an embedded-circuit metasubstrate: (a) the geometry and (b) return loss (after H. Mosallaei and K. Sarabandi⁷⁵ © IEEE 2007)

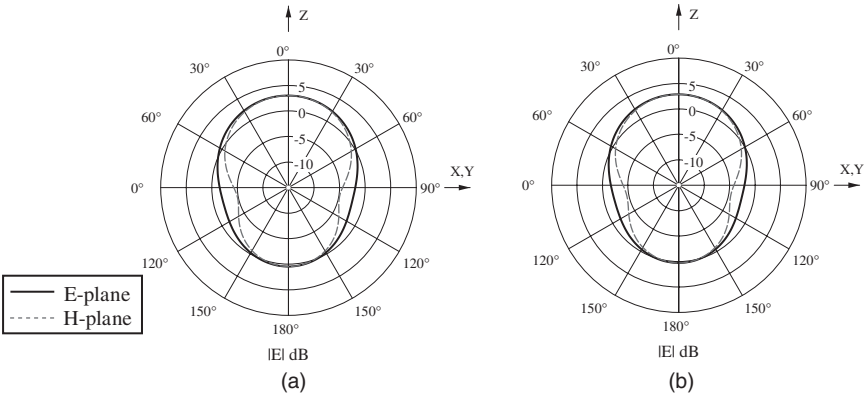

FIGURE 34-26 Radiation patterns of antenna printed on (a) dielectric and (b) metasubstrate (after H. Mosallaei and K. Sarabandi⁷⁵ © IEEE 2007)

To fabricate the metasubstrate, the first step is to realize an optimal design for the resonant loop circuits. A metallic loop terminated to an interdigitated capacitor seems like a reasonable choice for realizing LC inclusions. However, this is a nonoptimal use of the unit cell area because the interdigitation consumes too much valuable space inside the inductive loop and thereby inhibits optimal coupling to the incident magnetic field. It has been demonstrated in Buell et al⁷⁶ that a spiral loop is much more preferable because it uses less area to provide equivalent capacitance while simultaneously providing additional inductance, and hence additional permeability. A metasubstrate is fabricated utilizing the spiral inclusions illustrated in Figure 34-27.⁷⁶ It has a cell size of $\Delta x = \Delta z = 2$ cm, $\Delta y = 3.028$ mm (120 mils). The substrate is fabricated on 120-mil-thick Rogers RO-4003 dielectric. The spiral resonators are etched from 1/2 -oz-thick copper (0.017 mm) with a line-width (w) and spacing (s) of 0.127 mm (5 mils). In this design, $l_x = l_z = 16$ mm. To reduce substrate mass, 33/64-in-diameter air holes are drilled along the y -axis into the center of each spiral resonator cell. The final substrate mass is reduced by a factor of approximately 1/3, which is significant for a 2-cm-thick substrate. The substrate has a total size of $24 \times 24 \times 2$ cm and a weight of approximately 3.5 lb. It provides an effective permittivity of $\epsilon_{\text{reff}} = 13.13$,

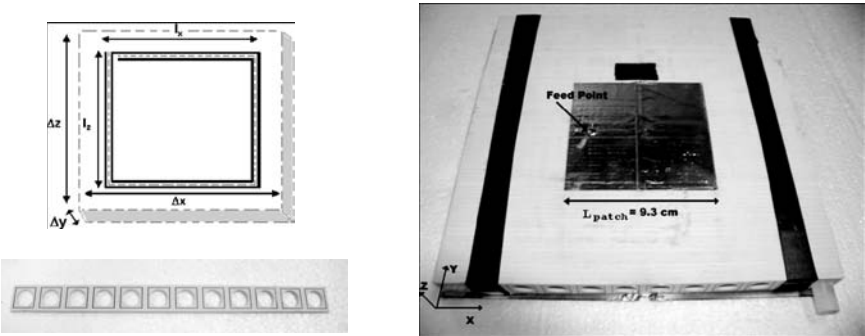

FIGURE 34-27 Fabricated metasubstrate utilizing spiral loop circuits (after Buell et al⁷⁶ © IEEE 2006)

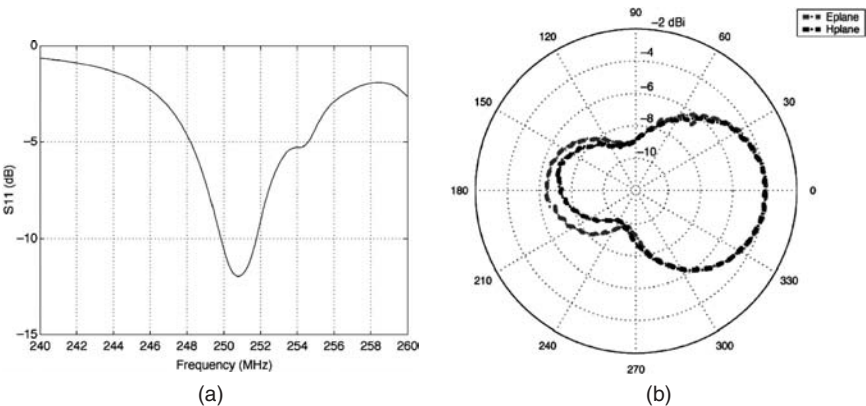

FIGURE 34-28 (a) Measured return loss and (b) radiation patterns of the patch antenna printed on the fabricated metasubstrate (after Buell et al⁷⁶ © IEEE 2006)

and an effective permeability with resonant frequency obtained around 285 MHz. Although here a design for the operation in UHF band is presented, the metamaterial unit cell can be properly redesigned for operation at any frequency of interest.

A probe-fed microstrip patch antenna resonant at 250 MHz is built on the meta-substrate (see Figure 34-27). To resonant at 250 MHz, the patch dimensions are found to be 9.3×9.3 cm. The measured return loss and radiation patterns are shown in Figure 34-28. A miniaturization factor of about 6.4 and efficiency around $e_r = 20\%$ are measured.

A better efficiency can be achieved if a thicker metallization is used. This will improve the magnetic loss tangent by a factor of 2. An additional source of loss is the dielectric loss tangent of the host dielectric material. Decreasing the host material dielectric loss tangent will significantly improve the efficiency of the dielectric medium, but not as strongly as improvements to the metallization would. To estimate the impact of changes in material loss tangent on antenna efficiency, the performance of a 250-MHz patch printed on a substrate with material parameters of $\epsilon_r = 9.8$, $\mu_r = 3.1$, and $\tan\delta = \tan\delta_e = \tan\delta_m$ is simulated in Figure 34-29. Obviously, the better material loss offers the better antenna radiation efficiency.

FIGURE 34-29 Radiation efficiency of a patch antenna at 250 MHz versus substrate material loss tangent on modeled metamaterial substrate (after Buell et al⁷⁶ © IEEE 2006)

In summary, it must be mentioned that although metasurfaces and metasubstrates theoretically present promising advantages; in practice, achieving low-loss wideband metamaterial would be a challenge. It is anticipated that the development of all-dielectric metamaterials to address some of these engineering concerns might help.

35.1 INTRODUCTION

This chapter gives an overview of the development history, key design methodologies, bandwidth issues, and applications for the reflectarray antenna, in particular the printed reflectarray.

The reflectarray is an antenna consisting of either a flat or slightly curved reflecting surface and an illuminating feed, as shown in Figure 35-1. On the reflecting surface, there are many isolated elements (e.g. open-ended waveguides, printed microstrip patches, dipoles, or rings) without any power-division transmission lines. The feed antenna spatially illuminates these isolated elements, which are predesigned to re-radiate and scatter the incident field with electrical phases that are required to form a planar phase front in the far-field distance. This operation is similar in concept to the use of a parabolic reflector that utilizes its unique curvature to reflect and form a planar phase front when a feed is placed at its focal point. Thus the term “flat reflector” is sometimes used to describe the reflectarray, which utilizes both technologies of parabolic reflector and array. As shown in Figure 35-2, there are several methods for reflectarray elements to achieve a planar phase front. For example, one is to use identical microstrip patches with different-length phase delay lines attached so that they can compensate for the phase delays over the different paths from the illuminating feed. Another is to use variable-size patches, dipoles, or rings so that elements can have different scattering impedances and, thus, different phases to compensate for the different feedpath delays. With the third method, for circular polarization only, the reflectarray has all identical circularly polarized elements but with different angular rotations to compensate for the feedpath length differences.

Reflectarrays using printed microstrip elements have been developed to achieve low reflecting surface profile, small antenna mass, and low manufacturing cost. These reflectarrays combine some of the salient features of the traditional parabolic reflector antenna and the microstrip array technology. Similar to a parabolic reflector, the reflectarray can achieve very good efficiency (> 50 percent) for a very large aperture since no power divider is needed and thus very little resistive insertion loss is encountered here. On the other hand, very similar to an array antenna, the reflectarray can have its main beam designed to tilt at a large angle (> 50°) from its broadside direction. Low-loss electronic phase shifters can be implanted into the elements for wide-angle electronic beam scanning. With this beam scanning capability

FIGURE 35-1 Configuration of a reflectarray antenna

FIGURE 35-2 Various reflectarray elements: (a) identical patches with variable-length phase delay lines, (b) variable-size dipoles or loops, (c) variable-size patches, and (d) variable angular rotations

of the reflectarray, the complicated high-loss beamforming network and high-cost transmit/receive (T/R) amplifier modules of a conventional phased array are no longer needed.

One significant advantage of the printed reflectarray is that, when a large aperture (e.g. 10-m size) spacecraft antenna requires a deployment mechanism, the flat structure of the reflectarray allows a much simpler and more reliable folding or inflation mechanism to be accomplished than is possible with a specifically curved surface of a parabolic reflector. The flat reflecting surface of the reflectarray also lends itself to flush mounting onto an existing flat structure without adding a significant amount of mass and volume to the overall system structure. A reflectarray with hundreds or thousands of elements, in the form of a printed microstrip antenna, can be fabricated with a simple and low-cost etching process, especially when produced in large quantities. Another major feature of this antenna is that, with a large number of elements in a reflectarray having elemental phase adjustment capability, it can achieve a very accurate contour beam shape with a phase synthesis technique.

With all the above capabilities, there is one distinct disadvantage associated with the reflectarray antenna: its inherent narrow bandwidth, which generally cannot exceed much beyond 10 percent depending on its element design, aperture size, focal length, etc. This narrow bandwidth behavior will be discussed further in a later section. Although the reflectarray has narrow bandwidth, due to its multitude of capabilities, the development, research, and application of the printed reflectarray antenna will continue throughout this century and beyond.

35.2 REVIEW OF DEVELOPMENT HISTORY

Although the reflectarray antenna has not been widely exposed to the antenna community until recently, it was invented more than 40 years ago. Since then, many interesting reflectarray technologies have been developed. This section briefly reviews the development of

this antenna technology throughout the past several decades. This review will not only inform a reader about this technology's evolution, but also may lead him or her, by combining old thoughts with new technologies, to other new discoveries.

Waveguide Reflectarray in the 1960s

The reflectarray antenna concept was first conceived in the early 1960s.¹ Either open- or short-ended waveguide elements with variable-length waveguides, as illustrated in Figure 35-3, were used to demonstrate the capability of achieving co-phased reradiated far-field beams. Because most wireless operations during this early time were done at relatively low microwave frequencies, the large-waveguide reflectarrays resulted in very bulky and heavy antennas, and thus this antenna concept was not pursued until more than ten years later. In addition, the efficiencies of these reflectarrays were not studied and optimized.

Spiralphase Reflectarray in the 1970s

In the mid 1970s, a very clever concept of "spiraphase" reflectarray was developed,² where switching diodes, as illustrated in Figure 35-4, were used in a four-arm spiral or dipole element of a circularly polarized reflectarray to electronically scan its main beam to large angles from the broadside direction. This is possible because, by angularly rotating a circularly polarized radiating element, its propagating electrical phase will also change by an appropriate amount proportional to the amount of rotation. However, due to the thick spiral cavity (quarter-wavelength depth) and large electronic components, the spiraphase reflectarray was still relatively bulky and heavy. Its aperture efficiency was still relatively poor. Thus, no continued development effort was followed. It should be noted here that, in order to have good efficiency for the reflectarray, the intricate relations between the element beamwidth, element spacing, and focal-length/diameter (f/D) ratio must be well designed; otherwise, a large backscattered component field or a mismatched surface impedance would result.

FIGURE 35-3 Conceptual drawing of the very early reflectarray using open-ended waveguides as elements

FIGURE 35-4 Reflectarray using a four-arm spiral element with switching diodes at center to achieve a 2-bit phase-shift system for circular polarization

Microstrip Reflectarray in the 1980s

With the introduction of printable microstrip antennas, the technologies of reflectarray and microstrip radiators were combined, a typical configuration of which is illustrated in Figure 35-5. The first mention of using microstrip elements for reflectarray³ was in 1978. During the same year, the first attempt to analyze the microstrip reflectarray element using the infinite array approach was carried out.⁴ Since then, various printed microstrip reflectarray antennas were developed in the late 1980s and early 1990s for the purpose of achieving reduced antenna size and mass. These printed reflectarrays came in various forms, as shown in Figure 35-2, and all had flat, low-profile, low-mass reflecting surfaces. The ones that used identical patch elements with different-length phase delay lines⁵⁻¹⁰ had their elements arranged similar to those shown in Figure 35-2a. The phase delay lines, having lengths on the order of half-wavelength long or less, were used to compensate for the phase

FIGURE 35-5 Microstrip reflectarray with identical patches but different-length phase delay lines

differences of different path lengths from the illuminating feed. The second approach, shown in Figure 35-2*b*, used elements that are made of printed dipoles with variable dipole lengths.¹¹ Different dipole lengths will yield different scattering impedances, which then provide the different phases needed to compensate for the different path-length delays. Similarly, microstrip patches with variable patch sizes,¹² shown in Figure 35-2*c*, were also developed. The concept of using circularly polarized microstrip patches with identical size but variable angular rotations,^{13,14} shown in Figure 35-2*d*, to form a co-phased far-field reflectarray beam was conceived and developed.

Recent Developments

In addition to the various reflectarray elements shown in Figure 35-2, several other reflectarray or equivalent developments during the 1990s are worth mentioning here. Printed variable-length dipole elements, shown in Figure 35-6, were used to form a frequency-scanned grating-reflector antenna with an offset feed.¹⁵ Printed annular rings of variable diameters arranged in Fresnel Zone configuration, as shown in Figure 35-7, were also used to focus the beam.¹⁶

In the 1996 Phased Array Conference, a 94-GHz monolithic reflectarray¹⁷ fabricated in a single wafer, using 1-bit PIN diode phase shifters, was reported to achieve wide-angle ($\pm 45^\circ$) electronic beam scanning. In the same conference, a 35-GHz reflectarray, using waveguide/dielectric elements with 3-bit ferrite phase shifters,¹⁸ was also reported to achieve $\pm 25^\circ$ beam scanning. One proposed technique,¹³ although not yet developed, is worth mentioning here. By using the angular rotation technique with circularly polarized elements, as depicted in Figure 35-8, miniature or micro-machined motors could be placed under each element to achieve wide-angle beam scanning without the need of T/R modules and phase shifters. For application in the spacecraft area, a deployable and low-mass

FIGURE 35-6 Printed dipole frequency-scanning grating-reflector antenna

FIGURE 35-7 Printed Fresnel Zone antenna with variable-diameter annular rings

1-m-diameter inflatable reflectarray antenna¹⁹ at the X-band frequency was developed. Another unique spacecraft application of the reflectarray was conceived²⁰ and developed²¹ by using its many elements, with a numerical phase synthesis technique, to form a uniquely shaped contour beam.

From all the above developments, it can be seen that, at the end of the 20th century, the reflectarray antenna technology was becoming mature enough for possible applications throughout the microwave and millimeter-wave spectra.

FIGURE 35-8 Miniature micro-machined motors used to achieve beam scan by employing the angular rotation technique with CP elements

FIGURE 35-9 Multilayer reflectarray to achieve wider bandwidth

In the early 2000s, the development of reflectarray has mushroomed, and several performance improvement techniques are worth mentioning here. One uses multilayer stacked patches, as shown in Figure 35-9, to improve the reflectarray bandwidth from a few percent to more than 10 percent.²² As an extension to the 1-m X-band inflatable reflectarray mentioned above, a 3-m Ka-band inflatable reflectarray consisting of 200,000 elements was also developed,²³ which currently is the electrically largest reflectarray. An X-band amplifying reflectarray was developed²⁴ for each element of the reflectarray, as shown in Figure 35-10, to amplify the transmitted signal and, thus, achieve very high overall radiated power. To achieve

FIGURE 35-10 Unit-cell element of an X-band amplifying reflectarray

FIGURE 35-11 Folded reflectarray to achieve a more compact antenna profile

good antenna efficiency, the most critical segment of the reflectarray design is its elements. The element performance was optimized by using the technique of genetic algorithm.²⁵ The reflectarray using subreflector and array feed configuration to achieve fine beam scanning was also studied.²⁶ To combat the shortcoming of narrow bandwidth, dual-band multilayer reflectarrays using annular rings²⁷ and crossed dipoles²⁸ are also being developed. Another development that is worth mentioning here is a folded reflectarray configuration,²⁹ where two reflecting surfaces, as depicted in Figure 35-11, are used to reduce the overall antenna profile due to feed height of a conventional reflectarray.

35.3 ANALYSIS AND DESIGN PROCEDURES

The design and analysis of a reflectarray can be separated into four essential steps, which are separately discussed below.

Element Characterization

The most important and critical segment of the reflectarray design is its element characterization. If the element design is not optimized, the reflectarray will not scatter the signal from the feed effectively to form an efficient far-field beam. Its beamwidth must correlate correctly with the reflectarray's f/D ratio to accommodate all incident angles from the feed. Its phase change versus element change (patch size, delay line length, etc.) must be calibrated correctly. One of the most popular techniques for calibrating the phase is to use the infinite array approach^{12,30} to include local mutual coupling effect due to surrounding elements. It is not feasible for the current computer technology to have a complete rigorous solution to include all the mutual coupling effect of all different elements since the reflectarray generally consists of too many elements. The infinite array approach, which assumes all elements are identical, can be done by using the method of moments (MOM) technique^{12,30} or equivalently by using a finite difference time domain (FDTD) analysis on a unit cell of a single element.³¹ A mathematical waveguide simulator, which simulates the infinite array approach, can also be adapted by using the commercial software—HFSS (a finite element technique)—to achieve the element phase information.

All of these techniques are used to derive the phase-versus-element-change curve, which is generally an S -shaped curve with a nonlinear relationship, as illustrated in Figure 35-12.

FIGURE 35-12 A typical *S* curve of a reflectarray element phase change versus element change

The antenna designer should minimize the slope at the center of the curve so that the phase change will not be overly sensitive to the element change. If the curve is too steep, the element change or fabrication tolerance may become an issue, in particular at high microwave frequencies.

Phase Delay Calculation

The path lengths from the feed to all elements are all different, which leads to different phase delays. To compensate for these phase delays, the elements must have corresponding phase advancements designed according to a unique *S* curve similar to that shown in Figure 35-12. The following gives an example of how the compensating phase is calculated for each element of a reflectarray with a broadside-directed beam. The differential path length for each element is given as

$$\Delta L_{m,n} = L_{m,n} - L_{o,o} \quad (35-1)$$

where $L_{m,n}$ is the distance between the feed and the m th element, which can be obtained by a simple geometry calculation. $L_{o,o}$ is the distance between the feed and a reference point on the reflectarray surface, e.g. the center point. $\Delta L_{m,n}$ is thus the differential feedpath length for the m th element. To achieve a collimated radiation, the phase advancement $\Delta\Phi_{mn}$ needed for the m th element is given by

$$\Delta\Phi_{mn} \text{ in degrees} = [\Delta L_{m,n} / \lambda_o - \text{integer of } (\Delta L_{m,n} / \lambda_o)] \times 360. \quad (35-2)$$

The above indicates that the compensating phase can be repeated every 360° and that the portion that is an integer multiple of a wavelength, or 360° , can be deleted.

Pattern Calculation

With all elements' compensating phases known, the far-field radiation patterns can be calculated by the conventional array theory, where the radiation of all elements is summed

together as follows. Consider a planar array consisting of $M \times N$ elements that are nonuniformly illuminated by a low-gain feed at position vector \vec{r}_f . Let the desired beam direction be specified by unit vector \hat{u}_o . Then the far-field pattern of the reflectarray in the \hat{u} direction will be of the form

$$E(\hat{u}) = \sum_{m=1}^M \sum_{n=1}^N F(\vec{r}_{mn} \bullet \vec{r}_f) \cdot A(\vec{r}_{mn} \bullet \hat{u}_o) \cdot A(\hat{u} \bullet \hat{u}_o) \cdot \exp[jk(|\vec{r}_{mn} - \vec{r}_f| + \vec{r}_{mn} \bullet \hat{u}) + j\alpha_{mn}] \quad (35-3)$$

where F is the feed pattern function, A is the reflectarray element pattern function, \vec{r}_{mn} is the position vector of the m nth element, and α_{mn} is the required compensating phase of the m nth element calculated by Eq. 35-2. $\cos^q \theta$ factor is used for both F and A functions with no azimuth (ϕ) dependence.

Geometry Design

To determine the geometry of a reflectarray is basically to determine its f/D ratio, which is governed by its desired aperture efficiency. The aperture efficiency (η_a) can be defined as the product of the illumination (η_i) and spillover (η_s) efficiencies: $\eta_a = \eta_i \times \eta_s$. By integrating the pattern function of Eq. 35-3, the illumination efficiency for a center-fed reflectarray can be obtained in a close form³² as given by

$$\eta_i = \frac{\left[\left((1 + \cos^{q+1} \theta_e) / (q+1) \right) + \left((1 - \cos^q \theta_e) / q \right) \right]^2}{2 \tan^2 \theta_e \left[(1 - \cos^{2q+1} \theta_e) / (2q+1) \right]} \quad (35-4)$$

and the spillover efficiency is given by

$$\eta_s = 1 - \cos^{2q+1} \theta_e \quad (35-5)$$

where q is the exponent of the feed pattern function represented by $\cos^q \theta$, and θ_e is half of the subtend angle from the feed to the reflectarray aperture. The reflectarray element is approximated by a cosine function. Equations 35-4 and 35-5 are calculated by assuming a circular aperture only for the demonstration of the design procedures. Similar closed-form equations can be easily obtained for square, rectangular, or elliptical apertures by performing proper integrations. To give an example of how Equations 35-4 and 35-5 can be utilized to optimize a reflectarray design, Figure 35-13 shows the calculated curve of spillover and illumination efficiencies versus the feed pattern factor q (feed beamwidth) for a 0.5-m 32-GHz reflectarray with a fixed f/D ratio of 1.0 ($\theta_e = 26.6^\circ$). It demonstrates that the maximum aperture efficiency is achieved at $q = 10.5$ or when the feed has a -3 -dB beamwidth of 29° . Another curve, shown in Figure 35-14, gives aperture efficiency as a function of f/D ratio for the same 0.5-m 32-GHz reflectarray when the feed beamwidth is fixed at 33.4° with $q = 8$. In this case, the maximum aperture efficiency is achieved when the f/D ratio is 0.87. It can be seen that curves derived from Eqs. 35-4 and 35-5 are essential in obtaining an optimum efficiency design.

The above discussion has been limited to center-fed reflectarray. Offset-fed reflectarray can also be optimally designed by using equations similar to Eqs. 35-4 and 35-5.

FIGURE 35-13 Spillover and illumination efficiencies versus feed pattern shape

35.4 BANDWIDTH ISSUES

The bandwidth performance of a reflectarray¹³ is no match to that of a parabolic reflector, where, theoretically, infinite bandwidth exists. For a printed microstrip reflectarray, its bandwidth is primarily limited by two factors. One is the narrow bandwidth of the microstrip patch elements on the reflectarray surface, and the other is the differential spatial phase delay.

FIGURE 35-14 Aperture efficiency versus f/D ratio

Limit by Element Bandwidth

The microstrip patch element generally has a bandwidth of about 3 to 5 percent. To achieve wider bandwidth for a conventional microstrip array, techniques such as using thick substrate for the patch, stacking multiple patches,²² and using sequentially rotated subarray elements have been employed. Bandwidths of more than 15 percent have been reported.

Limit by Differential Spatial Delay

The second reflectarray limiting factor, the differential spatial phase delay, can be best explained by referring to Figure 35-15, where the differential spatial phase delay, ΔS , is the phase difference between the two paths S1 and S2 from the feed to the reflectarray elements. This ΔS can be many multiples of the wavelength (λ) at the center operating frequency. It can be expressed as $\Delta S = (N + d)\lambda$ where N is an integer and d is a fractional number of a free-space wavelength λ . At each element location, d is compensated by an appropriate phase delay achieved by the reflectarray element design (achieved by variable patch size, variable phase delay line length, etc.). As frequency changes, the factor $(N + d)\lambda$ becomes $(N + d)(\lambda + \Delta\lambda)$. Since the design and the compensating phase for each element are fixed for the center frequency, a frequency excursion error will occur in the reradiated phase front. The amount of phase change in each path when compared to a reference path, say S1, is $(N + d)\Delta\lambda$, which can be a significant portion of a wavelength (360°).

To reduce the amount of frequency excursion error, the integer number N must be reduced. There are several methods to reduce N . One is to design the reflectarray with a larger f/D ratio and hence to minimize the difference between paths S1 and S2. The second way is simply to avoid the use of a reflectarray with a large electrical diameter. The effects of f/D ratio and diameter on bandwidth performance were given previously in Figures 35-13 and 35-14. The third method to reduce frequency excursion error is to use time delay lines or partial time delay lines instead of the phase delays. In other words, when using the phase delay line technique (not the variable patch size technique), instead of using $d\Delta\lambda$ for the delay line length, $(N + d)\Delta\lambda$ could be used for the delay line. Certainly, additional line insertion loss and needed real estate for the lines are issues to be encountered.

Another method to increase the bandwidth is to use, instead of a complete flat reflectarray surface, a concavely curved reflectarray with piecewise flat surfaces. This curved

FIGURE 35-15 Differential spatial phase delay of reflectarray

reflectarray will continue to have advantages over a completely curved parabolic reflector; for example, its beam is able to be scanned to large angles with a phase shifter inserted into each element, and, for a space-deployable antenna, the piecewise flat surfaces in some cases are more easily folded into a smaller stowed volume. To mitigate the bandwidth problem, a recent technique of using multilayer stacked-patch elements²² not only has increased the element bandwidth but also has reduced the effect of differential spatial phase delay. As a net result, the bandwidth has increased from a few percent to more than 10 percent. Multiband techniques can also be applied to the reflectarray. Recently, two dual-band techniques have been developed for the X- and Ka-band frequencies. One uses double-layer membranes with two different-size rings and variable angular rotations,²⁷ and the other also uses a double-layer approach with X-band crossed dipoles over Ka-band patches.²⁸ To summarize, although the narrow bandwidth characteristic is the primary shortcoming of a reflectarray, there are several techniques that can be employed to alleviate the problem associated with the bandwidth issue.

35.5 APPLICATIONS AND RECENT DEVELOPMENTS

In addition to the possible reflectarray applications mentioned in the introduction and review sections, it is worthwhile here to present some details of several important applications and recent developments.

Inflatable Reflectarray

A Ka-band circularly polarized inflatable reflectarray²³ with a 3-m-diameter aperture was developed by the Jet Propulsion Laboratory (JPL) and ILC Dover, Inc. for NASA's future spacecraft communication antenna application. As shown in Figure 35-16, the antenna

FIGURE 35-16 A 3-m Ka-band inflatable reflectarray (the shining structure in front of the aperture is the surface flatness measurement device). The second photo shows the expanded view of reflectarray elements on thin membrane.

uses a torus-shaped inflatable tube to support and tension a 3-m-thin membrane reflectarray surface. This circularly polarized reflectarray, having approximately 200,000 elements using the variable angular rotation technique,^{13,14} is considered to be electrically the largest reflectarray ever built. It is much easier for the reflectarray, having a “natural” flat surface, to maintain its required surface tolerance (0.3-mm rms in this case) by the inflatable structure than a “nonnatural” parabolic surface; in particular, for long space flight. This inflatable antenna was later improved to equip it with rigidizable inflatable tubes^{23,33} in order to survive the hazardous space environment, such as bombardment by space debris and strenuous thermal effect. This reflectarray achieved an aperture efficiency of 30 percent with room for improvement and excellent far-field pattern shape with average sidelobe and cross-polarization levels below -40 dB, as shown in Figure 35-17.

Shaped Contour Beam

A second important development of the reflectarray is the achievement of a shaped contour beam by using phase synthesis technique. This reflectarray, shown in Figure 35-18, was developed by the University of Massachusetts²¹ for a commercial application to provide Earth contour beam coverage. A typical calculated contour beam of this antenna, by using phase synthesis technique, is given in Figure 35-19. Since a reflectarray generally has more than thousands of elements, it thus has many degrees of freedom in design to provide an accurate and uniquely required contour beam. However, this capability of beam shaping is limited by its frequency bandwidth. A more recent reflectarray development³⁴ using triple-layer stacked patches achieved a specified contour beam shape within a relatively wide bandwidth of 10 percent.

Dual-band Cassgrain Reflectarray

A third important development is a dual-frequency reflectarray, where the two frequencies are widely separated, such as the X- and Ka-bands. The developed prototype antenna,

FIGURE 35-17 Measured radiation pattern of the 3-meter Ka-band inflatable reflectarray

FIGURE 35-18 Ku-band reflectarray with shaped contour beam capability (*Courtesy of Professor Dave Pozar, Univ. of Massachusetts*)

shown in Figures 35-20 and 35-21, is circularly polarized and uses variable angularly rotated annular rings.^{14,27} It was developed by Texas A&M University for JPL/NASA's future space communication application. This antenna, with a Cassegrain offset feed and an aperture diameter of 0.75 m, uses a multilayer technique where the X-band annular rings

FIGURE 35-19 A measured contour beam plot of the reflectarray shown in Figure 35-18

FIGURE 35-20 X/Ka dual-band Cassegrain reflectarray antenna (0.75-m diameter) using annular ring elements

are placed above the Ka-band rings and serve as a frequency-selective surface to let the Ka-band signal pass through. The measured results indicate that there is very little impact on the X-band performance due to the presence of the Ka-band elements. The measured radiation patterns at the X-band and Ka-band frequencies are shown in Figures 35-22 and 35-23, respectively. These patterns show excellent behavior with relatively low sidelobe and low cross-polarization levels. However, the measured Ka-band gain of the dual-frequency dual-layer antenna is about 1.0 dB lower than the Ka-band-alone antenna. The Ka-band-alone reflectarray has a measured aperture efficiency of 50 percent, while the dual-frequency dual-layer antenna has a Ka-band efficiency of about 40 percent. In other words, the X-band annular rings did impact somewhat the Ka-band performance. Efforts need to be carried out in the future to minimize this impact.

FIGURE 35-22 Measured X-band radiation pattern of the X/Ka dual-band reflectarray

Foldable Piecewise-Flat Globally Curved Reflectarray

A recent development that is worth mentioning is a reflectarray having a rectangular aperture that is intended for NASA/JPL's Wide Swath Ocean Altimeter (WSOA) radar application. This reflectarray uses variable-size patches as elements. The required rectangular aperture,

FIGURE 35-23 Measured Ka-band radiation pattern of the X/Ka dual-band reflectarray

FIGURE 35-24 Piece-wise flat reflectarray for space application

as shown in Figure 35-24, consists of five flat subapertures that are connected together to form a curved reflectarray.³⁵ The curving of the long dimension of the rectangular surface is to minimize the incident angles from the feed for the end elements and, thus, to optimize the radiation efficiency for all elements. The radiation efficiency here indicates the measure of the amount of energy of each element that is reradiated in the desired main beam direction. The advantage of using reflectarray with flat subapertures is to allow mechanical folding of the flat panels into a compact structure for spacecraft launch-vehicle stowage. Test data indicates that this reflectarray is functioning properly with good radiation patterns and an aperture efficiency above 50 percent.

Beam Scanning Reflectarray

One of the key advantages of a reflectarray is that its elements can be implanted with low-loss phase shifters and achieve wide beam scanning without the use of a complicated beam-former (power divider) and expensive T/R amplifier modules. As mentioned in Section 35.2, in the mid 1990s a 94-GHz monolithic reflectarray¹⁷ fabricated in a single wafer, using 1-bit PIN diode phase shifters, achieved wide-angle ($\pm 45^\circ$) electronic beam scanning. Also, a 35-GHz reflectarray, using waveguide/dielectric elements with 3-bit ferrite phase shifters,¹⁸ was reported to achieve $\pm 25^\circ$ beam scanning. More recent developments in this area include ferroelectric thin-film phase shifters^{36,37} for reflectarray. Interest in ferroelectric thin-film circuits developed because of their high power-handling capability, negligible DC power consumption, small size, and potential for low cost. Current research effort is to reduce the phase shifter's relatively high insertion loss (from many decibels to 1 or 2 dB), in particular at the millimeter-wave frequency band.

Another development worth mentioning here is the use of a miniature motor to rotate each element of a circularly polarized reflectarray. This concept was proposed in 1995¹³ and has not been investigated in detail until recently, in which case two miniature motors with two annular-ring reflectarray elements were used in a waveguide simulator³⁸ as well as a 5×1 -element array³⁹ to demonstrate the beam scan.

A third recent important development is the use of the tunable varactor diode^{40,41,42} to control the phase change, as illustrated in Figure 35-25. The phase is analog controlled by its variable control voltage. It not only provides more precision phase but also minimizes the number of control lines when compared to the conventional quantized switched-line phase shifters. For instance, a tunable varactor diode only needs a single variable-voltage control to achieve a full 360° of phase variation, while a 3-bit switched line needs 12 control lines with 45° of quantization error. It is important to minimize the number of control/bias lines in a reflectarray system where generally a huge number of elements is involved.

35.6 SUMMARY

The reflectarray antenna technology has come a long way. However, its development and application had not been widely adapted until about a decade ago when the printable microstrip reflectarray was introduced. Except for its narrow bandwidth characteristic, the reflectarray has many advantages over a parabolic reflector antenna type. The main beam of a reflectarray can be designed to tilt to a large angle from its broadside direction. Phase shifters can be implanted into the elements for wide-angle electronic beam scanning. For large-aperture spacecraft antenna applications, the reflectarray's flat surface allows the antenna to be made into an inflatable structure with relative ease in maintaining its surface tolerance compared to a curved parabolic surface. Its flat surface also can be made of multiple flat panels for ease in folding into a more compact structure for launch vehicle stowage. Very accurate contour beam shape can be achieved with phase synthesis technique for Earth coverage application. Due to these multitudes of capabilities, the door has just opened for the development, research, and application of the printed reflectarray antennas. Major areas that need continuing improvement of the reflectarray performance are its bandwidth, radiation efficiency, and beam scanning capability.

Acknowledgment

Portions of the research activities described in this chapter were carried out by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration.

36.1 IMPACT ON ANTENNA DESIGN

Antenna engineering design has many interesting and surprising features, not least of which is its ability to reinvent itself if the demand arises. Such has been the impact of mobile communications on antenna design, resulting in unbelievably compact and densely packaged dipole-like handset antennas housed entirely within the mobile phone case itself.

The dipole and monopole were some of the first antennas developed and, together with fundamental electromagnetic theory, have been well established over the past century. Yet new versions of these generic radiators continue to be analyzed, simulated, developed, and even researched today as is evident from the research journals worldwide. Quite simply, product demand is the driving force for this seemingly endless creation of different physical realizations of what is essentially an antenna capable of giving a dipole-like radiation pattern.

While the vectorial radiation field of an antenna is uniquely defined by the antenna itself, this is not so for typical engineering radiation patterns specified as the modulus of the radiation field whereby phase information is not retained. Furthermore, this specification is often made even less restrictive by only stating limiting values of sidelobes and other pattern features, between which the measured pattern must lie. Bandwidth specifications are similarly pinned down with only a simple limiting level on the S_{11} response, hence little information is demanded about the shape of the bandpass characteristic itself. The nonuniqueness of such specifications thus leaves plenty of scope to recast the antenna in a very different form.

The dipole antenna family, and in fact most other types of antennas, can be reinvented in a different physical form to satisfy the demands of new equipment products. An outstanding example is the microstrip patch antenna, made possible with printed antenna technology. When compared with conventional monopoles and loop antennas, the printed version can be expected to have a somewhat lower radiation efficiency but it has opened the door to many innovative new products requiring a very low profile dipole-like radiator that is compatible with cost-cutting manufacturing processes.

The previous example not only illustrates how new and very different physical realizations can be developed with similar radiation pattern characteristics but also highlights the need for a system's design approach whereby the performance of individual components is not the main criterion but rather the satisfactory performance of the entire system. The deployment of a system approach has gradually become more evident in mobile handset antenna design over some two decades.

The initial thinking was to mount a conventional antenna on the mobile phone case itself, and early examples were physically large and included balanced fed dipoles, monopoles, and loops. The astronomical demand for mobile phones together with the pull of user preference has resulted in the present-day integral handset antenna. Seldom does one ask of the performance of the antennas in isolation where it is understood that the matching and radiation efficiency data may be less impressive than that of conventional antennas. What matters is how it all functions together as a system.

36.2 CELLULAR HANDSET ANTENNA DESIGN ISSUES

Without doubt, integral handset antenna design is very complicated and presents the designer with perhaps the most formidable antenna design criteria demanded by a product. There are numerous design issues for cellular operation that are summarized next, but the integration as a system further complicates matters, and many, if not most, of the design

issues are interrelated, thus there is a high degree of iteration in the design work. The requirements for a global roaming satcom handset antenna have different constraints and are considered separately in Section 36.9.

Antenna Electrical Size

What constitutes an electrically small antenna is well established and seminal contributions include Wheeler,¹ Chu,² and Collin and Rothschild.³ The radian sphere⁴ of radius a is defined as

$$a = \frac{\lambda}{2\pi} \quad (36-1)$$

where λ is the free-space wavelength. If an antenna's physical structure lies within this sphere, then electrically small antenna characteristics will be evident. The effect of shape and volume of the antenna structure has also been considered by Wheeler.¹

For a lossless antenna, the effects are (i) a high Q factor and hence small bandwidth, (ii) a small radiation resistance resulting in a low radiation efficiency, and (iii) likely greater antenna sensitivity to mechanical and electrical tolerances. When the antenna has intrinsic losses, the bandwidth is less narrow.

It is widely acknowledged⁵ that for diminishing a

$$Q \sim 1 / (ka)^3 \quad (36-2)$$

where $k = 2\pi/\lambda$. From an antenna engineering standpoint, the interest^{6,7} over many years has centered on realizing a small antenna in practice that lies on or exceeds the performance limits represented by the Q formula. This topic has been vigorously revisited recently^{7,8} with the upsurge of activity in small antenna design for both mobile and wireless applications.

For handset antennas, it is the lower bands that enforce antenna electrical size constraints. For instance, at 800 MHz, $a = 5.97$ cm and the dimensions of a typical handset are $1 \times 4 \times 10$ cm, so if the antenna has dimensions of $1 \times 2 \times 4$ cm, it lies within the radian sphere. At 1800 MHz, $a = 2.64$ cm, so the situation is less critical. An unknown factor is, of course, the extent to which a given handset antenna couples to the handset circuit components and battery, etc., because this will in effect increase the electrical size of the antenna.

Ground Plane Electrical Size Effects

When a monopole is mounted on a horizontal ground plane (GP) of finite extent, the dipole-like radiation patterns can be corrupted with a variety of pattern effects depending on the electrical size of the GP. An excellent theoretical illustration with measurements has been given⁹ showing the increase in pattern distortion as a function of reduced GP electrical size. The mobile handset GP is enforced mainly by the metallized assembly consisting of the circuit board and its components, which as mentioned above is typically 4×10 cm. Any plastic outer case will have little effect.

Neglecting hand effects, such a GP could act as an electromagnetic counterpoise to a 10-cm monopole mounted in the same plane as the GP at 750 MHz. Operation at a lower frequency is possible using a monopole version of the sleeve dipole¹⁰ to isolate the handset

case, but the resulting antenna has greater height and is not acceptable today where the antenna element is usually mounted on the GP itself. The GP extent in one direction is only 4 cm and some degree of radiation pattern perturbation is likely to be experienced at the lower mobile bands. Consequently, it is common practice in research papers and manufacturers' data sheets to show measured and/or simulated handset antenna radiation patterns with the antenna embedded on the GP.

There continues to be much interest in creating a stand-alone chip type antenna¹¹ that is immune to the proximity of the GP and its components. Another way of addressing the latter requirements concerns a balanced feed arrangement,¹² but since this concept requires two identical antennas in phase opposition, its application¹³ so far has been confined to the higher mobile bands due to size limitations.

Time Varying Pattern Effects

Cellular handset antennas have to function in a rich multipath propagation environment which allows the use of antennas with polarization properties that are not tightly specified. Hand and head movement, together with the angular movement of the handset, creates further time varying effects which, together with multipath effects, are mainly beyond the designer's control. At the lower mobile bands below 1 GHz, the antenna's constrained electrical size commits it to smoother dipole-like patterns with few nulls and thus time varying effects can be better tolerated than at progressively higher frequencies where additional pattern nulls appear. The situation is further assisted by the self-correcting adaptivity of speech communication.

Increasing Band Coverage

It is generally thought that phone users have an appetite for mobile phones having additional functions that can obtain wider news and sales information and provide more games and a host of other facilities like GPS and wireless links. Financial returns from such a multimedia operation are likely to be very significant but at the same time the cost of the mobile handset must be constrained.

Not surprisingly, handset manufacturers aim to achieve several bands from one central antenna not only to maintain cost levels but also because there is little available space to do otherwise. A multifunction antenna is now commonly the stated requirement, and antenna designers have responded with a variety of configurations that demonstrate design concepts and feasibility. Just how far this concept can be extended remains to be seen, but antennas with three bands have been demonstrated.¹⁴ It is evident that the multiband operation may require some trading of other performance parameters such as radiation efficiency and antenna input match levels. This will limit the number of bands that can eventually be obtained from a single antenna.

Radiation Efficiency

Whatever type of antenna is chosen to embed in the handset, the designer will strive to minimize the power lost to dissipation in the antenna itself. A measure of the losses is the antenna radiation efficiency η_a defined by

$$\eta_a = P_{\text{rad}} / (P_{\text{rad}} + P_{\text{loss}}) \quad (36-3)$$

where the radiated power is P_{rad} and the power dissipated in the antenna is P_{loss} . In practice the antenna is likely to need a matching network, and losses in the latter are expressed as a matching network efficiency η_m where

$$\eta_m = \eta_a Q_m / (Q_m + Q_a) \quad (36-4)$$

where Q_m = matching network Q factor and Q_a = antenna Q factor. The combined efficiency of the antenna and its matching network is then $\eta_a \eta_m$.¹⁵ Further losses are of course incurred when the antenna is embedded in the handset, due to coupling to handset components, and finally when operating with the hand and head present, which account for much of the additional power loss.

36.3 HELICAL WIRE ANTENNAS AND VARIANTS

The remarkable property of wire antennas, or indeed any form of linear metal conductors, is that the resonant frequency is mainly determined by the electrical length of the current path. As such, a wire monopole (or dipole) can be compacted into an electrically smaller size. The antenna bandwidth, however, is more affected and increases for compacted structures occupying a greater volume.

A common example where the wire monopole is partially wound into a coil at some location on the wire¹⁶ is shown in Figure 36-1*a*. For handset applications, a spiral coil of wire alone constitutes the antenna (see Figure 36-1*b*) and for small diameters is known as the normal mode helical antenna (NMHA). The device gives dipole radiation patterns when placed on an electrically large GP but has circularly polarized radiation characteristics when the spiral diameter exceeds about one wavelength. The bandwidth, radiation efficiency, and radiation resistance at resonance are significantly reduced but the latter can be restored by tapping into the spiral, as shown in Figure 36-1*c*, at the expense of a more complicated construction. There are a multitude of variations, and in Figure 36-1*d* a second spiral coil is wound in antiphase directly on top of the first spiral coil, creating a large bandwidth but very poor radiation efficiency. This is referred to as the double wound antenna.¹⁷ Figures 36-1*e* and *f* show zigzag-like versions and other designs that can be configured in fractal form or generated by genetic algorithms. Some performance details for spiral antenna devices are compared to those of a wire monopole in Table 36-1.

A compact manufactured NMHA is illustrated in Figure 36-2 where the conducting path is printed into a groove in the cylindrical plastic former to avoid the increased production cost of winding on a wire.

TABLE 36-1 Performance of Spiral-type Antennas Compared with Monopole Antenna

Antenna Type	Resonance (MHz)	Bandwidth (MHz)	Loss (dB)	Efficiency (%)	Normalized Size	Resistance (Ω)
Monopole	150	~20	~0	~100	1	25
NMHA	142	~1.5	1.04	81	0.22	5
Double wound	150	~9	7.8	16	0.18	21

FIGURE 36-1 (a) Coil loaded whip antenna; (b) NMHA; (c) NMHA with tapping connection for matching; (d) double wound spiral antenna; (e) and (f) zigzag antennas. (Figures 16-1a to 1d reproduced by permission of K. Fujimoto and J. R. James¹¹ © Artech House, Inc. 2001.)

FIGURE 36-2 Example of typical NMHA mounted on a handset case showing construction¹¹ (Courtesy of Nippon Antenna Co. Ltd.)

FIGURE 36-3 (a) Printed zigzag antennas printed on dielectric films¹¹ (Courtesy of Allgon); (b) The structure rolled into a cylindrical shape mounted on a plastic former with and without the cover in place

The zigzag antenna configurations have an outstanding manufacturing advantage over the spiral devices because they can be printed on thin dielectric films and then rolled into a cylindrical or other three-dimensional shape. Such assemblies have less size reduction than the spiral types but have attracted use both mounted on a handset case, as shown in Figure 36-3, and embedded within the handset interior as a planar structure. Two printed films designed for different resonant frequencies can also be connected in parallel to obtain a dual-band antenna, and this is more difficult to achieve with spiral conductors.

36.4 EVOLUTION OF THE PIFA AND ITS VARIANTS

The planar inverted F antenna (PIFA) has come into prominence due to its common use in mobile phone handsets. In fact, the PIFA is often regarded as a generic antenna in its own right, but from physical fundamentals it is seen to be a derivative of both wire antennas and printed patch antennas. For instance, a low profile inverted L antenna (ILA) has a low radiation resistance, but by tapping the feed connection along the wire, it can be increased, which is the inverted F antenna (IFA), as shown in Figure 36-4a. This antenna is useful for low profile applications where only a thin wire can be used. Where space is available, the L -shaped wire can be replaced by a planar conductor of width L_1 , as shown in Figure 36-4b. The planar conductor increases the radiation resistance and offers a two-dimensional choice of feed position to facilitate matching. The end shorting plate of height H need not occupy the entire plate width, as shown in Figure 36-4b.

FIGURE 36-4 (a) Inverted *F* wire antenna and (b) typical PIFA

Examination of Figure 36-4 also reveals that the PIFA can be regarded as a quarter-wave patch antenna¹⁸ with an air-spaced substrate. The PIFA has both vertical and horizontal radiation surfaces, and the radiation patterns can be expected to contain significant cross-polarization, which is not a problem for cellular mobile phones since they have to operate in a high multipath environment. Being purely a simple bent metal antenna with no lossy substrate, the PIFA has good radiation efficiency. However, it is sensitive to its environment, and when embedded in a handset with the presence of the hand and head, the radiation efficiency reduces drastically.¹⁹ The radiation patterns are also significantly perturbed by the hand and head movement and appreciable power is dissipated in the head. However, the simplicity of the PIFA and the low manufacturing cost remain outstanding advantages that are attractive to an industry where cost-cutting is a paramount consideration.

The demand for multiband operation at no additional antenna cost has inspired the creation of the multiband PIFA; a dual-band example is shown in Figure 36-5. The simplicity of this antenna is remarkable and there would appear to be an unlimited number of ways of configuring the current paths on the top plate of the PIFA or indeed to other metal-plate antennas. This concept has been extended to the tri-band version shown in Figure 36-6.

FIGURE 36-5 (a) Dual-band PIFA (after Y.-X. Guo et al²⁰ © IEEE 2004) and (b) bandwidth characteristics of dual-band antenna

FIGURE 36-6 (a) Tri-band monopole (after G.-Y. Lee and K.-L. Wong²¹ © *Micro. Opt. Technol. Lett.* 2002); (b) Side view of monopole antenna mounted on the handset GP; (c) Measured and simulated bandwidth characteristics of tri-band antenna

As already mentioned, radiation patterns having a high cross-polarization content can be expected, and examples of radiation patterns for the tri-band antenna of Figure 36-6 are shown in Figure 36-7.

Similar performance can be obtained with the meander-line concept, which allows a printed zigzag conductor to be printed on a thin planar dielectric film prior to folding into the rectangular $6 \times 6.5 \times 25$ mm³ box shape illustrated in Figure 36-8. This tri-band antenna is very compact and covers the GSM (900 MHz), DCS (1800 MHz), and PCS (1900 MHz) bands.

The large degree of design freedom offered by these simple metal antenna structures has enabled manufacturers to generate their own in-house low-cost designs. Further compacting of these antennas can be achieved by loading the low-frequency resonant zones of the structure with a high-permittivity dielectric slab, albeit at the expense of a somewhat lower radiation efficiency and bandwidth for the low band and the extra cost of the ceramic material.

36.5 CERAMIC CHIP AND RESONATOR ANTENNAS

A major manufacturing problem with PIFAs and other air-spaced antennas embedded in the handset is that they are not stand-alone electronic components. These antennas couple to the handset components, and a previously proven antenna cannot be simply embedded into a new handset configuration without further design adjustments. The ceramic chip antenna concept goes some way toward alleviating this coupling problem and also reduces the antenna size at the expense of additional material costs. The fields are intensified within the ceramic material, and unwanted characteristics are the narrowing of the bandwidth together with some lowering of the radiation efficiency even though the intrinsic material loss ($\tan\delta_e$) is low. Numerous chip antenna designs have been described whereby a high-permittivity ceramic material is associated with a meander-line²³ or helical configurations.²⁴ The conducting lines can be readily printed onto the outer surface of the ceramic material. An example of a helical construction is illustrated in Figure 36-9a and its deployment as an antenna embedded in a handset is shown in Figure 36-9b together with radiation patterns.

The typical ceramic chip antenna is likely to be too small to permit resonant modes within its interior. In contrast, the dielectric resonator antenna (DRA)²⁵ relies on a mode being excited, which can be achieved by a small probe or coupled slot. Although the concept of a DRA was introduced by Richtmyer²⁶ in 1939, the practical versions were not investigated until the 1980s, no doubt due to the new availability of high-permittivity, low-loss, temperature-stable ceramic materials at that time. The feasibility of embedding a DRA within a handset has been investigated²⁷ but single mode operation has the characteristic narrow bandwidth which

FIGURE 36-9 (a) Constructional view of helical ceramic chip antenna¹¹ (Courtesy of Murata Manufacturing Co.) and (b) the chip antenna embedded in a handset and the radiation patterns

limits its application. In another development²⁸ a quadrifilar-type antenna structure is plated onto a high-permittivity dielectric cylinder. A balun structure at the base isolates the antenna from the GP, and there is a radiation null at broadside, thus reducing radiation exposure to the head. The bandwidth as anticipated is very narrow. The antenna is illustrated in Figure 36-10.

The demand for multiband handset antennas has prompted designers to develop DRAs that have more than one mode excited, thus providing bandwidth windows that correspond to the required cellular bands. This is not difficult if the resonator is not restricted in size, but for handset installation the DRA thickness must be < 10 mm, while the handset width and limited space allocation place severe constraints on the other dimensions. Such a multimode DRA has been described²⁹ and the mode generation is governed by the excitation mechanism, which is commonly a coupling strip plated on the dielectric surface. Additional conductors can be plated on the dielectric surfaces to provide additional bands, and the nature and location of the conductors are mainly determined by experiment and/or simulation.

The electrical compactness of DRAs, at least for the higher mobile bands, allows provision of balanced pairs¹² to reduce currents in the handset GP and hence reduce hand and other environmental effects. An example is given in Figure 36-11, which

FIGURE 36-10 Dielectrically loaded, balanced quadrifilar-type antenna (Courtesy of Sarantel Ltd.)

FIGURE 36-11 (a) Balanced ceramic antenna on GP³⁰ (Courtesy of Antenova Ltd.); (b) The 900-MHz bandwidth characteristic; (c) The 1800- and 1900-MHz bandwidth characteristics

covers the 900-, 1800-, and 1900-MHz bands.³⁰ The 900-MHz band remains unbalanced while the two higher bands are balanced. It is also claimed that there is less radiation exposure to the head.

The use of ferrite material to reduce the electrical size of wire monopoles and other antennas has received some attention³¹ over the past 60 or so years but has remained a specialized technique for a few applications. More recently³² its application to DRAs has emphasized the enhancements in antenna performance that can be achieved, these being a significant increase in bandwidth and the radiation efficiency. Best performance is obtained when there is approximate equality between the real parts of the material's complex permittivity and permeability. Theory and simulations³³ have established the performance benefits of applying this technique to handset antennas. An example³⁴ is given in Figure 36-12a, which shows a ferrite-loaded monopole antenna covering the four bands 1800 MHz (GSM), 1900 MHz (GSM), 2100 MHz (UMTS), and 2450 MHz (Bluetooth). The conducting rings facilitate the adjustment of the band shape. The quad-band bandpass characteristics are shown in Figure 36-12b together with a previous tri-band characteristic which did not cover the UMTS band.

(a)

(b)

FIGURE 36-12 (a) View of ferrite antenna on GP (after M. I. Kitra et al³⁴ © IEEE 2007) and (b) the bandwidth characteristics

TABLE 36-2 Performance of Ferrite Handset Antenna (after M. I. Kitra et al³⁴ © IEEE 2007)

	$\tan\delta_\epsilon = 0.03$ $\tan\delta_\mu = 0.03$	$\tan\delta_\epsilon = 0.0001$ $\tan\delta_\mu = 0.06$
ϵ'	6	6.38
μ'	6.6	6.18
Monopole length (mm)	4.5	4.5
Coverage at 1800, 1900, 2100, and 2450 MHz at -6 dB level	Achieved	Achieved
Efficiency (%) with the head present at 1800, 1900, 2100, and 2450 MHz, respectively	35.05, 32.6, 15.15, and 22.34	38.5, 34.9, 19.2, and 22

A summary of the simulated performances for various material properties is given in Table 36-2.

The complex permeability and permittivity of the material are defined as

$$\begin{aligned}\mu_r &= \mu' + j\mu''; & \tan\delta_\mu &= \mu''/\mu' \\ \epsilon_r &= \epsilon' + j\epsilon''; & \tan\delta_\epsilon &= \epsilon''/\epsilon'\end{aligned}\quad (36-5)$$

Simulation using a commercially available ferrite material designed for screening purposes with $\mu' = 2$, $\tan\delta_\mu = 0.06$, $\epsilon' = 24.1$, and $\tan\delta_\epsilon = 0.0001$ established that a quad-band performance was obtainable. The low radiation efficiency may be improved with the development of a ferrite material specifically for antenna rather than screening applications.

36.6 SAR MEASUREMENT AND MINIMIZATION

This section examines the effects on the user's health when using a mobile communications device. Methods for reducing the radiation absorbed in the head are also presented.

Radiation Exposure

The public has been concerned for many years about the electromagnetic radiation effects from microwave ovens, overhead power lines, and household electrical installations even though no established evidence of harm has emerged. Non-ionizing electromagnetic waves in the microwave and lower frequency bands create thermal effects in tissues when the water molecules and dissolved ions are made to vibrate. The water content is therefore an indication of the level of absorption. Nonthermal effects are due to the interaction of the applied field with the molecules where it is considered that the latter align themselves along the electric field to minimize potential energy.³⁵ Elegant theories and mathematical models have been published, for instance, "perturbation of DNA due to soliton waves," "effects on body organs and glands," and "acceleration and retardation of seed growth at specific millimeter wave frequencies." There remains a large amount of literature globally on this topic, but the results are often ambiguous and no clear evidence appears to have emerged so far.³⁶

It is not surprising, therefore, that the astronomical growth of mobile phone usage has been accompanied by much public concern, particularly as the handset is held close to the head and earlier analog handsets could dissipate a watt of power in the brain. Despite extensive worldwide research and strong support from governments for over a decade, no evidence of a health risk has been uncovered so far. Protests about the siting of base station masts and power lines are continuing, but at the present time the situation with mobile phones remains calm and stable, with most users aware that minimizing handset use is desirable, particularly for children. Text messaging has escalated for children and eases the exposure problem.

Manufacturers for their part have reduced exposure levels with the introduction of digital systems and continue to be responsibly mindful of the situation. On the research front, the electromagnetic exposure to the head and other body regions continues to be of major interest, such as the development of low SAR handsets (as described later in this section), the effect of metal spectacles,³⁷ body-worn jewelry,³⁸ metal spectacles on the mucous membranes,³⁹ the exposure to passengers in automobiles when using mobile phones,⁴⁰ to mention but a few. Below we give background details of some current work in this field.

Radio Frequency Dosimetry

With the concern about mobile phone exposure to the human body and particularly the head, it was evident that a regulatory process was urgently needed. The radiation exposure to any part of the human body is now assessed by the Specific Absorption Rate (SAR), which is defined by

$$\text{SAR} = (\sigma / 2\rho) | \mathbf{E} |^2 \text{ W/kg} \quad (36-6)$$

where σ = tissue conductivity, ρ = tissue density, and $| \mathbf{E} |^2$ = the square of the electric field intensity in the tissue. Background details are given in Fujimoto and James¹¹ (Chapter 6, Section 6.5, and Chapter 7). Radio frequency dosimetry in the human body is very complex due to many factors that affect the absorption rate in tissues. Safety guidelines recommend that the 1g averaged peak SAR should not exceed 1.6 W/kg and the whole body averaged peak SAR should be less than 0.08 W/kg. The 1g averaged peak SAR is preferred because it represents local variations more accurately. Each mobile phone user has a usage profile ranging from those who use their mobile phone occasionally to those in a busy occupation necessitating many hours of continuous phone use each day. An idea of how SAR needs to be interpreted is given in Fujimoto and James¹¹ (Chapter 6, Section 6.5). To determine the likely SAR for a mobile phone, it must be measured in as near a natural scenario as possible together with a model of the human head composed of representative artificial tissue. Table 36-3 summarizes the electrical properties of some common tissues.

Purpose-built equipment is available to assist in standardization, but computer modeling has played a major role in rapidly evaluating different human body and handset situations; these aspects are detailed below.

Measurement of SAR

Although computer modeling has proliferated, the direct practical measurement of SAR in a phantom head and body is regarded as an important complementary tool. Handset manufacturers have now built up their bespoke practical measurement equipment over several years with phantom models comprised of tissue simulating fluid with the appropriate electrical parameters as listed in Table 36-3. Elaborate three-dimensional electrically small

TABLE 36-3 Electrical Parameters of Human Body Tissues

Frequency (MHz)	Relative Permittivity ϵ'	Conductivity σ (S/m)
300	45.3	0.87
450	43.5	0.87
835	41.5	0.90
900	41.5	0.97
1450	40.5	1.20
1800	40.0	1.40
1900	40.0	1.40
2000	40.0	1.40
2450	39.2	1.80
3000	38.5	2.40

probes are positioned within the phantom fluid by sophisticated control systems, enabling the SAR to be rapidly assessed within a few minutes. The homogeneous tissue fluid enables a bulk SAR assessment to be performed but cannot represent the layering of different tissues and the presence of organs and glands. It does, however, allow the rapid comparison of different handset antennas and the effects of different handset orientations and separation distance from the body region. Most of the measurements are concerned with the absorption in the head, with or without a phantom hand model, and the variation in SAR for the same handset can be up to 100 percent depending on the measurement conditions.⁴¹ Consumer groups have published league tables of SAR head absorption for commercially available mobile phones but its influence on customer purchasing preference is not very apparent, maybe because of the strong fashion element associated with phones, particularly with younger people.

A photograph of a measurement system is given in Figure 36-13, showing the phantom in the forefront undergoing probe measurements in its right ear region. Details of the probes and control apparatus are given in Fujimoto and James¹¹ (pp. 338–340).

There is also some demand from universities and research establishments for ready-made commercially available SAR measurement equipment. One such example is the SPEAG Dosimetric Assessment System (DASY 4), which provides a six-axes robotic arm scanning the inside of a phantom head with facial features that are filled with tissue simulating liquid.⁴²

FIGURE 36-13 View of phantom measurement equipment (after K. Fujimoto and J. R. James¹¹ © Artech House, Inc. 2001)

FIGURE 36-14 DASY 4 SAR measurement system by SPEAG

The system is computer controlled, enabling measurement of SAR to be performed in a short time. A photograph of the equipment is shown in Figure 36-14.

Techniques for Minimizing SAR

A variety of earlier attempts sought to reduce the handset antenna radiation to the hand and head regions. A pull-up metal mesh shield around the handset case was manufactured but, as might have been expected, it interfered and reduced the handset transmitted and received power. This idea has very recently been revisited with success using a metamaterial shield⁴³ and a view of the latter in position on the handset case is shown in Figure 36-15.

A way of reducing SAR in the head has been described⁴⁴ that is based on the presence of a ferrite material screen. The research was simulated using FDTD with a detailed head model. It is claimed that provided the handset GP currents are not perturbed, then the SAR in the head is reduced without a reduction in radiation efficiency. An early attempt to reduce the head SAR by creating a radiation pattern null in the direction of the head involved a slot/patch combination.⁴⁵ A layered spherical head constituted the simulation model. The antenna was bulky and unlikely to be applicable to present-day handset requirements, particularly with the demand for single multiband antenna operation.

Computer modeling is now a foremost tool associated with the minimization of SAR, particularly for the head region. The models have ranged from simple homogeneous cube blocks, spheres, and layered spheres to complex, more-realistic head models exhibiting the heterogeneous regions of the head and brain. These anatomical models are very detailed and thus escalate computer processing requirements. Some models can be freely downloaded on the Web. Two different anatomical models^{46,47} are illustrated in Figures 36-16*a* and *b*.

FIGURE 36-15 Metamaterial shield on a handset case (after G.Goussetis et al⁴³ © URSI 2005)

Much research has been carried out on the comparison of different head models and it has been deduced that even though a heterogeneous head model will affect the SAR distribution within the head, it has little effect on the maximum integrated SAR, which is determined mainly by the antenna itself and its distance from the phantom.^{48–50} It is concluded that the maximum averaged SAR is lower in most cases in a heterogeneous head model compared to a homogeneous head model and that a spherical head can be used to give a reasonable, slightly pessimistic assessment.^{50–52}

(a)

(b)

FIGURE 36-16 (a) Visible human head (after U. Tiede et al⁴⁶ © IEEE 1996); (b) 1.1-mm resolution image of human head with 26 tissue types (after W. Whittow⁴⁷ © Sheffield University 2004)

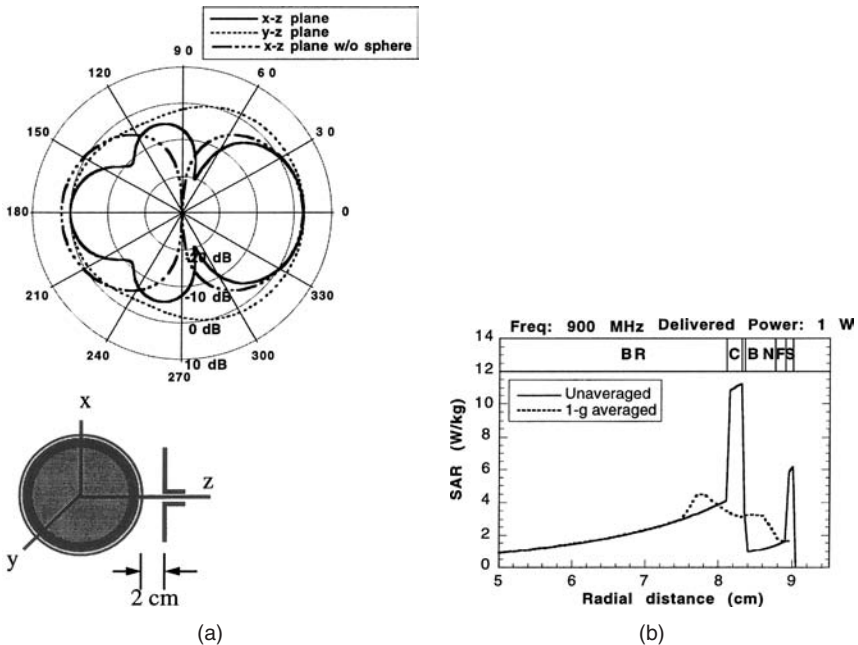

FIGURE 36-17 (a) Far-field gain patterns of the half-wavelength antenna with and without the six-layered spherical head (after K. Fujimoto and J. R. James¹¹ © Artech House, Inc. 2001); (b) 1g averaged and unaveraged SAR distributions along z axis at 900 MHz (BR = brain, C = cerebrospinal fluid [CSF], D = dural, BN = bone, F = fat, and S = skin)

Currently, the IEEE Standards Coordinating Committee 34, Subcommittee 2, Work Group 2 is proposing new FDTD computational techniques for determining the SAR in the human body.⁵³ It is expected that this standard will provide better guidelines for simulations involving heterogeneous heads.⁵⁴

A layered spherical head has been investigated using the eigenvalue expansion method, and an interesting example of the results is shown in Figures 36-17a and b (Fujimoto and James¹¹ pp. 373–374). The result demonstrates that the absorption in the skin exceeds that in the CSF at higher frequencies.

The majority of head model simulation research appears to mainly involve the use of PIFAs and other handset antennas that couple strongly into their environment, as described earlier in this chapter. The head SAR levels can therefore be near the recommended SAR limits.¹⁹ The ferrite-loaded handset antenna described in Section 36.5 represents a significant advance in techniques for reducing the head SAR, and the reductions in SAR are very significant. Table 36-4 gives details of the SAR in the head for this ferrite antenna. A spherical homogeneous head model was used in this research.

TABLE 36-4 SAR in the Head for Ferrite Handset Antennas³⁵

Handset Antenna	Frequency Band Coverage (MHz)	SAR in the Head (10g [W/kg])
Ferrite antenna (Figure 36-12)	1800, 1900, 2100, and 2450, respectively	0.076, 0.11, 0.06, and 0.0006, respectively

The excellent low SAR in the head is brought about by the use of an antenna monopole excitation probe, the orientation of the probe, and the use of ferrite material, and, for the balanced version, the deployment as well of two coupled antennas in phase opposition. As far as we are aware, these ferrite handset antennas are probably the only way of effectively reducing the SAR in the head while maintaining good prospects for realistic manufacturing potential.

36.7 PROVISION FOR GPS AND BLUETOOTH

The provision for GPS and Bluetooth services in recent years was the commencement of adding value to mobile phones. Handset manufacturers are clearly influenced by the relative ease of embedding additional software processing chips within the handset. Additional bulky sensors are invariably required to input, output, and display the information, and this has not been an insurmountable obstacle for TV reception and camera phones where the display panel and camera can protrude somewhat outside the case. The clamshell handset also eases the space problem. The power of the chips continues to increase significantly while chip prices continue to fall. In keeping with this trend, handset manufacturers are deterred from increasing the number of antennas within the handset, both for cost reasons and because of the acute shortage of space. Therefore, we can expect to have only one multiband handset antenna that will encompass the new bands in addition to the established original bands. The isolation between adjacent bands needs to be small to avoid additional software filtering.

We have already shown in this chapter that some of the multiband antennas are in fact able to include the Bluetooth transceiver band at 2450 MHz. One thing in the designer's favor is that at this higher frequency, the Bluetooth antenna is less electrically small with a quarter-wave length of 3.06 cm. For GPS receiver provision in the L_1 1575.42-MHz band, the antenna size limitation is more critical with a quarter-wave length of 4.76 cm. Both GPS and Bluetooth are low-level signal devices and consequently they involve no SAR issue.

A way of reducing the GPS antenna length has already been demonstrated¹⁹ and involves an IFA plated onto a dielectrically loaded PIFA. The dielectric loading condenses the IFA fields and hence the antenna length. This example is illustrated in Figures 36-18*a* and *b*, showing a view of the dielectric loaded PIFA and the isolation between the PIFA and the IFA.

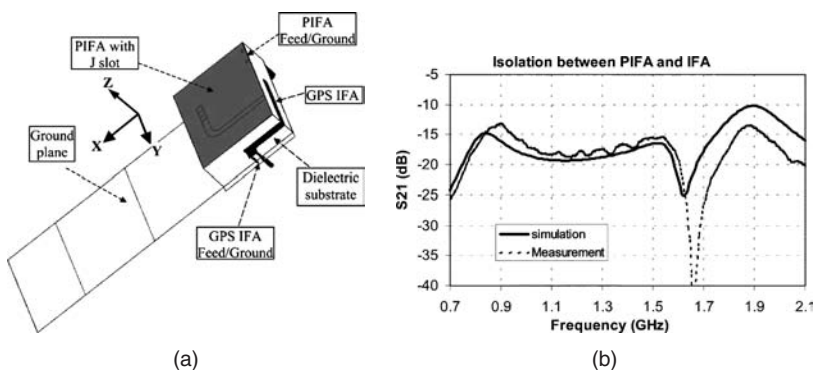

FIGURE 36-18 (a) View of dielectric loaded PIFA with mounted IFA (after Z. Li and Y. Rahmat-Samii¹⁹ © IEEE 2005); (b) Isolation between the PIFA and IFA antennas

How handset manufacturers continue to provide for GPS and Bluetooth depends very much on their own preferred handset and antenna designs, but the examples shown in this section illustrate the feasibility of adding these two services to mobile phones.

36.8 MEASUREMENT OF HANDSET ANTENNAS

The mobile phone handset is a remarkable electronic product: it is packed with communication circuitry that must fit in the handset case, and it must be affordable by the public at large. The complexity of handsets has demanded new thinking about not only how to measure the circuit functions during the manufacturing process but also its overall performance when assembled. All of this must be accomplished in a cost-effective way. The situation is further complicated by the continually increasing processing speeds and the associated high-frequency EMC difficulties within the handset. Instrument manufacturers have responded in earnest and numerous suites of sophisticated instruments are now available to handset manufacturers to automate their component and subsystem production lines.

Measuring the performance of the finished product is a somewhat less-well-defined task because it has to embrace the relationship of the handset with its environment. This includes not only radio propagation effects in the everyday urban scenario but, as already discussed in this chapter, the absorption of waves by the operator's body and, in particular, head. To what extent these issues are addressed will depend on the handset manufacturers but the cost of testing will be a major consideration and it has to be assumed that some sampling of the manufacturing output will take place.

The performance of an antenna in cellular operation can be defined and related to a particular route. Multipath reflections from moving vehicles, people, airplanes, doors in buildings, etc., create random fluctuations in the propagating radio wave polarization and signal strength. For measurement purposes, the wave polarization can be resolved into vertical polarization (VP) and horizontal polarization (HP), so upon moving the mobile handset along a particular urban route, the mean powers P_v and P_h , respectively, associated with these polarized components can be measured. The antenna will not be able to capture all the polarized power, and $P_r < (P_v + P_h)$, where P_r is the mean antenna power that would have been received over the same route, in the same time period. The antenna performance is defined⁵⁵ by its mean effective gain (MEG), where

$$\text{MEG} = P_r / (P_v + P_h) \quad (36-7)$$

$$\text{MEG} = \int_0^{2\pi} \int_0^\pi [P_v / (P_v + P_h) G_\theta(\theta, \phi) P_\theta(\theta, \phi) + P_h / (P_v + P_h) G_\phi(\theta, \phi) P_\phi(\theta, \phi)] \cdot \sin \theta d\theta d\phi \quad (36-8)$$

where (θ, ϕ) are spherical angular coordinates, $G_\theta(\theta, \phi)$ and $G_\phi(\theta, \phi)$ are the θ and ϕ components of the antenna power gain pattern, respectively, and $P_\theta(\theta, \phi)$ and $P_\phi(\theta, \phi)$ are the θ and ϕ components of the angular density functions of the incoming plane waves, respectively.

The recent trend toward extreme handset compactness and internal integrated antennas does not allow the handset antenna to be evaluated in isolation from the handset itself. In principle the MEG assessment could be applied to the handset itself, but it is clearly not affordable as a production test. Measurements on handset reception and transmission are also carried out⁵⁶ in a controlled environment, such as an anechoic chamber, but the process can again be very time-consuming and indeed costly.

The use of a reverberation chamber to test antennas in Rayleigh fading propagation conditions is well established, but its recent application⁵⁷ to mobile handset testing appears to offer manufacturers an efficient, low-cost method of assessing handset performance. An anechoic chamber requires highly absorbent walls, but a reverberation chamber is a large, metal-walled cavity capable of supporting many modes, which are then greatly perturbed by rotating reflectors within the excited chamber. This mode-stirring action is random enough to create a Rayleigh distributed transfer function between the receiving and transmitting antennas inside the chamber: in this application, these are the radiating handset and the receiving wall probe. The Rayleigh distribution model is a useful approximation of realistic mobile propagation conditions, and a demonstration chamber has been described⁵⁷ that has many attractive features. For instance, a phantom tissue head model can be placed in close proximity to the handset under measurement to enable the actual operating radiation efficiency to be obtained. The chamber can also test the addition of diversity functions and the newly emerging MIMO systems. The installation costs and operating times are low and compatible with handset manufacturing requirements.

36.9 SATCOM HANDSET ANTENNAS

Unlike cellular phones, satcom phone systems have had a very uncertain start due to the inadequate public take-up, which has led to financial difficulties for manufacturers. The systems have, however, survived in a leaner, more responsive form and a stable market has been developed. Around 1998 the systems under development were Iridium, Globalstar, ICO, and Thuraya. A summary of their salient technical details are listed in *Mobile Antenna Systems Handbook*¹¹ (p. 582). Iridium, Globalstar, and ICO are based on LEO, LEO, and MEO constellations, respectively, while Thuraya has a GEO satellite. Phased-array antennas directing spot beams to earth are used on all systems. Global roaming is provided by satcom phones, enabling the user to communicate from any place on earth. The user community includes military, business people, politicians, emergency services, those working in remote parts of the world or at sea, and so on, and this service differs greatly from that of the cellular phone system. A point in favor of the handset manufacturers is that the handset cases are less restricted in size than cellular phones, cost is not such a limitation, and the handset antenna can protrude well above the handset case. It was evident⁵⁸ in 1998 that the perceived market may not be adequate although the global roaming capability would attract support from the defense sector.

These satcom systems introduced new problems for handset antenna designers because of the low signal margins and the need for circular polarization.⁵⁸ The quadrifilar helix antenna (QHA) is extensively used, and reduced-diameter versions have been developed, giving some loss of bandwidth capability while ensuring compact user convenience. QHAs are fitted with a balun to feed the spiral arms from an unbalanced feeder, and various designs exist. A more conventional QHA is shown in Figure 36-19.

The current Iridium 9505A handset has a size of $158 \times 62 \times 59$ mm and has many added-value features including fax and data; an auxiliary handset antenna is also supplied. The Globalstar SAT600

FIGURE 36-19 Quadrifilar helix antenna (QHA) (after C. Kilgus⁵⁹ © IEEE 1964)

FIGURE 36-20 Thuraya 7101 handset¹¹ (Courtesy of Thuraya)

handset has a size of $177 \times 58 \times 39$ mm and offers a dual-mode facility combining cellular GSM900 and the satcom channel. Add-on facilities for the Internet are also available. The Thuraya 7101 handset, shown in Figure 36-20, offers data, fax, and GPS facilities; its size is $146 \times 53 \times 27$ mm.

As already mentioned, the QHA is constructed so that it can be pulled up out of the handset's case for use, thus giving it an elevated position clear of the user's head. Construction details for the Thuraya handset antenna are given in Figure 36-21, which shows the narrow-diameter QHA with the GSM NMHA mounted on its tip.

FIGURE 36-22 (a) Thuraya handset antenna passband characteristics¹¹ (Courtesy of Allgon); (b) Thuraya handset antenna's LHCP and RHCP elevation radiation pattern

The Thuraya earth-to-space link is 1626.5–1660.5 MHz with a space-to-earth link of 1525.0–1559.0 MHz. The Thuraya passband characteristics are shown in Figure 36-22a, and the antenna elevation radiation pattern is shown in Figure 36-22b.

36.10 FUTURE TRENDS

The mobile communications market will continue to grow fueled by user demand for increased functionality, aesthetics, smaller handsets, longer battery life, and ubiquitous access. Some future trends are presented next.

- In the immediate future, handset manufacturers will continue to add value to handsets by way of low-cost processing software. This of course will be dependent on the consumer takeup, which from past experience is dictated by individual requirements, fashion, and quite likely other serendipity factors. When the new services require extended band coverage, handset antenna innovation will continue to be much in demand.
- The system design approach will continue to be much in evidence in handset antenna design. This takes a holistic view of how all the components function together even if their individual performance may be degraded. When compared with conventional antennas, present-day handset antennas, with their low efficiency and proximity to other components, would have been seen as very poor radiators a few decades ago.
- Increasing the data rates of mobile phones will continue to receive research attention as more services are sought. New processing algorithms and techniques are being addressed, including the use of multiple antennas and quantum computing.⁶⁰
- The clamshell type of mobile handset has provided more space on handsets for facilities and displays while allowing the handset to be compacted when not in use, but additional antenna design problems are invoked.⁶¹ Other types of handset case designs can be expected as services increase.
- The quest for a single multiband handset antenna that will cover all the band requirements for new services is inhibited by well-established fundamental antenna action whereby antenna resonances are necessary to achieve good matching, bandwidth, and radiation efficiency. Resonance is determined by the length of current paths and sets constraints

on antenna size even if material loading and other compacting techniques are used, as described in this chapter. A future breakthrough in antenna design cannot be ruled out. Much attention has been focused recently on how materials can be synthesized using metamaterials⁶² but to date the cell sizes of the latter remain too large for the synthesis of an electrically small antenna.

36.11 SYMBOLS

A	radius of minimum sphere
DRA	dielectric resonator antenna
GP	ground plane
GPS	global positioning system
IFA	inverted F antenna
K	free-space wave number
LEO	low earth orbit
MEG	mean effective gain
MEO	medium earth orbit
NMHA	normal mode helical antenna

CONTENTS

37.1 INTRODUCTION	37-2
37.2 SUSPENDED PLATE ANTENNAS	37-2
37.3 PLANAR MONOPOLE ANTENNAS	37-11

37.1 INTRODUCTION

High data speeds and multiband operations of modern wireless communication systems have significantly increased the demand for broadband antennas that are capable of supporting such requirements. In general, the systems need low-cost solutions with desired performance in terms of impedance bandwidth, polarization, and gain. Owing to unique merits such as small volume or low profile, low manufacturing cost, and easy integration into planar circuits, planar antennas are playing important roles in various wireless communication applications.

The planar antennas can usually be categorized in terms of radiation performance into microstrip patch antenna, suspended plate antenna (SPA), planar inverted-L/F antenna, and planar monopole/dipole antenna.¹ Usually, they are attractive to antenna engineers due to their low profile and/or small volume. The changes in such antenna design are, in general, from the specific requirements of applications. For example, the microstrip patch antenna in its basic forms has a low profile, which is conducive to conformal design, but suffers narrow impedance bandwidth on order of 1 percent. In contrast, the planar monopoles usually have a high profile above a ground plane but enjoy broad bandwidth.

Making a trade-off between antenna profile and impedance, as well as radiation performance, the SPAs are good options for fixed base stations in wireless communication systems, and planar monopoles/dipoles for mobile wireless terminals. Accordingly, a variety of techniques have long been developed to further enhance the broadband performance of the SPAs and planar monopoles. Due to the merits of acceptable performance, low profile, and, in particular, low manufacturing cost, the SPAs and planar monopoles have widely been applied in high-speed wireless communication systems.

This chapter is divided into two parts, suspended plate antennas, and planar monopoles for high-speed wireless communications. The basic characteristics of the antennas will be introduced. The state-of-the-art designs will be covered, and the important issues for the antenna applications will be addressed.

37.2 SUSPENDED PLATE ANTENNAS

In this section, the SPAs will be introduced as base station antennas for modern broadband wireless connections such as high-speed wireless local area networks (WLANs) based on IEEE 802.11. The impedance and radiation characteristics of the SPAs are described first. Then, the techniques used to broaden the impedance bandwidth of the SPAs are addressed. After that, the techniques for enhancing the radiation performance of the SPAs are introduced. Finally, the applications of the SPAs to WLANs will be exemplified as a case study.

Definition

An SPA with a thick, low-permittivity dielectric substrate can be considered as a variation of microstrip patch antenna, as shown in Figure 37-1.¹ The planar radiator may be of any shape and placed above a ground plane. The planar radiator may be supported by a dielectric substrate with very low permittivity. Besides air, the dielectric substrate may be low-loss dielectric foam with a relative dielectric constant, ϵ_r , of ~ 1 . The dielectric substrate may be multilayered partially with air. The substrate thickness h is usually around 0.06 times the operating wavelength. The antenna may be fed in various ways. In Figure 37-1

FIGURE 37-1 Coordinate system and geometry of a probe-fed SPA above air: (a) three-dimensional view and (b) side view

the SPA is fed by a coaxial probe at a distance d away from the edge of the radiator. The operating frequency f_o of the SPA can be estimated by

$$f_o = \frac{c}{\lambda_o} = \frac{c}{2\sqrt{\epsilon_r}(l+h)} \quad (37-1)$$

where λ_o denotes the operating wavelength at the frequency f_o , c is the speed of light (299,792,458 m/s), and ϵ_r designates the relative dielectric constant. The length l , width w , distance d , and thickness h are in meters.

The SPAs can be fed in many ways like microstrip patch antennas. Typically, the SPAs can be excited by a microstrip line, a probe, and an aperture-coupled feeding structure, as shown in Figure 37-2.

Figure 37-2a describes the very popular feeding structure of the planar antennas, where a stripline is directly connected to the edge of the SPA.² Different from the microstrip patch antenna with a thin dielectric substrate supporting the radiator, the stripline for the SPAs is usually suspended above a ground plane with a large thickness. The large spacing between the feeding stripline and ground plane causes a wide stripline of characteristic impedance of 50 Ω . For example, within a frequency range of 1–10 GHz, the width of a stripline is 5.1 mm for $h = 1$ mm and 10 mm for $h = 2$ mm. Therefore, a coaxial probe, namely the inner conductor of a coaxial connector, is used to vertically (not horizontally) excite the end of the stripline. As a result, the frequency-dependent input impedance of the probe is observed.

FIGURE 37-2 Three types of feeding structures for SPAs

In Figure 37-2*b*, the SPA is fed by a coaxial probe attached to the radiator directly while its outer conductor is connected to the ground plane.³ This configuration greatly simplifies the feeding structure. Due to the large spacing between the radiator and ground plane, this is a proper solution for the SPAs. The feeding probe can also be used to support the radiator when no dielectric substrate is used below the radiator. However, both the stripline and coaxial probe feeds may cause narrow impedance bandwidth due to the narrowband impedance transition between the stripline or probe and radiators. Moreover, such asymmetric feeding structures degrade the radiation performance, especially at higher frequencies with high cross-polarization radiation levels and/or squinted radiation from the boresight axis (beam-squint effect).

Figure 37-2*c* shows an electromagnetically coupled feeding structure,⁴ where a microstrip line centrally feeds the radiator through a nonresonant slot right below the radiator, which is cut from the ground plane. The symmetric configuration of the antenna to some degree alleviates the degraded radiation performance problems by suppressing the high cross-polarization radiation and the severe beam-squint effect. The nonattaching transition structure also improves the impedance bandwidth to some extent.

Important Features

Consider the SPA and coordinate system shown in Figure 37-1 again. The radiator is a square with a length $l = 58$ mm. A coaxial probe feeds the radiator with a distance d away from the radiator edge. Figure 37-3 shows the input impedance of the probe when the thickness h is 5, 8, and 11 mm. The start and stop frequencies are 2 and 3 GHz, respectively. From the Smith chart in Figure 37-3, the variation of the input impedance for varying thickness h is clearly observed. When the thickness becomes larger, the input impedance becomes larger, in particular, with larger inductance. This is an important feature of the SPAs. Therefore, to achieve a broad impedance bandwidth, it is necessary to employ the techniques to compensate for the large inductance.

FIGURE 37-3 Input impedance of the probe-fed SPA shown in Figure 37-1 with $d = 0$ mm, $l = 58$ mm, and $h = 5, 8$, and 11 mm

FIGURE 37-4 Return losses of the SPA shown in Figure 37-1 with $l = 58$ mm and $h = 5, 8$, and 11 mm.

Figure 37-4 shows the return losses of the SPA shown in Figure 37-1. The location of the feed point is optimized for good impedance matching as $h = 5$ mm. The achieved impedance bandwidths for -10 -dB return loss are, respectively, 4.7 percent, 7.1 percent, and 6.2 percent at $h = 5, 8$, and 11 mm. The larger the thickness, the broader the impedance bandwidth. However, for the larger thickness, such as 11 mm, the good matching cannot be achieved by changing the position of the feedpoint, so that the achieved impedance bandwidth is not larger as expected. Therefore, the impedance-matching techniques should be applied for broad impedance bandwidth.

Owing to the large thickness, the radiation performance of the SPAs is slightly different from that of the conventional microstrip patch antennas. Figure 37-5 shows the radiation patterns in both E and H planes at the lower-edge, center, and higher-edge frequencies of the impedance bandwidth. In the E planes, the cross-polarization radiation levels are very low and thus can be ignored. With the increase in operating frequency, the sidelobe levels greatly increase, and the beam-squint effect can be observed at the higher-edge frequency due to the asymmetric configuration of the antenna. In the H planes, the copolarized radiation patterns are hardly changed. However, the cross-polarization radiation levels increase by 5.4 dB when increasing the frequency.

In short, the longer probe results in higher impedance, in particular, inductance. The larger antenna thickness offers potential for a broad impedance bandwidth but degrades the radiation performance with higher cross-polarization radiation levels in the H planes and higher sidelobe levels as well as the beam squinting in the E planes. As a result, it is necessary to develop the techniques to broaden impedance bandwidth and enhance the radiation performance in the applications of the SPAs in wireless communication systems.

Techniques for Broad Impedance Bandwidth

In the SPA design, the large thickness and low permittivity of the substrate provides the potential for a broad impedance bandwidth due to low antenna Q values. For example, the probe-fed SPAs in their basic forms with air as their substrate usually can achieve around 7 percent impedance bandwidth for -10 -dB return loss.¹ The achieved bandwidth is limited by the high impedance caused by the longer feeding probe. To further broaden the impedance bandwidth, the techniques for impedance matching have been developed and applied.¹

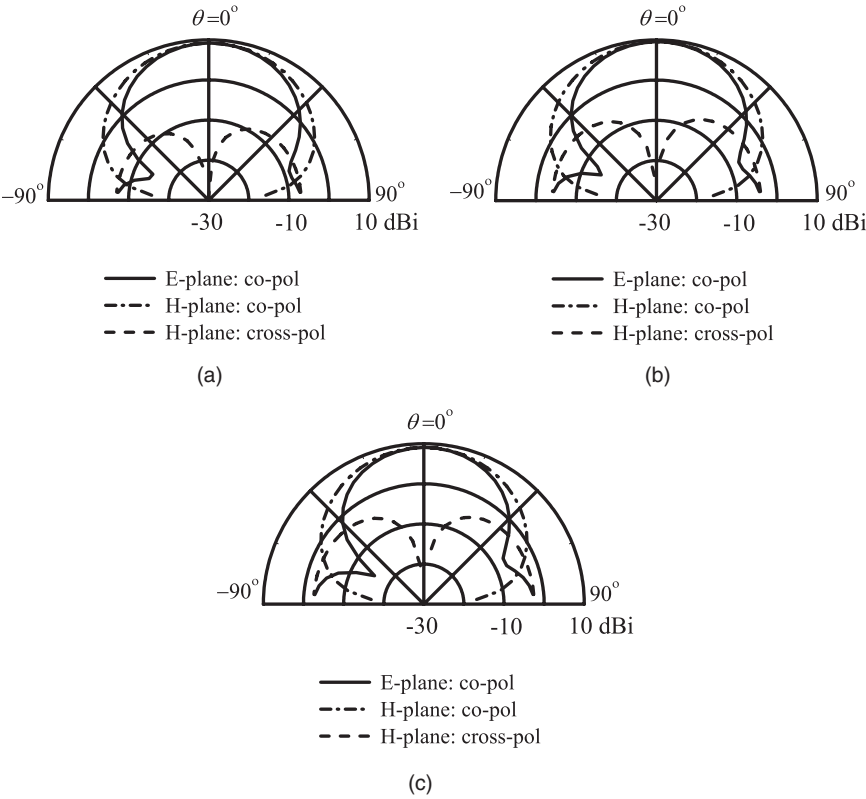

FIGURE 37-5 Radiation patterns for the probe-fed SPA shown in Figure 37-1 with $l = 58$ mm and $h = 8$ mm at (a) lower-edge frequency, 2.28 GHz; (b) center frequency, 2.36 GHz; (c) higher-edge frequency, 2.44 GHz

Figure 37-6 shows the techniques for broadening impedance bandwidths of the probe-fed SPAs, which are extensively used in wireless communication systems. Figure 37-6a shows the method to offset the large inductance caused by a longer probe.⁵ An annular slot is cut around the feedpoint so that the radiator is fed through capacitive coupling. The capacitive loading can also be introduced between the radiator and feeding probes in other ways.⁶⁻⁸

Figure 37-6b illustrates the technique to counterbalance the large inductance and achieve a broad bandwidth by slotting the radiator.⁹ The slot cut from the radiator acts as an impedance-matching network across a broad bandwidth. The slot can be of other shapes.¹⁰ Such a technique can be applied without any increase in the size of antenna and can easily be fabricated at a low cost; two factors that make the applications of planar antenna arrays appealing.

The introduction of strong electromagnetic coupling between the feeding probe and radiator is an important and effective way to achieve broadband impedance matching.¹¹ The idea has been applied to the SPAs with great success, as shown in Figure 37-6c. Due to the application of the L-shaped feeding probe, the impedance bandwidth can reach up to more than 36 percent.¹²

FIGURE 37-6 Techniques for broadening impedance bandwidth of the SPAs

The key to achieving the broadband impedance response of the SPA is the broadband transition between the feeding probe and the radiator. Figure 37-6d shows the other way to modify the transition, where a vertical conducting sheet is used between the feeding probe and the radiator.¹³ The vertical sheet basically acts as a broadband impedance-matching network.

As an example, an SPA fed by an L-shaped probe is designed that operates at 2.4 GHz. The geometry of the SPA is shown in Figure 37-7a, where a rectangular stub (25×4 mm) forms the horizontal portion of the L-shaped probe and is vertically excited by a probe with a radius of 0.65 mm. By adjusting the length and height of the vertical portion of the L-shaped probe as well as the height of the radiator, the impedance locus forms a tight loop around the center of the Smith chart, as shown in Figure 37-7b. The strong electromagnetically coupled structure functions as a broadband impedance-matching network. Therefore, the well-matched bandwidth for –10-dB return loss reaches up to 25 percent, ranging from 2.04 GHz to 2.62 GHz.

FIGURE 37-7 (a) Geometry of an L-shaped probe-fed SPA and (b) impedance in Smith chart

FIGURE 37-8 Radiation patterns for gain of the L-shaped probe-fed SPA.

Figure 37-8 shows the radiation patterns in both E and H planes at frequencies 2.3 and 2.6 GHz. With the increase in frequency, the copolarization sidelobe levels in the E planes increase by 5.2 dB. The beam-squint effect is observed at the higher frequency of 2.6 GHz. In the H planes, the cross-polarization radiation levels become high also by 5.2 dB at 2.6 GHz. The ratios of co- to cross-polarization radiation levels are reduced from 15.8 dB at 2.3 GHz to 10.4 dB at 2.6 GHz. Therefore, the L-shaped probe-fed SPA features a broad impedance bandwidth but suffers the degraded radiation performance.

Techniques for Enhanced Radiation Performance

For base station antennas in wireless communication systems, the pure radiation polarization and stable maximum radiation direction are often required to avoid possible interference between different wireless systems and to save radiation power. The techniques to enhance the radiation performance of the broadband SPAs have been developed. As mentioned in *Broadband Planar Antennas: Design and Applications*,¹ the structurally asymmetric and electrically unbalanced antenna design usually suffers high cross-polarization radiation levels and beam-squint effects. Consequently, the solution to alleviate the degraded radiation performance problem is to modify the feeding structure of the SPAs to keep the antenna geometry symmetric and feeding structure balanced.

Figure 37-9 demonstrates some of the solutions that can be easily applied to the SPA design with the enhanced radiation performance. First, a dual-probe feeding configuration is illustrated in Figure 37-9a.¹⁴ Two feeding probes are used to excite the symmetric radiator simultaneously. The probes are symmetrically located in the E plane with respect to the H plane so that the antenna configuration is kept geometrically symmetric. The out-of-phase RF signals from the two probes form an electrically balanced feeding structure. As a result, the currents that distribute symmetrically and in balance at the radiator effectively suppress the cross-polarization radiation levels in the H planes and beam-squint effect in the E planes.

However, the dual-probe feeding scheme needs a broadband feeding network to form a feeding system with two anti-phase probes, although this can be eased in array design.¹⁵ To simplify the dual-probe feeding structure, a single-probe scheme is presented in Figure 37-9b.¹⁶ The radiator is fed by a probe through a half-wavelength strip. The probe

FIGURE 37-9 Feeding schemes applied to SPAs for enhancement of radiation performance: (a) dual-probe; (b) probe-fed half-wavelength strip; (c) dual-probe-fed center slot (d) simplified dual-probe-fed center slot scheme.

vertically excites one of the ends of the strip. The horizontal portion of feeding strip is half-wavelength long at the center operating frequency. Another end of the strip is vertically attached to the planar radiator. The RF signals in the two ends are expected to be out of phase. There is strong electromagnetic coupling between the horizontal portion of the strip and radiator, which achieves a good impedance matching within a broad bandwidth of 20 percent. Due to the balance-like feeding configuration, the cross-polarization radiation levels are effectively reduced so that the ratio of co- to cross-polarization levels is higher than 20 dB across the whole bandwidth.

The beam-squint effect in the E planes is, however, observed due to the asymmetric geometry caused by the feeding structure. A modified dual-probe feeding structure is used to enhance the radiation performance, as shown in Figure 37-9c, where the two out-of-phase probes are positioned around the center of the radiator, and a narrow slot is used to separate two feeding points.^{17,18} The separation between the two probes is small. Varying the length of the center slot can shift the resonant frequency and improve impedance matching. As discussed in *Broadband Planar Antennas: Design and Applications*,¹ the current distribution at the radiator will be kept symmetric so that the cross-polarization radiation is effectively suppressed in all directions. Such a structure also needs a feeding network in the single element design similar to the conventional dual-probe scheme. A modified version was proposed and used as shown in Figure 37-9d, where a grounded pin is used to replace the second probe. The radiation performance of the SPAs with such a simplified feeding scheme is comparable with that shown in Figure 37-9c.¹⁹

Applications in High-Speed Wireless Communications

As mentioned in previous sections, the SPAs feature broad impedance bandwidth and acceptable radiation performance. One more important merit is that the SPAs have a cost-effective design, because they can be readily fabricated with conducting sheets partially or completely without use of any expensive dielectric substrate. Such an advantage enhances the competence of such

an antenna technology in the massive wireless market. The application of the SPA in wireless communication systems, for example, the access point (AP) of WLANs, is exemplified with an actual product design.

As is well known by now, wireless networks can offer many advantages over wired networks due to mobility. With wireless networks, users are free from the tether of an Ethernet cable at a desk. Also, the wireless networks are flexible, fast, and easy to use, deploy, and maintain. The WLAN is a mature option for wireless networks, which are based on the IEEE 802.11 protocol and widely used. One of the WLAN's operating frequency bands (IEEE 802.11b) is the 2.4-GHz band (2.4–2.4835 GHz for North America and Europe; 2.471–2.497 GHz for Japan; 2.4465–2.4835 GHz for France; and 2.445–2.475 GHz for Spain). Thus, the antennas for the WLANs should cover the band of 2.4–2.5 GHz as well.

Figure 37-10a shows a photo of one design that has been successfully applied in the APs of WLANs as a product. The SPA was formed by a piece of copper sheet and supported by two stands above a 100×100-mm ground plane at a distance of 7.5 mm, as shown in Figure 37-10b. The stands were symmetrically cut and bent from the radiator and separated by a center slot. One stand was grounded as a shorting pin and the other was fed by a 50-Ω microstrip line through the ground plane. Adjusting the length of the slot can change the operating frequency and improve impedance matching. The detailed optimized parameters are shown in Figure 37-10b. The antenna is embedded in a casing of the APs for indoor WLAN wireless access applications.

Figure 37-11 shows the measured return loss and radiation patterns for the SPA. The bandwidth for –15 dB can cover the operating band of 2.4–2.5 GHz very well, as shown in Figure 37-11a. The measured radiation patterns in both the E and H planes at 2.4 and 2.5 GHz in Figure 37-11b and c show the gain in the boresight direction is higher than 8.5 dBi. The wider coverage of 76° in the H planes and slight tilt beam direction of 5–10° in the E planes are conducive to application of the SPA design in the indoor WLAN AP applications, where the APs are operating at the mode of point-to-multiple point.

It is concluded that the suspended plate antenna is one type of broadband microstrip antenna but with many unique features such as larger antenna thickness, broader impedance bandwidth, more easily degraded radiation performance, and lower fabrication cost. A variety of the techniques for the enhancement of impedance and radiation performance have long been developed. The more cost-effective designs based on suspended plate antennas have been accepted by the massive wireless communication markets.

37.3 PLANAR MONOPOLE ANTENNAS

In this part, the state-of-the-art planar monopole antennas will be introduced as embeddable terminal antennas for mobile ultrawideband (UWB) devices, for instance, wireless universal serial bus (USB) dongles. First, the state-of-the-art planar monopoles are briefly summarized. Unique design criteria for UWB antenna design are described. After that, the planar monopoles applied to wireless USB are introduced.

The State of the Art

In general, UWB antennas indicate frequency-independent designs, for instance, TEM horn antennas, as shown in Figure 37-12a.²⁰⁻²² The antenna radiates linearly polarized TEM waves. Figure 37-12b shows a photo of a planar two-arm spiral antenna. The operating frequency range is determined by the inner and outer radii of the spiral. The radiated wave is a circularly polarized wave at the boresight. The spiral antenna is usually backed by a lossy or conducting cavity to improve impedance matching at low frequency and axial ratio by reducing the reflections from the end of the spiral arm. The phase center will change with operating frequency when a conical spiral antenna is used.²³ Bi-conical antennas may be the earliest antennas used in

FIGURE 37-12 Frequency-independent antennas: (a) a TEM horn antenna; (b) a planar two-arm spiral antenna backed by a conducting cavity; (c) a bi-conical antenna; (d) two discone antennas

wireless communications because of their relatively stable phase centers and broad impedance bandwidths.²⁴ Figure 37-12c displays an asymmetrical finite bi-conical antenna with a broad impedance bandwidths.^{25–27} Figure 37-12d shows a typical discone antenna.

The existing frequency-independent antennas having a constant performance at all frequencies also include self-complementary log-periodic structures, such as planar log-periodic slot antennas, bidirectional log-periodic antennas, log-periodic dipole arrays, two- and four-arm log spiral antennas, and conical log-spiral antennas.²⁸

Furthermore, the cylindrical antennas can achieve broadband impedance characteristics by using resistive loading to form traveling wave along the dipole arms.^{29–31}

However, the antennas mentioned above are seldom used in portable/mobile devices due to the constraints of bulky size and high manufacturing cost, although they have been widely used in radar systems, electromagnetic compatibility (EMC), and channel measurements, as well as base stations for wireless communications. Therefore, planar monopoles or disc antennas have been alternatively used in wireless communications because they have shown excellent performance in impedance and radiation and because they have the significant advantage of small size.^{32–35} The earliest planar dipole may be the bow-tie antenna invented by Brown-Woodward.³⁶

Figure 37-13 reviews the planar trapezoidal designs.^{37–40} A general radiator with dimensions of W_u , W_b , H , and h that is installed above a large ground plane forms a planar monopole. The monopole antenna can be excited by a coaxial cable through a surface-mounted adapter (SMA) connector. The triangular monopole antenna is the case with $W_b = 0$ or $W_u = 0$, which can be considered as the planar versions of bi-conical antennas.

FIGURE 37-13 Review of the planar trapezoidal monopoles

The rectangular monopole antenna can be formed as $W_b = W_u \neq 0$, which is the planar version of cylindrical monopole antenna. The frequency corresponding to the lower edge of impedance bandwidth of the planar trapezoidal monopole can be estimated by Equations 37-2 and 37-3.

$$F(\text{GHz}) = \frac{0.25 \times 300}{H + h + \frac{W_u + W_b}{4\pi}} \quad (37-2)$$

$$F(\text{GHz}) = \frac{0.25 \times 300}{\sqrt{H^2 + \left(\frac{2 \max(W_u, W_b) - W_u - W_b}{2} \right)^2} + h + \frac{W_u}{2\pi}} \quad (37-3)$$

where

$$\max(W_u, W_b) = \begin{cases} W_u & W_u \geq W_b \\ W_b & W_b \geq W_u \end{cases}$$

and all dimensions are in millimeters. Equation 37-3 is the modified version of Eq. 37-2 to estimate the frequency corresponding to the lower edge of the impedance bandwidth and has been used to estimate the frequency corresponding to the lower edge of the impedance bandwidth of a rectangular radiator as a special case of polygonal radiators.

The rectangular planar monopole antenna can be derived from the trapezoidal planar antenna, as shown in Figure 37-13.⁴¹⁻⁴⁵ The monopole performance is mainly determined by the shape and size of the planar radiator as well as the feeding section. The overall size of the monopole and shape of the radiator dominate the frequency corresponding to the lower edge of the impedance bandwidth. The feed gap, the location of the feedpoint, and the shape of the radiator greatly affect the impedance matching.⁴⁶⁻⁴⁹ Figure 37-14 shows a rectangular planar monopole antenna and its modified versions. By modifying the shapes of the bottom sides of the radiators, the impedance matching of the planar rectangular monopole can be further improved, as shown in Figure 37-14*b*, *c*, and *d*, where the impedance transition

FIGURE 37-14 A rectangular planar monopole antenna and its modified versions

between the coaxial probe and the radiator has been improved by using step transition, two branch feeding strips, and a beveled radiator.^{46,47,49–51} A broadband impedance transition will ensure an impedance matching across a broad bandwidth. A shorting pin can also be used to make the planar antenna more compact.⁵² The impedance and radiation performance of four types of square planar monopole antennas were studied.⁴⁸

By slotting the radiators of the planar monopoles, the impedance bandwidth of the monopole can be improved where the current distributions on the radiators are changed, as shown in Figure 37-14e and f.^{53–55} By adding a horizontal strip, the height of the planar monopole can be reduced because of the longer effective current path, as shown in Figure 37-14g.⁵⁶

Theoretically, the radiators of the planar monopole antennas can be of any shape for broad operating bandwidth. The elliptical planar monopole antenna is one of the important types of planar monopoles in planar antenna design due to its broadband-even high-pass impedance performance. Figure 37-15 illustrates the elliptical monopoles in their general forms (Figure 37-15a), circular monopole (Figure 37-15b), semicircular monopole (Figure 37-15c), rectangular monopole with a semicircular bottom (Figure 37-15d), and annular monopole (Figure 37-15e).^{57–62}

FIGURE 37-15 Elliptical planar antennas and their variations

FIGURE 37-16 The prototypes of printed PCB monopoles: (a) a microstrip-fed triangular monopole; (b) a microstrip-fed circular PCB monopole; (c) a microstrip-fed rectangle+semicircle PCB monopole; (d) a microstrip-fed rectangular PCB monopole; (e) a CPW-fed triangle+semicircle PCB monopole; (f) a directly cable-fed rectangular PCB monopole with a strip; (g) a directly cable-fed circular PCB monopole with a slot; (h) a CPW-fed circular slot PCB antenna (from left to right and from the first to the second row).

However, in mobile wireless applications, the antennas are expected to be embeddable or easy to be integrated into wireless devices in system design. Therefore, the antennas directly printed onto a printed circuit board (PCB) are the most promising designs. Such antennas are usually constructed by etching the radiators onto the dielectric substrate of PCB stabs and a ground plane around the radiators.

Figure 37-16 demonstrates some prototypes of PCB antennas. It can be seen that the PCB antennas can be fed by a microstrip transmission line (Figure 37-16a–d), a coplanar waveguide (CPW) structure (Figure 37-16e and h), or directly by an RF cable where the inner conductor is connected to the upper radiator and the outer conductor is grounded into a system ground (Figure 37-16f and g), as shown in Figure 37-16.

For the microstrip-fed cases, the ground planes are usually etched on opposite surfaces, which are connected into the system ground. The ground planes are etched close to the feeding strip on the same surface as the feeding strip for the CPW-fed PCB monopoles. The directly cable-fed monopoles are often used in scenarios where the PCB monopoles are not close to the main board and an RF cable is used to connect the antenna into the main board—for example, the antennas embedded into the cover of a laptop computer.

Antennas Applied in High-Speed UWB Wireless Communications

UWB is a technology for the transmission of information by using an extremely large operating bandwidth. Since the first Report and Order by the Federal Communications Commission (FCC) released the unlicensed use of UWB on February 14, 2002, the UWB technology has been expected to be the next-generation technology for short-range but high-speed wireless communications.⁶³ The frequency range of 3.1–10.6 GHz has been allocated for such applications. The emission limit masks are regulated by regulators such

FIGURE 37-17 Emission limit masks for indoor and outdoor UWB applications

as the FCC for co-existence with other electronic systems, as shown in Figure 37-17. The emission power limits are lower than the noise floor in order to avoid possible interference between UWB devices and existing electronic systems. The masks may vary against regions or countries but the maximum emission levels are always kept lower than -41.3 dBm/MHz.

The extremely large spectrum provides room to use extremely short pulses on the order of picoseconds. Thus, the pulse repetition or data rates can be low or very high, typically up to giga pulse/second. The pulse rates are dependent on the applications.

Due to the unique requirements of UWB systems, the antenna design faces many challenges. Besides the requirements for conventional broadband antennas in terms of impedance bandwidth, gain, radiation patterns, and polarization, the special requirements for the UWB antenna in general include the following two points.

First, both the frequency and time domain responses of the UWB antenna should be taken into account due to the extremely wide bandwidth and direct pulsed signals. The frequency domain response includes all conventional parameters such as impedance, radiation, and transmission. The impedance bandwidth is measured in terms of return loss or voltage standing wave ratio (VSWR). Usually, the return loss should be less than -10 dB or $VSWR < 2:1$. An antenna with an impedance bandwidth narrower than the operating bandwidth tailors the spectrum of transmitted and received signals, acting as a bandpass filter in the frequency domain, and reshapes the waveforms of radiated or received pulses in the time domain. The radiation performance includes radiation efficiency, radiation patterns, polarization, and gain. The radiation efficiency is an important parameter especially for small antenna design, where it is difficult to achieve impedance matching due to small radiation resistance and large reactance. For the small antenna with weak radiation directivity, the radiation efficiency is of greater practical interest than the gain. The radiation patterns show the directions where the signals will be transmitted.

Second, the effect of the modulation schemes of the systems on the antenna design should be taken into consideration. The wireless communication systems based on UWB technology can be OFDM based or pulsed based. In an OFDM-based system, the whole UWB band is occupied by many sub-bands, where each sub-band having a few hundred megahertz (larger than 500 MHz) can be considered as broadband. Within the sub-bands, the effect of nonlinearity of the phase shift on the receiving performance can be ignored because the phase varies very slowly with frequency. Therefore, the design of the antenna is more focused on achieving constant frequency response in terms of the radiation efficiency,

gain, return loss, radiation patterns, and polarization over the operating band, which may fully or partially cover the UWB bandwidth of 7.5 GHz.

The pulse-based UWB systems usually require linear phase, impedance, and gain responses that can entirely cover the operating bandwidth or partially cover the bandwidth where the majority of the pulse energy is distributed. To prevent the distortion of the received pulses, a UWB antenna that can produce radiation fields of constant magnitude and a phase shift that varies linearly with frequency is desired.

In brief, an OFDM-based UWB system has almost the same requirements as those in a broadband system but with an extremely broad bandwidth, which usually varies from 50 percent (for the lower UWB band of 3.1–5 GHz) to 100 percent (for the entire UWB band of 3.1–10.6 GHz). However, paying additional attention to pulse-based UWB systems is needed, where a UWB antenna usually acts as a bandpass filter that reshapes the spectra of the radiated/received pulses. To design a good UWB antenna, we should keep the following important design factors in mind:

- Enough impedance bandwidth to cover the operating bandwidth
- Steady directional or omnidirectional gain radiation patterns
- High and constant gain along desired direction(s)
- Linear phase, especially for pulse-based systems
- Consistent polarization
- Mobility with small size/low profile
- Low design complicity
- Low material/manufacturing cost

Based on these requirements, a circular planar dipole antenna is exemplified. Figure 37-18 shows a pair of the circular planar dipoles, which are face-to-face positioned for transfer function (S_{21}) measurement. The planar circle has a radius of 10.5 mm and feed gap of 2.2 mm. The identical antennas are used as transmit and receive antennas in the test setup shown in Figure 37-18, a pair of the planar dipole antennas with a separation of 100 mm and positioned in parallel and face-to-face.

FIGURE 37-18 A pair of circular planar dipole antennas

FIGURE 37-19 (a) Return loss $|S_{11}|$ and magnitude of $|S_{21}|$; (b) the phase response of $|S_{21}|$ of the circular dipole antenna

Figure 37-19 demonstrates the return losses $|S_{11}|$ and the magnitude of the transfer function $|S_{21}|$ for the dipole shown in Figure 37-18. The circular planar dipole antenna demonstrates the broad impedance bandwidth covering the entire UWB band and broad transmission coverage 2–8.5 GHz within a 10-dB variation. The results shown in Figure 37-19 are simulated.

Antennas in UWB-based Wireless USB

The most promising applications of UWB technology in the short-range and high-speed wireless interfaces may be wireless USB (WUSB), which replaces wired USB to match the data rate of USB 2.0 at 480 Mbps. The technology is a hub-and-spoke connection that supports dual-role devices in which a product such as a camera can act either as a device to a host laptop/desktop or as a host to a device such as a printer. In this section, a printed PCB antenna will be designed for a WUSB dongle, which is used in a laptop environment.

Figure 37-20a shows a printed PCB antenna on a dielectric substrate with a popular USB flash drive. The radiator and ground plane are etched on opposite sides of the PCB, as shown in Figure 37-20b. The radiator consists of a rectangular section and a horizontal

FIGURE 37-20 A small PCB antenna for a WUSB dongle

(a)

(b)

FIGURE 32-21 (a) Placement of the antennas; (b) the antennas under test

strip, which is used to reduce the length of the rectangular radiator.⁵⁶ A rectangular notch was cut close to the horizontal strip.⁶⁴ The effects of the ground plane on the performance of the printed PCB antenna have greatly been reduced because of the introduction of the notch. The radiator is fed by a microstrip line from the left side of the radiator. The excitation is located at the bottom end of the microstrip line. The gap between the radiator and the ground plane is typically around 1 mm. The ground plane has a size of a typical wireless USB dongle, where the system will be installed.

A WUSB dongle is placed beside a laptop. The laptop usually has a metallic and lossy cover and main body. To reduce the effects of the cover and body, the antenna is installed as far as possible from the cover and main body. As an example, the effect of the laptop on the radiation performance of the antenna is investigated. Figure 37-21 shows a dongle with a small printed PCB antenna installed at an IBM ThinkPad laptop under test. The keyboard panel of the laptop measures $250 \times 300 \times 25$ mm. The screen measures 250×300 mm and is opened as if it is in use such that the angle between the screen and the keyboard panel is 100° . The antenna can be placed at different positions. Here, two different positions on the laptop for analysis are shown in Figure 37-21. The antenna can be placed at the right side of the back panel P1 and at the edge on the right-side panel P2. The size of the ground plane of the antenna does not affect the impedance and radiation performance significantly because the effect of the ground plane on the antenna performance has been significantly reduced.⁶⁴ Therefore, no matter if the dongle is electrically connected to the metal casing or not, the performance of the antenna is unchanged.

Figure 37-22 plots the radiation patterns for the total fields in the horizontal (x - y) plane when the PCB antenna is placed at two positions on the laptop and in free space. The coordinate system is shown in Figure 37-20. By comparing the gain for the antenna in free space and at positions P1 and P2, it can be seen that the antenna at P1 has higher gain than that at P2 due to the blockage effect of the cover on the radiation from the antenna in

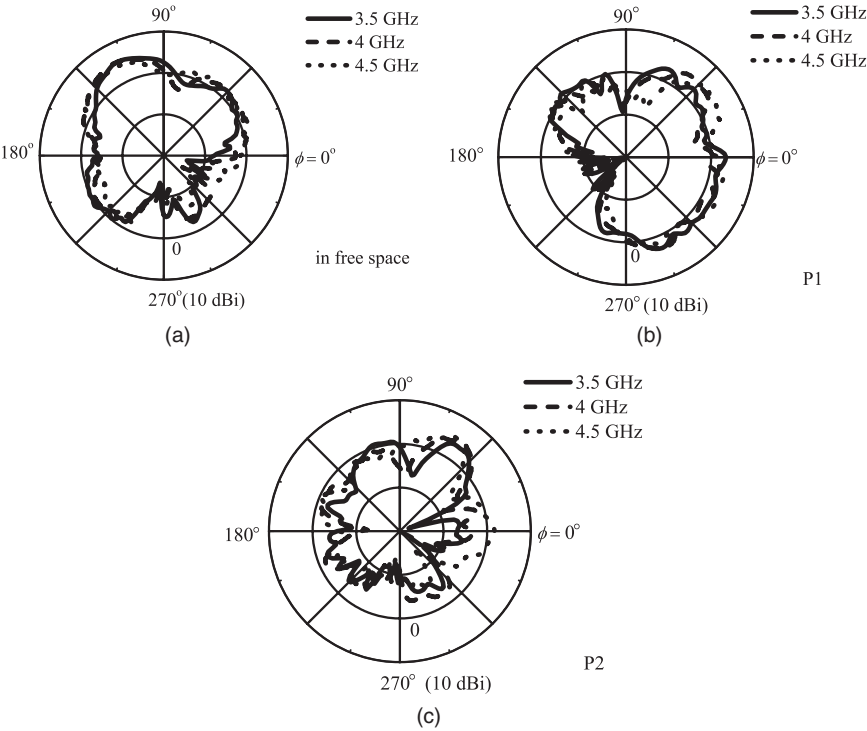

FIGURE 37-22 Measured gain patterns for total fields in the x - y plane (a) in free space and (b) for the antenna positions P1 and (c) P2 on the laptop

proximity of the laptop. The reflection from the cover leads to the stronger radiation from the antenna at P1 in the span of 160° – 90° – 0° – 270° than that within the rest range. The radiation for the antenna at P2 is nearly omnidirectional but with several nulls and lower gain than that for the antenna at P1 in most of the directions, although the blockage of the cover on the antenna at P2 should be less than that on the antenna at P1.

In short, UWB is a promising technology for short-range high-speed wireless communications. To accommodate the special requirements for the antennas, the traits of UWB systems should be studied carefully and effects of the installation environments on the antenna performance should be taken into account in the system's point of view, in particular for small and embedded antennas.

38.1 OVERVIEW OF ANTENNAS FOR MEDICAL APPLICATIONS

Antennas used for medical applications span applications in imaging, communication with implantable medical devices, heating for treatment of cancer, cardiac abnormalities, and hypothermia, measurement of fields for assessment of RF safety, augmentation of healing, and reduction of pain. Some of these applications have gained worldwide acceptance and are currently used with human subjects, and others are still in the research and development stage. This chapter describes the nature of the human body environment in which these antennas are commonly used, relevant regulations and guidelines, and the antennas and their applications.

38.2 THE ENVIRONMENT

The Regulatory Environment

There are two types of regulations of particular interest to designers of antennas for medical applications. The first is the allowable frequency. Applications that are used external to the body or for short periods of time (hyperthermia treatment, pain control, cardiac ablation, etc.) utilize the Industrial, Scientific, and Medical (ISM) bands (433, 915, 2450 MHz) in both the United States and Europe. Higher frequencies have the advantage of smaller antenna sizes, but the disadvantage of lower depths of penetration within the body. Implantable medical devices that are meant to stay in the body for a long period of time have been allocated a band of their own in the United States, the Medical Implant Communication Service (MICS) band from 402–405 MHz.¹ The maximum bandwidth that can be used by a single device is 300 kHz in this band. The maximum power limit is 25 μ W Equivalent Radiated Power (ERP).^{2,3} MICS shares its frequency allocation with the Meteorological Aids Service (METAIDS), which is used primarily by weather balloons, and is therefore specified for indoor use.

The second type of regulation of interest in the design of antennas for medical applications is the limit on allowable absorbed power in the body. The limits for whole-body exposure are generally not the limiting factor. Instead, limits on localized power are more critical. Localized power is defined by specific absorption rate (SAR), which is calculated as

$$\text{SAR (W/kg)} = \frac{\sigma |\bar{E}_p|^2}{2 \delta} \quad (38-1)$$

where σ is the electrical conductivity of the tissue (S/m), \bar{E}_p is the peak value of the electric field, and δ is the density of the tissue (kg/m^3). Localized SAR for nontherapeutic applications is limited to 2 W/kg in any 10-gram region of the body with an approximately cubic volume.^{4,5,6} An important exception is made in the new IEEE Safety Standard⁵ for the pinna (the outer ear) for an increased limit of 4.0 W/kg for the general public and 20.0 W/kg for occupational exposures. For therapeutic applications such as cardiac ablation and hyperthermia, the absorption limit does not apply, and care must then be taken not to damage surrounding tissues by overheating them.

The question of whether electromagnetic radiation causes harm to the body at nonthermal levels has been hotly contested and remains a topic of ongoing research. A focused

review of this research was completed by the NIEHS in 1999.⁷ Significant research and ongoing professional oversight have lead to today's RF exposure standards, which are meant to ensure safe levels of RF fields.⁸ Still, designers of antennas for medical systems should be aware of public fears that may accompany their use and should anticipate being asked to address this question.

The Physical Environment

Antennas used for medical applications are strongly impacted by the lossy dielectric materials that make up the human body. This presents challenges when antennas are used for a communication system, because the tissues absorb the power and detune the antenna. This depends strongly on the frequency and the location and depth of the antenna in or near the body, and significant variation can be seen from patient to patient. Figure 38-1 shows the electrical properties of muscle and fat as a function of frequency.⁹ At low frequencies, the conductivity of the tissue dominates the impact on the field, and at high frequencies, the dielectric values tend to dominate. Table 38-1⁹ shows the electrical properties of several different tissues in the body at 433 MHz, which is a commonly used ISM frequency. Muscle is highly conductive and therefore very lossy, whereas fat has lower conductivity and therefore lower loss. These two tissues are near extremes in the body. A common rough approximation is that the body can be modeled using average properties of 2/3 muscle. This is suitable for addressing global questions such as total power absorbed in the body, but is generally not suitable for evaluating near field effects such as peak SAR.

The lossy tissues in the body have several effects on antennas used for medical applications. When antennas are used for deliberately depositing power in the body for hyperthermia or cardiac ablation, for instance, the power tends to stay more localized around the antenna, where it is absorbed and converted to heat. For cardiac ablation or in vitro hyperthermia applicators, this is good, because it means that the heat will not penetrate to nearby structures that are not meant to be heated. For external, whole-body applicators for hyperthermia or for medical imaging applications, this loss means that it can be difficult to get the power to penetrate deep within the body. Lower frequencies are used when possible, and regions near the surface of the body (such as the breast) are easier to work with than areas deep within the torso. Multiple antennas must be used outside the body and focused in some way in order to get the power deep into the body.

For biotelemetry (communication) applications, the same types of problems are seen. Communication with subcutaneous implants loses less power in the body than communication with deep body implants, for instance. Power lost in the body has two effects: it is wasted and cannot be used for communication, and the RF exposure limits typically limit

the power that can be used for communication and hence the range or bandwidth of the system. Also, the lower the frequency used (to enable penetration and minimize power loss), the larger the antenna must be. Determining the exact impact of the body on the antenna generally requires precise calculation of the antenna in the presence of the human body. This typically requires numerical methods that are described in the next section.

Numerical Simulation of Antennas in or near the Human Body

Several methods for analyzing antenna arrays for medical applications exist.¹⁰ For simple cases where the biological structure can be approximated as uniform or by very simple models such as layers or cylinders, classical methods such as analytical analysis^{11,12} or method of moments^{13,14} can be used. If the structure of the body varies so much that anatomically precise modeling is rendered imprecise by variation between individuals, these simple analyses can be used to determine an optimal array design for the range of expected variation between individuals. An example of this was done in Hadley¹⁵ for design of coils for vascular MRI. Another example in which the body can be modeled as near-uniform is in the case of arrays for hyperthermia of the brain. In Furse and Iskander¹⁶ stepped-impedance dipoles were modeled using method of moments in an homogenous brain with a localized (nonhomogenous) tumor. Method of moments with a simple pulsed basis function (which is the most numerically efficient form) has limitations for heterogeneous models, however, due to artificial charge buildup on the dielectric interfaces.¹³ Higher-order basis functions can overcome this limitation, although the computational complexity is significantly increased.¹⁷ In addition, the method of moments is very computationally expensive when heterogeneous models are evaluated. It requires $N \log N$ computations, where N is the number of cells in the model, including those making up the heterogeneous object.

A more efficient method for calculation of heterogeneous objects is the finite difference time domain (FDTD) method, which has led to its tremendous popularity for numerical bioelectromagnetic calculations. For example, a interstitial array of hyperthermia applicators simulated using method of moments¹⁶ was simulated with a fraction of the computational resources using FDTD.¹⁸ Several individual hyperthermia applicators have been simulated using FDTD.¹⁹ FDTD requires N^2 computations, where N is a cell in the (normally cubical) FDTD grid. Unlike method of moments, every cell in space (including at least a minimal amount of air surrounding the model) must be included in the discrete model, so the total number of cells, N , is likely to be larger. However, the significant improvement in computational efficiency generally makes this trade-off favor FDTD for bioelectromagnetic simulations. Complete detailed analysis of breast cancer imaging modalities was also done

with FDTD,^{20–43} as well as hyperthermia systems,⁴⁴ and evaluation of cell phones (including those with dual antennas) near the human head.^{45,46} Antennas for implantation in the body (mostly microstrip or Planar Inverted F (PIFA) types) have been simulated with FDTD and in some cases optimized with genetic algorithms.⁴⁷ Deep hyperthermia applicators (annular phased arrays) have been simulated extensively with FDTD.^{48,49}

Several FDTD developments have been important for bioelectromagnetic simulations, including the development of frequency-dependent methods (FD)²TD,⁵⁰ low-frequency FDTD methods,⁵¹ efficient FDTD computation,⁵² and evaluation of temperature using the bioheat equation.⁴⁹

Model development is one of the significant challenges of numerical bioelectromagnetics. Models have progressed from the prolate spheroidal models of the human used during the 1970s⁵³ to roughly 1-cm models based on anatomical cross sections used during the 1980s⁵⁴ to a new class of millimeter-resolution MRI-based models of the body that have been the hallmarks of research since the 1990s.^{55–58} Today, probably the most widely used models are derived from the Visible Man Project.⁵⁹

Once a tissue-segmented model has been chosen, the electrical properties of the tissues are defined. The properties of human tissue vary significantly with frequency, so it is essential to use data accurately measured at the frequency of interest. There is a wide range of published data on measured tissue properties,^{53,60–71} and work is still underway to measure and verify these properties. These and other references are electronically searchable at the University of Utah Dielectric Database OnLine.⁷²

38.3 ANTENNAS FOR MEDICAL IMAGING

One of the most promising uses of antennas in medical applications is for imaging the location of leukemia,⁷³ breast tumors,^{20–43} and cardiac anomalies.^{74,75} Microwave imaging methods rely on the fact that the electrical properties of normal and malignant tissue are significantly different^{60–67} and that there is significant variation from tissue to tissue. Location of breast cancer shows particular promise, because its relatively low loss allows electromagnetic fields to propagate to the tumor and back, and the proximity of the tumor to the outer surface of the body means that the signal does not have more than a few inches to propagate. Two major microwave imaging methods utilize antenna arrays. Tomography^{20–27} attempts to map a complete electrical profile of the breast, and confocal imaging^{28–43} maps only the location of significant scatterers. Both of these methods have used antenna arrays made up of wideband elements to send and receive the test signals. Microwave thermography picks up the passive electromagnetic fields from the body.^{76–92} Magnetic Resonance Imaging (MRI) uses a strong magnetic field to cause the magnetic dipoles in the body to precess and then uses an array of loops to pick up the fields when they relax back to their normal state.^{11,93–113}

Tomography for Breast Cancer Detection

Microwave tomography is used to provide a complete spatial mapping of the electrical properties in the region of interest. During the acquisition phase, an array of antennas surrounds the region of interest. One of the antennas in the array is used to transmit a signal, normally a sine wave,²⁰ set of sine waves,^{21–22} or a broadband signal,²³ and all of the other antennas are used to receive the reflected signal. The array is scanned so that each antenna transmits each frequency, and these signals are received by each of the other antennas. After all of the data has been acquired, it is processed by comparing the received data with what

would be expected from a simulated model of the region. A numerical “forward model” is used to predict how much power is transmitted from the transmit antenna, passes into and reflects from the breast/tumor model, and is received by the receive antenna. Originally, the simulated model is just a good guess for what might be present, generally a generic breast model with no tumor. The differences between the measured and expected received data are used to modify the original guess to obtain an ideal model that best matches the measured data. This “inversion” is used to predict what model could have produced the measured data.

Microwave tomography for breast cancer has been demonstrated by several groups.^{20–27} In the Dartmouth system,²⁰ for instance, sine waves from 300–1000 MHz (being expanded to 3 GHz) are transmitted from a circular array of 16 transmit/receive monopole antennas, shown in Figure 38-2, to produce 2D reconstructed images of the breast. Quarter-wave monopole antennas (in the fluid) that were built by extending the inner conductor of semi-rigid coax were used for this application. Monopoles were chosen because they are easy to model as a line source in a 2D reconstruction algorithm with high accuracy.²⁰ Water-filled waveguide apertures have also been used for tomography, but the monopole antennas were found to be as accurate and easier to build.²⁴

Microwave tomography has been validated experimentally.²⁷ The presence of 1.1- or 2.5-cm saline tubes (representing tumors) in excised breast tissue are seen to be clearly visible.²⁶ Objects as small as 4 mm in diameter have been imaged at 900 MHz.²⁷

Confocal Imaging for Breast Cancer Detection

Confocal imaging for breast cancer detection is another exciting application of antenna arrays in medical imaging. Confocal imaging is similar to ground-penetrating radar. Unlike microwave tomographic imaging, this method does not provide a complete electrical mapping of the region of interest. Instead it identifies locations of significant scattering. This method typically uses a single antenna scanned in a flat array pattern above the breast or a cylindrical array of very small broadband antennas.²⁸ For planar imaging, the patient lies face up, and the antenna is physically scanned in a plane above the breast.^{29–31} For cylindrical imaging, the patient lies face down, with the breast extending into the cylindrical array

FIGURE 38-2 2D monopole array used for tomographic imaging of the breast (after P. M. Meaney et al²⁰ © IEEE 2000)

through a hole in the table.^{32,33} Matching fluid surrounding the breast, similar to that used for microwave tomography, is suggested in this case. Both methods provide similar results.³³ One antenna in the array transmits an ultrawideband (UWB) pulse, which propagates into the breast, where it is reflected off significant electrical discontinuities, and is received in parallel by the other antennas in the array. Knowing the physical spacing between the array elements, the different delays between the transmit antenna, scattering point, and receiving antenna can be calculated geometrically. The received pulses representing a specific point in space can then be time delayed appropriately for each antenna, added up, and integrated to indicate the magnitude of the scattered energy from that point in space. This is effectively correlating the signals received from that point at all antennas.

The antennas used for confocal imaging must be UWB and small enough to fit within the relatively small array area. Resolution of less than 1 cm requires a bandwidth of at least 5 GHz. The lossy nature of tissue attenuates high-frequency signals, limiting the upper frequency to about 10 GHz. Initially, resistively loaded bowties were suggested for the planar configuration,^{29–31,35,37} while dipole antennas were suggested for the cylindrical system.^{32,33} Resistively loaded Vee dipoles have also been proposed.³⁶ In the cylindrical configuration, multiple antennas are present in the array, although they are not simultaneously active. In the planar system, a single antenna is scanned over the surface, creating a synthetic antenna aperture. To overcome the inherent inefficiency of resistively loaded antennas, a modified ridged horn antenna operating from 1 to 11 GHz has been introduced.³⁸ Most of the antennas are designed to observe copolarized reflections from the breast; however, two resistively loaded bowtie antennas in the shape of a Maltese cross, as shown in Figure 38-3, have also been proposed to pick up the cross-polarized reflections.³⁰ Cross-polarized reflections from simple tumor models were also examined.^{34,39}

The antenna shown in Figure 38-3³⁴ consists of two cross-polarized bowtie antenna elements, an octagonal cavity behind the bowtie elements, and a metal flange attached to the cavity. The broadband bowties have flare angles of 45°. They are 1.67 cm long, which is a half-wavelength at 3 GHz in fat (similar to breast). The octagonal cavity blocks waves radiated away from the breast. The cavity is approximated as a circular waveguide filled with fat material for matching and size reduction. The first cutoff frequency is set to be

FIGURE 38-3 Cross-polarized antenna for confocal imaging. The properties of the substance inside the cavity and the medium outside the antenna are similar to fat ($\epsilon_r = 9$; $\sigma = 0.2$ S/m) (after X. Yun et al³⁴ © IEEE 2005).

2 GHz for 2 to 4 GHz operation. The cavity length is a quarter wavelength, which is 11 mm at 3 GHz. The flange consists of an inner and outer component, and is designed to block unwanted waves such as surface waves. The antenna performance does not change significantly when the flange size is varied between 10–6.25 mm, therefore, the width of the outer flange is set to be 6.25 mm. The inner flange is designed to prevent possible electric field overshoot at the inner corners of the opening of the octagonal cavity or at the ends of the bowtie elements. A slotline bowtie antenna has also been proposed.⁴⁰

A resistively loaded monopole antenna, shown in Figure 38-4, suitable for use in a cylindrical array was proposed by Sill and Fear.^{41–43} Based on the Wu–King design^{114–115} this antenna was designed to be usable from 1 to 10 GHz immersed in canola oil ($\epsilon_r = 3.0$) for matching to breast tissue. The antenna is fabricated using high-frequency chip resistors (Vishay 0603HF, by Vishay Intertechnology, Malvern, PA) soldered to a high-frequency substrate (Rogers RO3203 series by Rogers Corporation, Chandler, AZ). The substrate ($\epsilon_r = 3.02$ and $\sigma = 0.001$ S/m) has electrical properties similar to those of the canola oil. The antenna is soldered to a subminiature A (SMA) connector and attached to a metal plug for connection into the oil-filled test canister.

The cylindrical confocal imaging system has been experimentally tested.^{41,43,116} Simulated tumors as small as 4 mm have been detected using a 3D system.

Microwave Radiometry

Microwave radiometry is a passive method where the natural electromagnetic radiation or emission from the body is measured to allow detection or diagnosis of pathogenic conditions.⁷⁷ This method has been proposed for detection of breast cancer^{80,90,91} and brain cancer,⁸¹ in which the metabolism of cancer cells increases the localized temperature 1 to 3°C. This method has also been used for fluid and blood warming,⁷⁷ for detection of rheumatology,⁷⁹ and for monitoring temperature rise during hyperthermia treatment.⁷⁸

Typical antennas include open-ended rectangular waveguides,^{82–85} small-loop antennas,⁸⁷ and a horn antenna with a dielectric lens.⁸⁸ Working around 3 GHz, all of these antennas have radiation patterns that have minimal penetration into the body, thus strongly weighting them to monitoring of surface temperatures.^{89,92} Increased focus, and therefore better spatial accuracy, was obtained with an array of six rectangular aperture antennas filled with low-loss

FIGURE 38-4 Fabricated resistively loaded monopole antenna soldered to an SMA connector and attached to a metal plug (after J. M. Sill and E. C. Fear⁴³ © IEEE 2005)

dielectric ($\epsilon_r = 25$), which were scanned over the object of interest in an overlapping pattern. Preliminary results indicated promise for location of breast tumors.⁹⁰⁻⁹¹

Magnetic Resonance Imaging

Magnetic Resonance Imaging (MRI) uses a very strong magnetic field (0.5T, 1.5T, 3T, 4T, 7T, perhaps in the future 8T) to make the magnetic dipoles in the body precess (line up). When they are released, a set of receiver coils picks up the magnetic field created when these dipoles return to their normal orientations (position may change a lot as in blood imaging, diffusion, etc.). The relaxation properties of the different tissues affect the relative received signal intensities, and a 3D map of the body can be produced.

There are two basic types of receiver coils used for MRI. Volume coils, such as the quadrature birdcage head coil shown in Figure 38-5,¹¹ are used for imaging large and deep anatomic structures of the body and provide homogeneous field profiles. For high-resolution applications that are more localized, such as angiographic imaging, hippocampus imaging, and functional imaging, in which the object features are very small, volume coils pick up less signal and more noise, thus having a lower signal-to-noise ratio (SNR) and poor-quality images. Modifications such as the use of an RF reflector or “endcap,”¹¹ and modified shapes such as the elliptical⁹⁴ or “dome”^{95,96} coils, have been developed. Smaller-volume surface coils⁹⁷ have been shown to improve image quality, particularly when combined into phased arrays⁹⁸⁻¹⁰⁶ such as the one shown in Figure 38-6. Phased-array coils are closer to the area of interest, so they pick up larger signal strength, and are smaller, so they pick up less noise, thus having a higher SNR. They are designed to overlap so that the mutual inductance between coils is zero, and so that the impedance at the preamplifier is very low, for optimal SNR.⁸ Part of the price for this improved image quality is the complexity of the receiver and data acquisition system, as each antenna is received on an individual channel. The image processing is also more computationally expensive, as the signal from each antenna is weighted depending on its proximity to the target region (and hence expected relative SNR), phase shifted, and combined with the other similarly processed signals.

FIGURE 38-5 Quadrature birdcage coil with endcap used for whole-volume head imaging (reprinted with permission from J. R. Hadley et al¹¹ © *Journal of Magnetic Resonance Imaging* 2000)

FIGURE 38-6 (a) Two-element phased-array coil design. Dashed lines indicate the breaks in the underside of the double-sided copper section of the coil. (b) Image of finished phased-array coils (enclosed in foam) with triax balun cables and phased-array port connector box (reprinted with permission from J. R. Hadley et al¹¹ © *Journal of Magnetic Resonance Imaging* 2000).

Among the practical considerations that are challenging with phased-array coils are the data acquisition time and the limited field of view, particularly for applications where the region of interest (an arterial occlusion, for instance) may not be precisely known and is therefore easy to miss. Phased-array coils have been used for numerous magnetic resonance angiography (MRA) applications including peripheral^{107,108} abdominal, intracranial, and carotid imaging.^{109–111} Recent coil designs have started to integrate phased-array elements into volume-like coils with the ability to control how the image is constructed to achieve maximum image quality.^{112,113} For these applications, the coil array functions much like the phased array in a synthetic aperture radar application. The image quality for the different coil types and configurations depends strongly on the application. The optimal image construction algorithm depends strongly on the application and region of interest, making the flexibility of being able to synthetically develop large or small subarrays very attractive.

38.4 HEATING

Hyperthermia

Hyperthermia (HT)^{117,118} is a method of treating cancer by heating the body. The tissue is typically heated to 41 to 45°C for 30 to 60 minutes. Often, this involves focusing the energy on the tumor region, relying on the tumor to be more sensitive to heat than the surrounding healthy tissues. This may be due to poor internal vasculature of the tumor or its higher conductivity and permittivity caused by increased water and ionic content. HT has also been shown to increase the effectiveness of radiation or chemotherapy.^{119–120} The most commonly used frequencies for hyperthermia are 433, 915, and 2450 MHz. The type of antenna or antenna array used for HT depends on whether it is to be administered superficially, interstitially, or deep-body.

Superficial HT applicators include microstrip,¹²¹ waveguide,¹²² current sheets,¹²³ inductive,¹²⁴ and the dual concentric conductor antenna, or DCC, shown in Figure 38-7.^{125–128} The DCC is particularly attractive, because it can be easily fabricated on flexible, printed,

FIGURE 38-7 DCC antenna geometry, E fields in the ring slot and edge currents (after P. F. Maccarini et al.¹²⁶ © IEEE 2004)

circuit-board material, which makes it easy to conform to virtually any part of the human body. The DCC aperture is a ring-slot configuration fed simultaneously on all four sides. Prediction and optimization of the heating is normally done by analyzing the near fields of the antenna (the heating region) numerically.¹²⁶

Interstitial applicators for HT are typically monopole antennas made from coaxial cables with the center conductor extending beyond the outer ground shield of the cable.¹²⁹ These antennas have a tear-drop-shaped radiation pattern, so the majority of the heating is near the feedpoint of the antenna (where the ground shield stops), leaving the tip of the antenna extended beyond the useable heating range. The heating distribution can be made more uniform by varying the width of the conductor¹⁶ or adding a choke to the antenna.¹³⁰ Numerous other designs of interstitial applicators also exist. The heating pattern can be adjusted within the array by phasing the antenna elements¹⁶ or by using nonuniform insulation.¹³¹

Deep-body HT applicators are generally based on annular phased arrays (APA) of waveguides,¹¹⁸ coaxial TEM apertures,¹³² printed antennas,^{129,133} and induction systems.¹³⁴ Originally, APA systems contained only one ring of 2D applicators surrounding the patient. The ring could be scanned vertically. Significant improvement with a true 3D HT system with the applicators vertically offset has been observed.¹²⁹ The first clinically used 3D-type applicator is the SIGMA-Eye applicator (BSD Medical Corp., Salt Lake City, UT¹³⁵). A detailed description of this applicator and different numerical antenna feed models can be found in Nadobny et al.¹³⁶

Among the ongoing antenna design challenges in this area is the design of antennas that can be used to also monitor temperature and administer radiation therapy.^{128,133,137} One prototype combination device is shown in Figure 38-8 and another in Figure 38-9. Another research area is the use of optimization approaches to predict and control the heating pattern.^{138,139}

FIGURE 38-9 Schematic of combination applicator showing component parts: parallel catheter arrays for brachytherapy sources and thermal mapping sensors, PCB antenna array, and water coupling bolus (after P. Stauffer et al.¹³³ © IEEE 2004)

Treatment of Hypothermia

Patients who have experienced hypothermia are at great risk during the rewarming process. Conventional methods such as warm water baths use external sources of heat, which warm the peripheral regions while the heart is still cold. The demand for increased circulation to the extremities can overload the heart. EM applicators can produce deeper heating than methods that simply heat the body surface and rely on thermal conduction to carry the heat to the deeper tissues. EM heating provides heat deeper into the body, which increases cardiac output and circulates warmed blood to the peripheral tissues without overloading the heart.¹⁴⁰

Cardiac Ablation

Microwave catheter ablation uses monopole antennas inserted in catheters to the heart to treat cardiac arrhythmias by creating deep lesions that destroy the source of the arrhythmias. Frequencies of 915 or 2450 MHz are typically used.^{141,142} Ablation requires localized temperatures of 50–90° C for a short time, typically a few minutes. Microwave ablation has also been used in conjunction with traditional balloon angioplasty to soften arterial plaque.¹⁴³

38.5 COMMUNICATION (BIOTELEMETRY)

Wireless communication systems and their associated implantable antennas are needed for communication with implantable medical devices such as cardiac pacemakers and defibrillators,¹⁴⁴ neural recording and stimulation devices,¹⁴⁵ and cochlear¹⁴⁶ and retinal¹⁴⁷ implants. Designing antennas for embedded applications is extremely challenging because of reduced antenna efficiency, impact of the environment on the antenna, the need to reduce antenna size, and the very strong effect of multipath losses. In addition to the present needs for embedded antennas, the expansion of MEMS, which are expected to play a dominant role in next-generation technologies, will add dramatically to the applications for imbedded antennas. Ultra-small devices (small enough to be injected in a human vein, for instance) and the desire to communicate with them will inevitably lead to the need for miniaturized antennas embedded in lossy environments. Emerging medical telemetry devices have led

to recent advances in the design of small, biocompatible antennas that can be implanted in the human body.^{148–175}

Major challenges exist for implantable antennas. Not only do they have to be long-term biocompatible, but they must also be small, passive or highly efficient (to reduce battery requirements inside the body), and able to transmit power through the highly lossy body structure. In addition, they must meet the maximum SAR guidelines, which can be quite challenging. The very near field of the antenna is the inductive zone where power is not radiated. If lossy material is in the inductive zone of the antenna, which it normally is for implanted antennas, this near field power is absorbed and shows up in the SAR measurements or calculations. Thus, SAR is often the limiting factor for power transmitted from an implanted device.

In the majority of wireless telemetry cases for implantable devices, inductively coupled coils often wound around a dielectric or ferrite core are used.^{152–167,176} In these cases, the time-varying magnetic field generated by the primary coil is received by the secondary coil, which results in an induced current in the implanted coil. Frequencies are often lower than 50 MHz to ensure that the presence of the human body does not significantly obstruct the coupling between the coils. In this case, the most important parameters for the design of the telemetry system are the self and mutual inductances of the coils. Several methods can be used to determine these parameters depending upon the frequency of interest and the geometrical shape of the coils. For the simplest traditional coil geometries (circle, square), analytical approximations of self and mutual inductances are often used, whereas more sophisticated methods (such as the partial inductance method and similar methods) can be used in the case of geometrically complex coils. A measure of the quality of coupling between two coils is given by the coupling coefficient K between two coils ($0 \leq K \leq 1$), defined by

$$K = \frac{M_{12}}{\sqrt{L_1 L_2}}$$

where M_{12} is the mutual coupling between coils 1 and 2, and L_i is the self inductance of coil i . To maximize the power delivered to the load in these applications, usually a capacitor is inserted in parallel with the inductance of the coil and the resistance of the load to form a parallel resonant LC circuit. Many other parameters may affect the design of inductively coupled coils for biomedical telemetry systems, such as implant size, maximum power, temperature increase in the implanted device, and specific absorption rate of power (SAR given in W/kg) induced in the tissue.¹⁷⁷

Most inductive telemetry links are used for subcutaneous applications due to power restrictions for passive devices. Data rates are generally low, and size/weight and biocompatibility issues plague these devices. However, recent advances continue to reduce the power requirements and provide more biocompatible designs. The Utah Electrode Array (UEA), for example, uses a pickup coil printed on a ceramic substrate and integrated with the implanted neural electrode array, as shown in Figure 38-10.¹⁴⁵ The implanted coil is energized by an external inductive programmer/reader that powers the implanted circuitry while transferring telemetry data.

Radiofrequency links are also being developed for communication with medical implants. For cardiac telemetry, a dipole¹⁷¹ and spiral or serpentine microstrip,^{173,174} and a waffle-type patch¹⁷⁸ have been designed for implantation in the shoulder. An insulated wire antenna has also been used, and this wire may be used as the lead between the heart and the battery pack/controls of the pacemaker.¹⁶⁸ The antenna can be treated as a waveguide, where the lossy body acts as the outer conductor of the waveguide. The insulated antenna in tissue may be matched with a load resistor connected to the conducting tissue in order to reduce or eliminate the reflection.¹⁶⁹

FIGURE 38-10 Utah Electrode Array packaged with a custom ASIC and printed receiver coil (after K. Guillory and R. A. Normann¹⁴⁵ © *J. Neurosci. Methods* 1999)

Another type of antenna used for communication with cardiac devices is the circumference antenna, which is a monopole antenna that is mounted around the edge of the pacemaker case, as shown in Figure 38-11.^{169,170} The 94-mm-long circumference antenna shown in Figure 38-11 was centered in a plastic insulator with a thickness of 10 mm. The bandwidth where the SWR of this antenna is less than 2 is 42 MHz, which is larger than the required MICS allocation of 3 MHz.

For smaller implants, a microstrip patch antenna has been successfully used for a retinal prosthesis,¹⁷⁵ and a small dipole has been designed for communication with a brain implant.¹⁷²

Deep-torso devices will experience more loss than subcutaneous devices. Furthermore, the location in the body controls the radiation pattern shape as well as magnitude. For example, the calculated radiation patterns for a small, multiturn loop antenna implanted in

FIGURE 38-11 Circumference antenna on a pacemaker model (after A. Johansson,¹⁶⁹ Figure 5-3)

FIGURE 38-12 Calculated azimuthal radiation patterns for a 418-MHz vertical source: vertically polarized pattern (solid line) and horizontally polarized pattern (dotted line) (after W. G. Scanlon et al.¹⁵⁶ © IEEE 2000)

the vagina are shown in Figure 38-12. Measured net body losses (power absorbed in the body) for this 418-MHz antenna are 19.2 dB. The bodyworn radiation efficiency is

$$\eta_b = \frac{P_{\text{body}}}{P_{\text{air}}} = 1.2\%$$

where P_{air} is the total power radiated by the antenna in air, and P_{body} is the total power radiated (external to the body) by the antenna implanted in the body. At 916.5 MHz, the measured net body loss is 24.3 dB, and the bodyworn radiation efficiency is 0.37 percent.¹⁵⁶ The substantial losses in the body have so far limited deep-torso implants to communication with receivers held on or very near the body.

38.6 PULSED ELECTROMAGNETIC FIELDS

Pulsed electromagnetic fields (PEMFs) have been developed for a number of medical applications. These fields are generally delivered by electrodes connected directly to the body, and as such are not truly an application of antennas. However, since this method is showing significant promise for many different medical applications, and since UWB antennas are being used in many other areas, it is not unlikely that antenna design concepts could be applied to PEMF applicators in future applications.

Bone and Tissue Healing

Pulsed electromagnetic fields have been found to be highly effective for healing fractures and soft-tissue injuries, particularly those that do not respond to ordinary healing methods. As early as 1812, passing “electric fluids” through needles inserted in the fracture gap was found to stimulate bone healing, and by the mid-1800s, this DC current stimulation was

considered the method of choice for slow-healing fractures. Today's bone-healing PEMF systems typically use a 72-Hz single-pulse pattern. While the full biological mechanism is not minutely understood, it appears PEMFs of this type are able to retard the osteoclasts that destroy bone while increasing the rate of new bone formation.¹⁷⁹

Pain Control

Pulsed electromagnetic fields have also been used for controlling pain. Electrodes are placed strategically around the knee, shoulder, back, etc., and PEMF is applied. This has been found to provide both short- and long-term pain relief, although the exact reason is not fully understood. This method is currently used in both human and veterinary medicine.¹⁷⁹

Drug Delivery and Electrochemotherapy

Pulsed electromagnetic fields can be used for a wide variety of needle-less drug delivery applications. Iontophoresis is a method to electrically force drugs across a transdermal interface using a relatively small voltage (0.1–10 V) across the skin boundary. This method appears not to create structural changes in the cells or the skin, but rather just creates ion pathways that a conductive fluid (drug) will follow through pre-existing aqueous pathways. At present, a limited number of drugs can be delivered using this method.¹⁸⁰

Pulsed electromagnetic fields can also be used to treat cancer, using a new therapy called electrochemotherapy, which has been used for a variety of cutaneous tumors, including head and neck tumors, melanomas, superficial breast cancer lesions, etc. In this therapy, the resistance of malignant cells to penetration by certain chemotherapeutic agents is temporarily lowered by electroporation, which creates temporary pores (pathways) in the membranes of the malignant cells by the application of short DC pulses that generate electric fields of several kV/cm. Once the cells are porated, the chemotherapeutic agents can enter the malignant cells and destroy them. Electrochemotherapy not only can increase the efficacy of certain chemotherapeutic agents, but also can reduce side effects because malignant cells can be destroyed with much lower doses of chemotherapeutic agents than with conventional chemotherapy.^{180,181}

38.7 SENSING

In addition to receiving and transmitting power for communication or imaging and depositing power for heating applications, antennas can be used as sensors. Antennas are used as probes for dielectric properties and electric or magnetic fields.

Dielectric Measurement Probes

Measurement of the electrical properties of tissues has been done extensively to facilitate research, numerical modeling, etc. High-frequency in vivo and in vitro dielectric measurements of tissue are typically made using an open-ended coaxial probe.¹⁸² The coaxial probe is sensitive to material that lies within a fringing capacitance zone adjacent to the probe tip. A two-wire, dipole-type probe has also been used.¹⁸³ Another application of dielectric property measurements is in vivo measurement of brain fluid.¹⁸⁴

FIGURE 38-13 Miniature printed dipole antenna for measurement of electric fields to determine cell phone RF exposure compliance (H. Bassen and G. Smith¹⁸⁵ © IEEE 1983)

Electric and Magnetic Field Probes

Miniature electric field probe antennas have been designed for assessment of compliance of electromagnetic devices with RF exposure guidelines.¹⁸⁵ Measurement of SAR requires evaluation of the localized electric field, which should not be perturbed by the probe. This requires a very tiny electric or magnetic field receiver, such as the one shown in Figure 38-13. Because this probe is inherently sensitive to the polarization of the electric field, three perpendicular probes are used, as shown in the SPEAG probe in Figure 38-14. A magnetic field probe is also shown in this figure, with three perpendicular receiving loops.¹⁸⁶

38.8 FUTURE DIRECTIONS

The medical applications of antennas described in this chapter are by no means all inclusive. New technology is rapidly being developed, and creative new ideas continue to emerge. The basic capabilities of antennas to transmit information, deliver heat, sense electrical properties, and receive information for imaging will continue to lead to new applications for antennas in medicine. At the risk of tabloid-type predictions, the following are some expectations for where antennas will continue to grow in medical applications.

Communication with medical devices is an area that is rapidly expanding. The first medical devices were cardiac devices that had large battery packs and control systems and minimal data up/downlink requirements that could be managed in a doctor's office. Today these devices are pressing for higher data rates, real-time communication, and more efficient links. Their size has been continually shrinking and promises to shrink radically, due mainly to advances in battery technology. Emerging nerve stimulation or recording devices require far less power than cardiac devices, and therefore do not require batteries at all. Prosthetic nerve devices hold promise for artificial vision, hearing, smell, balance and muscle control, nerve "repair," and a new level of treatment of brain malfunction for Parkinson's disease, depression, epilepsy, and more. New packaging techniques and ultra-efficient electronics are driving the need for superminiaturized antennas. This demand is likely to grow dramatically with the success of microscale electronics, microfluidics, and microscale sensors and actuators. Smart pills have shown the capability of "untethered" communication systems in the body, and other applications are likely to utilize this freedom in the future, such as moving through the bloodstream for diagnosis or treatment.

Devices used for heating have either been large, external devices that attempt to focus power, or much smaller devices inserted through a vein/artery or laproscopic surgical opening. These devices are also likely to shrink in size with the miniaturization of electronics, providing opportunity for more precise control of heat delivery.

Although medical imaging is a relatively mature field, new methods and radical enhancements to mainstream methods continue to emerge. New antenna designs for imaging tend to be larger numbers (arrays) of small antennas. Enhancing the bandwidth while miniaturizing the antenna continues to be a focus in many applications. Arrays that are nonuniform and nonplanar are likely to be important in many applications. With the ability to place antennas in the body for medical implant devices, it would not be surprising to see the development of imaging systems that can be swallowed, injected, or placed in body orifices for better imaging of sensitive structures.

Antennas are an integral part of medical devices today, and hold promise to play a significant role in the development of emerging devices for future medical systems.

39.1 INTRODUCTION

Automobile communications are rapidly expanding with the emergence of many new telecommunication technologies (e.g., XM Radio and Sirius Satellite Radio, WiFi, Bluetooth, mobile TV, Dedicated Short Range Communication, etc.), as illustrated in Figure 39-1. This chapter reviews the antenna technologies that are being used for these various communication systems. In addition, this chapter reviews the antenna requirements as established by vehicle manufacturers in terms of radiation/reception characteristics, cost, aesthetics, reliability, functionality, repairability, design flexibility, RFI/EMC immunity, and buildability (i.e., the ability to place the antenna into the production process of an automobile assembly plant).

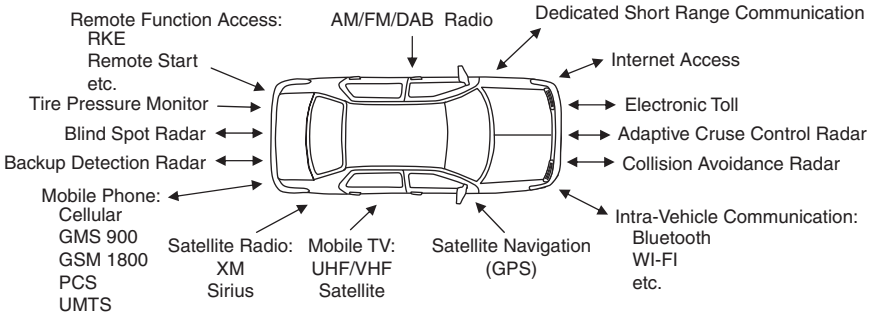

FIGURE 39-1 Mobile communication services

39.2 AM ANTENNAS

The AM broadcast frequency band is from 0.530 to 1.710 MHz with its wavelengths varying from 566 to 175 m. These wavelengths are considerably longer than the maximum dimension of any automobile antenna system (i.e., antenna element and vehicle body structure). Thus, the AM car antenna is considered to be a very small antenna.¹ Illustrated in Figure 39-2a is the geometry of an automobile at a height h (where $h \ll \lambda$) above the earth's surface, and its simple electromagnetic model is shown in Figure 39-2b. The AM impedance path through each wheel-bearing and tire structure (relative to the earth's surface) is modeled by a lump

FIGURE 39-2 AM frequency model for vehicle above earth's surface

impedance element (Z) while the vehicle-earth capacitance is modeled by a lump capacitor element (C). This capacitor can be approximated by using image theory and representing the undercarriage of the vehicle as a flat planar conductor at a height h above the earth's surface. The dielectric characteristics for various soil conditions (ranging from dry to 16.8 percent moisture) were measured at 1 MHz and found to range from a relative dielectric constant (ϵ_r) of 2.5 to 20 with a loss tangent ($\tan\delta$) of 0.017 to 4.0.² Dry soil has a low loss tangent and can be treated as a lossy dielectric, whereas moist soil has a high loss tangent and can be treated as a lossy conductor. The vehicle-earth capacitance is known to have a significant effect on the AM reception of the vehicle. This capacitance, for a medium-sized automobile, was measured to be approximately 250 pF.³

Early Automobile Antennas

Factory-installed vehicle radio systems began to appear in 1923 with the crude addition of a rather large receiver, antenna, battery, and speaker.⁴ The actual integration of the radio system into the vehicle had to wait until the early 1930s when vehicle manufacturers provided an in-dash radio with a factory-installed antenna. At that time, many of the exterior vehicle panels were made of composite materials (wood, canvas, glass, etc.) that allowed the development of a variety of hidden antenna systems: the Under-Car, Spare Wheel, Running Board, Rooftop Screen (commonly known as the Chicken Wire Antenna), Rooftop Wire (a long wire threaded into the fabric of the roof), and Retractable Mast Antenna (see Figure 39-3). Of these early systems, the rooftop screen antenna gave best reception due to its large size, height above ground, and location away from the car engine.

FIGURE 39-3 Early AM vehicle antenna systems

However, a major setback for this antenna came in 1934 in the form of the all metal “Turret Top” roof manufactured by General Motors, which was quickly adopted by other automobile manufacturers.⁵ The advent of the all-metal roof resulted in the mast antenna becoming the dominant vehicle antenna until the end of the 20th century. The length of these early mast antennas generally ranged from three to five feet. The longer the antenna element, the higher the AM gain, but the more unsightly it became.

Mast Antennas

A very short monopole antenna mounted on a perfectly conducting infinite ground plane has a radiation resistance given by the following expression (i.e., when the wavelength is much longer than the antenna length, antenna length is much longer than its radius, and current distribution is assumed to be triangular in shape⁶):

$$R_A = 40 (\pi\ell/\lambda)^2 \quad (39-1)$$

where ℓ is the length of the antenna, λ is the wavelength, and $\ell < \lambda/30$. This formula can be used to obtain a good approximation for R_A for antenna lengths up to $\lambda/8$. The reactance for a very short monopole is capacitive with values given by the following expressions⁷:

$$X_A \approx -60[\ln(\ell/a) - 1] / [2\pi\ell/\lambda] (\Omega) \quad (39-2)$$

and

$$C_A \approx [2\pi\ell/\lambda] / (60\omega[\ln(\ell/a) - 1]) (\text{F}) \quad (39-3)$$

where X_A is the antenna reactance, C_A is the antenna capacitance, a is the radius of the antenna element, ω is the angular frequency ($2\pi f$), f is the RF operating frequency, and $a \ll \ell$.

A typical automobile mast antenna has an average height (ℓ) of about 30 inches (0.76 m), and an average diameter ($2a$) of about 1/8 inch (3.2 mm). When this mast is mounted on a perfectly conducting infinite ground plane and operated at 1 MHz, it will have an ℓ/λ of 0.0025, a/ℓ of 0.0021, radiation resistance of 0.0025 Ω , reactive impedance of $-19.7 \text{ K}\Omega$, and capacitance of 8.1 pF. It should be noted that the reactive impedance is several orders of magnitude greater than the radiation resistance. Thus, this antenna can be viewed as a capacitor probe.

The radiation efficiency for a small monopole antenna is given by the following equation:

$$e = R_A / (R_A + R_{\text{Ohmic}}) \quad (39-4)$$

where e is the antenna radiation efficiency, and R_{Ohmic} is the ohmic loss of the antenna element. The typical automobile mast element is constructed of materials having high conductivity (e.g., Ni-Cr stainless steel with a conductivity $\approx 10^6/\Omega \text{ m}$) that results in the antenna currents being confined to the thin outer layer of the conductor. For this current condition, the following equation can be used to determine the ohmic loss of the antenna element⁸:

$$R_{\text{Ohmic}} = \ell R_s / 3P \quad (39-5)$$

where $R_s = (\omega\mu/2\sigma)^{1/2}$ is the high-frequency surface resistance, P is the circumference ($2\pi a$), μ is the permeability, and σ is the conductivity of the antenna element. A Ni-Cr stainless steel mast antenna with a height of 30 inches, diameter of 1/8 inch, operated at 1 MHz,

FIGURE 39-4 Efficiency of a very small monopole antenna

and mounted on a perfectly conducting infinite ground plane has an R_A of 0.0025Ω , R_s of 0.002Ω , R_{Ohmic} of 0.050Ω , and radiation efficiency of 4.7 percent. A plot of the efficiency versus frequency is contained in Figure 39-4 for the frequency range from 0.1 to 10 MHz. It should be noted that this simple antenna model does not take into account any of the effects associated with the vehicle body structure. The selection of the coaxial cable, from the antenna to the radio, is important in achieving quality AM reception. Shown in Figure 39-5 is a simple electrical model for the automobile's AM antenna-radio system (i.e., a Norton equivalent circuit with the negligible resistance and inductance components removed), where I_{AN} = induced short-circuit antenna current, I_R = current passing through the radio capacitor, C_A = antenna capacitance (including vehicle structure effects), C_C = coaxial cable capacitance, and C_R = radio capacitance.

The three modeled capacitors form a current divider circuit with the radio current given by $I_R = I_{\text{AN}} (C_R / (C_R + C_C + C_A))$. The input capacitance of the radio is about 75 pF, capacitance of the 30-inch mast antenna is about 10–15 pF, and antenna base-mount capacitance is about 15 pF. The length of coaxial cable for a front-mounted fender mast antenna is approximately 5 feet, while the length for a rear-mounted fender mast can be over 20 feet.

FIGURE 39-5 Norton equivalent circuit for vehicle AM antenna-radio system

Because of the increase in cable capacitance, the front-mounted mast antenna system (including its associated coaxial cable) has an effective AM gain several dB greater than a rear-mounted mast antenna system (assuming the same type coaxial cable is used for both antennas). In order to avoid excessive AM signal loss, the rear-mounted antenna requires the use of a very low-capacitance/length cable (<10 pF/ft), or possibly a pre-amplifier. A mast mounted in the center of the roof has the best reception because of its increased overall height and acceptable cable length (about ten feet). Unfortunately, a 30-inch roof mast antenna is viewed as being incompatible with vehicle aesthetics and more susceptible to damage (by low tree branches, garage door height clearance, car wash facility, etc.). Table 39-1 contains a chart that compares common automobile antennas. The fender-mounted mast was the dominant vehicle antenna until the end of the 20th century.

A retractable mast antenna consists of several segmented elements (making electrical contact with each other by means of sliding contacts), a storage cylinder for the retracted elements (located beneath the sheet metal of the fender), and an antenna feed system attached to the cylinder. It is viewed as a partially hidden antenna in that it can be lowered when the radio is not in use. Its AM characteristics are much like those of the fixed mast antenna, but it has a slightly lower AM gain resulting from the additional shunning capacitance of the cylinder-feed system.

Trunk Lid Antennas

The 1953 to 1955 Corvette had a unique hidden trunk lid antenna. This antenna took the form of a galvanized-steel screen⁹ embedded into the bottom surface of its fiberglass trunk lid. The center conductor of the radio coaxial cable was soldered to the screen (before it became a permanent part of the trunk lid). The outer shield of the cable was grounded midway between the antenna and radio with a ground strap that was attached to the underside of the body frame. This antenna had acceptable AM reception, but was replaced in 1956 by a retractable rear-mounted fender mast that cost less and was easier to service.

39.3 AM/FM MAST ANTENNAS

In the process of establishing the FM broadcast service (i.e., from 87.7 to 107.9 MHz), the Federal Communications Commission (FCC) determined that urban (man-made) RF electrical noise was predominantly vertically polarized (by about 10 to 20 dB). In an attempt to achieve the best quality of reception (i.e., signal/noise), the FCC initially selected horizontal polarization for FM broadcasting. However, the dominant vehicle antenna during the 1960s and until the end of the 20th century was the vertical mast antenna. Thus, the automobile mast antenna was being operated in a cross-polarized mode that lowered its reception gain by about 10 dB (i.e., the average horizontal polarization gain of a vertical mast is about 10 dB below its average vertical polarization gain). This problem was eventually addressed by the FCC by allowing most FM broadcast stations to transmit both polarizations. The result is that some broadcast stations transmit signals using both polarizations at equal power levels, some using circularly polarized signals, some using vertically polarized signals at lower power levels, some using only horizontally polarized signals, and a lesser number using only vertically polarized signals.¹⁰ Thus, the FM reception environment contains a mixture of both vertically and horizontally polarized signals having different power levels depending on the particular broadcast station and signal propagation conditions. To help determine real-world polarization characteristics of the FM broadcast environment, a limited polarization measurement survey was conducted using randomly selected FM broadcast signals (52) from a variety of suburban and rural locations. The result of this survey is plotted in Figure 39-6.

This data indicates that the majority of the measured signals are elliptically polarized with horizontal elliptically polarized signals (i.e., their horizontal component being greater than their vertical component) slightly more numerous (35) than vertical elliptically polarized signals (i.e., their vertical component being greater than their horizontal component) (27). Four signals were judged to be circularly polarized (i.e., differences between the horizontal and vertical polarized components being less than ± 1 dB while their phase differences being within $90^\circ \pm 10^\circ$). Six signals were judged to be horizontally polarized (i.e., differences between the horizontal and vertical polarization components being greater than 15 dB).

FM vehicle antennas should receive broadcast signals equally well from any direction. Hence, these antennas should be designed to have omnidirectional patterns in their azimuth plane. However, it has been demonstrated that the FM characteristics of an automobile antenna are very dependent on the structure of the vehicle. This is due to the various dimensions of an automobile (including its window openings) being comparable to the wavelengths of FM signals. Because of this vehicle body dependence, automobile manufacturers state their antenna specifications (i.e., gain, VSWR, max/min pattern values, etc.) for an antenna mounted on the intended production vehicle. These antenna specifications can vary from one automobile manufacturer to another.

FIGURE 39-6 Measured polarization characteristics of FM broadcast signals

The complex interaction of the antenna with the vehicle body prevents analytical techniques from being used in the design process of these antennas. The present limitations of EM simulation software and computer capabilities restrict their use to only approximate solutions. Thus, an iterative FM antenna design process is used that consists of the following steps:

1. Design a prototype antenna using simulation techniques and/or hands-on experience.
2. Build a reasonable facsimile of this antenna.
3. Mount the antenna on the intended production vehicle (or a reasonable mock-up of it).
4. Measure its RF characteristics.
5. Determine if the antenna meets the design goals and, if not, repeat the process.

This type of design approach is very time-consuming, costly, and demanding on supplier resources. However, there is an expectation that future advancements in EM simulation software and more powerful computers will provide the tools needed to more accurately design vehicle antenna systems and greatly reduce the need for an iterative design process.

Passive Mast Antenna

The AM/FM mast system is basically a monopole antenna having a height of about $\lambda/4$ at 100 MHz (i.e., about 30 inches). Placement of the mast antenna in the middle of the roof gives best gain for vertically polarized signals with nearly omnidirectional reception patterns. These patterns become more directional as the antenna is moved near the front, rear, and/or side edges of the roof. A tilted roof mast antenna has an increased

FIGURE 39-7 Common fixed AM/FM mast antenna locations

gain for horizontally polarized signals and reduced gain for vertically polarized signals (see Figure 39-7). Placement of the mast on the front or rear fender will reduce AM/FM gain and increase FM pattern directionality. However, the aesthetic benefit of a fender-mounted antenna generally outweighs the minor degradation in its reception performance. In addition, moving a fender mast closer to or further away from the vehicle's pillars will affect its FM characteristics.

The retractable AM/FM mast antenna consists of multiple sliding elements, or a single sliding element (see Figure 39-8). The multiple-element antenna is generally mounted on the passenger side of the front or rear fender, while the single-element antenna is generally mounted at the driver side of the roof pillar where it can be manually raised and lowered by the driver. The AM/FM characteristics of these antennas are similar to those of the fixed mast, with the AM gain being slightly lower because of the additional capacitance from the cylindrical-tube feed system.

The power mast antenna consists of several sliding antenna elements, an electric motor for raising and lowering these elements, a cylindrical tube for storing the retracted elements (located beneath the sheet metal of the vehicle), and an antenna feed system, generally attached to the side of the storage cylinder. Common locations for this type of antenna are on the passenger side of the front or rear fender. The power mast is raised when the vehicle radio is turned on and lowered when the radio is turned off. Hence, these antennas

(a) Fixed-length mast antenna (b) Retractable mast antenna (c) Power mast antenna

FIGURE 39-8 Production mast antennas (Courtesy of Hirschmann Car Communication, Inc.)

are hidden when not in use. The AM/FM characteristics of these antennas are similar to those of fixed mast with a slightly lower AM gain resulting from the additional shunning capacitance of the storage cylinder and antenna motor drive mechanism.

Active Mast Antennas

The active mast antenna became commercially available in the early 1970s. The fundamental advantage of this type of antenna is a reduced physical length (e.g., 16 inches), which is achieved by adding an AM/FM pre-amplifier module at its feed port. This module consists of two separate pre-amplifiers: one for the AM band and another for the FM band. Pre-amplifiers are susceptible to strong signal degradation and must be designed to be highly linear devices with signal-level conditioning circuitry to reduce overload, cross-modulation, and intermodulation effects.

The AM pre-amplifier is basically a buffer amplifier with a voltage gain of unity, high input impedance (Z_{in}), low output impedance (Z_{out}), and power gain of Z_{in}/Z_{out} . To reduce antenna loading, the input impedance of the amplifier is much greater than the AM reactive impedance of the antenna. To reduce coaxial cable loss, the output impedance of the amplifier is much smaller than the reactive impedance of the coaxial cable. The FM pre-amplifier generally has a gain of several dB, and a good impedance match with the coaxial cable.

39.4 AM/FM WINDOW GLASS ANTENNAS

The dimensions of the vehicle and its enclosed compartments (i.e., passenger, trunk, and engine compartment) are electrically small compared to the wavelengths of AM broadcast signals. Therefore, an AM signal that propagates into these compartments is significantly attenuated, and the reception characteristics of an AM antenna placed within these compartments will be greatly reduced. However, the placement of an antenna in a nonconductive outer panel of the vehicle can significantly circumvent this attenuation phenomenon, as was demonstrated by the early AM roof screen, roof wire, and trunk lid antennas. This signal attenuation phenomenon is less of a problem at FM frequencies where the dimensions of the vehicle and its enclosed compartments are comparable to the wavelengths of the FM signals. At the beginning of the 21st century, the placement of AM/FM antennas in vehicle windows became a very common practice. This mounting technique is analogous to a cavity-back antenna system where the vehicle cavity is below the cutoff frequency for AM, but potentially near resonance at FM frequencies. The characteristics of these window antennas are very dependent on the vehicle body structure, and this strong dependency requires that these antennas be designed specifically for the vehicle on which they are to be used. There are three fundamental types of AM/FM window antennas:

- Fine-wire in-glass antenna
- Frit on-glass antenna
- Transparent conductive film in-glass antenna

Fine-Wire In-Glass Antennas

The windshield is formed by a heat laminating process that binds together two pre-cut glass sheets (i.e., an outer and inner sheet) with a sheet of polyurethane adhesive material (sandwiched between the two glass sheets). The fine-wire windshield antenna

required an additional manufacturing step of adhering fine wires to the polyurethane sheet before lamination. These wires had a very small diameter (in order to successfully insert them in between the glass sheets) and were coated with a dark dull color (to make them less visible).

The GM passive wire windshield antenna was the first production wire in-glass antenna, which was introduced in the 1969 Pontiac Grand Prix.¹¹ It was constructed using two 0.003-inch-diameter wires that were formed into inverted L-shaped geometries, as shown in Figure 39-9. The inclined vertical wire elements were designed to capture AM broadcast signals, while the horizontal wire elements were designed to act as load elements (i.e., capacitively coupled with the front edge of the roof). Its AM capacitance was approximately 40 pF and the AM gain was several dB below the 30-inch mast antenna. For FM operation, the wire elements were similar to bent $\frac{1}{2}\lambda$ mast antennas, with resonance achieved by selecting appropriate lengths for the inclined vertical and horizontal elements, gap width between the inclined vertical elements, and gap widths between the horizontal elements and the front edge of the roof. The FM impedance was approximately 210 Ω and the FM gain was several dB below the 30-inch ($\lambda/4$) mast antenna. In addition, the FM antenna patterns of the windshield antenna were more directional than those of the mast antenna.

The antenna wire was connected to the radio's coaxial cable at a small half-oval shaped opening that was designed into the outer glass sheet of the windshield at its bottom center edge. The two antenna wires and a small pigtail lead were fastened to a thin copper strip that was attached to the polyurethane sheet material. The small half-oval opening was hermetically sealed to protect the connection from weathering effects. The center conductor of the coaxial cable was connected to the pigtail lead, while its outer shield was attached to a DC grounding strap. This feed location placed the antenna terminals very close to the engine and instrument panel (IP), exposing it to high levels of electrical noise. The result was that the quality of its AM reception (signal-to-noise ratio, or SNR) was significantly lower than that of a front-mounted fender mast. To help improve reception, extra RF noise-suppressing techniques were used for the engine, a grounded sheet of aluminum foil was positioned beneath the IP padding, and grounding straps were mounted between the hood and engine firewall.

Other types of passive fine-wire antenna systems were investigated but did not achieve the same acceptance as this windshield antenna. However, AM and FM pre-amplifiers have been used to improve the gain characteristics of these antennas. This approach was employed for a number of European vehicles starting in the mid-1980s.¹² These antennas were constructed in a similar fashion as that of the passive windshield antenna. An example of this type of active windshield antenna is shown in Figure 39-10. The embedded wire had an inverted U-shape geometry with wire lengths and gap spacings selected for best reception. The AM and FM pre-amplifiers were located at the base of the pillar.

FIGURE 39-9 AM/FM wire windshield antenna

FIGURE 39-10 AM/FM active windshield antenna

Frit On-Glass Antennas

The first frit on-glass antenna was located in the rear window of the automobile, where the rear window defogger lines were used as the antenna elements with suitable RF interface circuitry placed between the defogger grid and the coaxial cable. The geometries of these antennas were dictated by the design requirements for the rear window defogger. The defogger grid consists of equally spaced parallel lines connected at each end to frit bus bars. The defogger frit material is a paste-type mixture of silver, ceramic, and a vitrifying binder material that is "silk-screened" on the inside surface of the rear window and heat treated to fuse the frit paste to the glass surface. The result is a low-resistance material having an extremely strong bond to the glass. The resistance of the defogger line is controlled by its width, which is usually about 0.8 mm with a resistance per unit length of approximately $0.17 \Omega/\text{inch}$. The bus bars are significantly wider (about 12.7 mm) to provide a low-resistance feed path for the DC heater current. Experience has demonstrated that these finite conducting frit lines can be used for AM/FM antenna purposes.¹³ However, the early passive rear defogger antennas (e.g., see Figure 39-11) were unacceptable because of their poor AM/FM gain and impedance mismatch.

A different rear window antenna geometry that uses additional frit lines located in the region above the defogger grid (as shown in Figure 39-12) was determined to have acceptable AM/FM performance.¹⁴ Its AM gain was several dB below the gain of a mast antenna, but its SNR was found to be equal to both the mast and active backlite antennas (when mounted on this same type vehicle). It was determined that vehicle radiated noise was the dominant noise received by these antennas in fringe reception areas. This was validated by reception

FIGURE 39-11 Early passive rear window antenna

FIGURE 39-12 New passive rear window antenna

FIGURE 39-13 Early active rear window antenna

tests conducted in a large number of AM fringe broadcast environments that were located throughout the continental United States. The only noticeable difference in AM reception was the radio seek function, which was corrected by changing the seek reference level of the radio from 62 μ volts to 18 μ volts.¹⁵ This antenna was placed into production in 2001.

Advancements in AM/FM pre-amplifiers and impedance matching circuits have significantly improved the performance of the rear window antennas. This has resulted in rear window antennas being the dominant AM/FM type of automobile antenna at the beginning of the 21st century. Shown in Figure 39-13 is one of the earlier active defogger antennas.¹⁶ Like the mast antenna, the defogger antenna is a small capacitive type AM antenna with its capacitance ranging from 75 to 400 pF depending on its geometry and proximity to the vehicle sheet metal. Its AM impedance is high (e.g., a reactive impedance of 2 k Ω for an antenna with a 75 pF capacitance at 1 MHz) compared to the low impedance of the defogger heater supply circuit. To AM isolate this antenna from the defogger heater supply circuit, a bifilar choke was placed between the antenna tap-off point of the grid and heater supply connection. An AM buffer amplifier was placed at the antenna port with its output connected to the radio's coaxial cable via an RF choke. An FM choke was placed in-series with the bifilar choke for FM isolation purposes. Acceptable FM reception is achieved with the use of an impedance matching circuit and a low noise pre-amplifier having a gain of several dB. This antenna was popular in Europe where fringe reception was not as critical an issue as it is in the United States. The FM reception was reported to be good for horizontal polarization (for application in Europe) and vertical polarizations (for application in the United Kingdom).

The next evolutionary step for the active rear window antenna was to add some additional frit patterns above and/or below the defogger grid. The addition of these separate frit lines eliminated the need for the bifilar choke, thereby eliminating some rather heavy components.¹⁷ An AM pre-amplifier, FM pre-amplifier, and matching circuit module was added, as shown in Figure 39-14. Many rear window antenna geometries have been placed into production by automobile manufacturers with no clear indication as to which provides best reception. The search for a universal antenna geometry that works well on all vehicle body styles does not yet exist, and may have to wait until adequate simulation software becomes available. The frit side-window antenna is another form of active antenna that is a very common on-glass antenna for SUVs.

FIGURE 39-14 Active rear window antenna

FIGURE 39-15 Solar-ray windshield antenna

Transparent Film In-Glass Antennas

The transparent conductive film antenna consists of a shaped film (with a sheet resistance of about 4 ohms per square) placed between the windshield's inner and outer glass sheets.¹⁸ The film consists of multiple layers of an antireflective metal oxide layer (e.g., oxide of zinc and tin), an infrared reflective layer (e.g., silver), and a primer layer (e.g., titanium).¹⁹ These multiple layers are sputtered on the inside surface of the outer glass sheet and are used for both solar control (i.e., infrared heat-load reduction) and antenna purposes. The film geometry has an upper horizontally elongated principle element parallel to the upper edge of the windshield opening with a length of a quarter wavelength at 100 MHz (see Figure 39-15). A small vertical film element connects the lower edge of this principle element to the upper edge of a much larger lower secondary element that covers the entire nondarkened region of the windshield. The upper horizontal edge of the lower element is located at a distance below the lower edge of the upper principle element so that coupling between them is minimal. The side edges and lower edge of the lower element form a parasitic slot transmission line with the sheet metal of the vehicle. The effective length of this slot transmission line is a multiple of half wavelengths (i.e., at 100 MHz). This lower secondary element is used as an impedance matching device for the principle element at FM frequencies and to increase AM gain. The antenna feed port is located at the upper center edge of the windshield, and can be either directly connected or capacitively coupled (by means of an added frit grid on the inside surface of the windshield) to the principle element.²⁰ The AM gain for this antenna is greater than or equal to that of the mast antenna (depending on the antenna feed coupling technique) while its FM gain and pattern characteristics are comparable to those of the mast antenna.

39.5 AM/FM PANEL ANTENNAS

The use of nonconductive vehicle body panels (i.e., other than the glass windows) for antenna purposes was investigated by a number of groups over the past decades. These panels included the roof, trunk lid, hood, side body section, bumper, roof rack, spoiler, etc. In general, these types of antennas have poor antenna characteristics and are difficult to

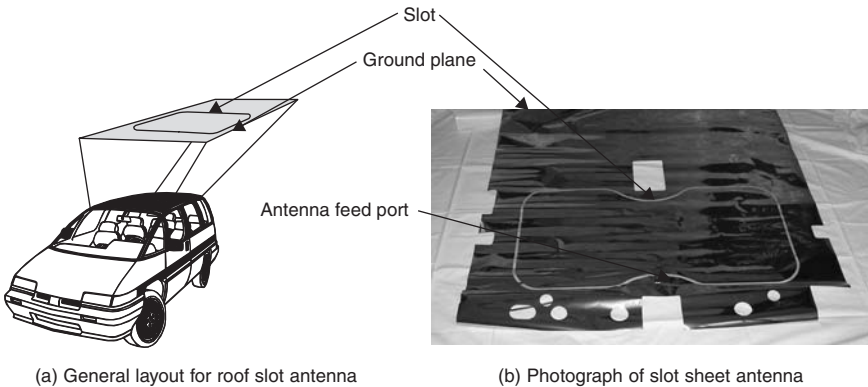

FIGURE 39-16 Roof slot antenna

incorporate into the vehicle production process. In addition, replacing a sheet metal panel with a composite panel has proven difficult for vehicle manufacturers because of fit-and-trim difficulties, “orange-peel” paint-finish concerns, and cost.

One successful application of a panel antenna was the GM APV roof slot antenna that was placed into production in 1992.^{21,22} This vehicle had composite outer panels that permitted the placement of an annual slot sheet antenna in between its roof panel and headliner (see Figure 39-16). The antenna consisted of a copper film (one micron thick) sputtered on a 1-mil polyester sheet that included an etched 6-mm-wide slot gap having a slot perimeter of about 3.0 m. A thin protective overcoat was placed on top of the copper film to mitigate atmospheric corrosion effects. The antenna feed port was located at the front center point of the slot, with the inner conductor of the coaxial cable connected to the inner copper portion of the antenna, and its outer shield connected to the outer copper portion of the antenna. The AM gain for this antenna was several dB greater than a front fender mast antenna, while its FM characteristics were comparable to those of the mast antenna. A smaller slot antenna with a side feed connection and capacitive load elements was placed into production in the GM 1997 Impact Electric Vehicle.

39.6 FM DIVERSITY ANTENNAS

With the increase in demand for high fidelity FM radio performance, vehicle manufacturers are giving greater attention to reducing the adverse reception effects associated with vehicle movement (i.e., turning corners, traveling in regions of signal blockage, etc.) and multipath signal conditions. These effects can be significantly reduced by using various antenna diversity techniques: space diversity, field-component (polarization) diversity, angle (lobbing antenna pattern) diversity, frequency diversity, and time diversity. However, the general driving public has a negative view of placing several mast antennas on its vehicles. To avoid this porcupine appearance, OEMs generally favor the use of one mast antenna in conjunction with a window glass antenna, or multiple window glass antennas. The outputs of these antennas are processed to obtain best reception using a number of known diversity algorithms such as switch, maximal-ratio, equal-gain, and feed combination.²³ These diversity antennas have a variety of geometric shapes and use multiple locations about the vehicle.²⁴

39.7 RKE AND TPMS ANTENNAS

The remote keyless entry (RKE) and tire pressure monitoring system (TPMS) both operate at the same frequency (315 MHz with a 1-MHz bandwidth) using low RF power levels (to preserve battery life).

RKE Antennas

About 80 percent of U.S. cars are sold with RKE systems that consist of a key fob transmitter and a vehicle receiver system for locking/unlocking vehicle doors, unlocking the trunk, and activating an emergency alarm system. The majority of RKE systems use one-way (simplex) communication from an “activated” key fob (i.e., activated by pressing one of the fob buttons) to the vehicle, while more complex systems use two-way communication (half-duplex) to establish an additional channel from the vehicle to the key fob. The two-way system incorporates a “passive” feature where a vehicle’s transmitter is continuously polling to detect the presence of its corresponding key fob. Initially, the “activated” key fob system had a range capability of about 15 m while the “passive” key fob system had a range of about 1 to 2 m. However, the addition of the remote-start function has resulted in an increase in operating range to about 150 m with interest to extending it to 500 m or more. RKE antenna specifications are commonly stated in terms of its operating characteristics. For example, it may be required that the minimum operating distance of the system be measured every 15 degrees about the vehicle with at least 90 percent of these distances being greater than 15 m.

The antenna inside the fob is generally a small printed-circuit loop antenna that couples through the user’s “hand-arm-body,” thereby creating an effective “extension” of the fob’s antenna. The arm and body position of the user has a significant impact on the antenna’s operating range. However, some of the newer longer-distance operating systems are using dielectric fob antennas that greatly reduce this coupling. The RF path loss between the fob transmitter and RKE receiver depends on the distance between them, the height of each, and reflection characteristics of the earth’s surface. The transmitted RF signal travels along a direct path, and a reflected ground path. These two signals will combine or interfere with each other causing the received signal power to fluctuate about its expected inverse square of the distance (“free space”) characteristic for distances less than 10 m and inverse fourth of the distance characteristic for distances greater than 10 m.²⁵ These propagation characteristics must be taken into account in the RKE’s power budget considerations.

The receiver antenna located inside the vehicle can be mounted internal or external to the receiver box. An internal antenna is generally a wire, meander-line, or loop that is designed to fit inside the plastic housing of the receiver. This arrangement requires the antenna to be fairly small and in close proximity to the receiver’s electronic circuitry (thereby potentially creating self-induced EMC problems that reduce receiver sensitivity). An external antenna can avoid the size restriction and self-induced EMC problems. An external antenna requires the addition of a coaxial cable and an appropriate antenna mounting location. The use of an external antenna significantly increases the operating range of an RKE system over that of an internal antenna. A “hands-free” (passive) RKE system can require up to five antennas (mounted in different locations throughout the interior of the vehicle) to improve azimuth coverage and to determine the fob location (e.g., inside or outside the vehicle).

TPMS Antennas

The function of the tire pressure monitoring systems is to measure the pressure and temperature inside the tires of the vehicle. The majority of these systems use a battery-type

(a) TPM value stem sensor

(b) Normalized simulation results

FIGURE 39-17 A TPM system (after H. J. Song et al²⁶ © IEEE 2004)

microprocessor module to monitor the pressure and temperature of each tire, and an RF transmitter to transmit this data to an in-vehicle receiver. To help extend the microprocessor's battery life (to ten years), a motion sensor is used to control the data transmitting rate (e.g., a longer rate when the vehicle is parked, and a shorter rate when it is in motion). A vehicle with a TPMS can have as many as five transmitting antennas (including one for the spare tire) and one receive antenna. The tire sensor is usually mounted on the drop-center of the wheel or as part of the wheel's valve stem assembly as shown in Figure 39-17a.²⁶ The valve stem antenna is a very small antenna with a length of about $\lambda/100$. Plotted in Figure 39-17b²⁶ is simulated data for a four-wheel TPMS system with a maximum max/min value of 35 dB that was in close agreement with experimental data. TPMS antenna specifications are commonly stated in terms of the system's operating characteristics, and can take the form of sensor operating status versus the angle of rotation for each wheel.

39.8 UHF/VHF TV ANTENNAS

The recent introduction of DVD television systems into the U.S. automobile and SUV market has generated interest in the possible addition of a mobile terrestrial TV system in U.S. vehicles. The cost of these systems is a significant consideration since a good mobile TV system requires a complex diversity receiving system with several vehicle antennas that operate over a very wide frequency bandwidth (i.e., 54–88, 174–216, and 470–806 MHz). This system should really consist of two separate sub-diversity systems: one for picture quality and another for audio quality.²⁷ The quality of reception will improve as the number of antennas is increased, with a minimum of four antennas needed for satisfactory picture and audio reception. The picture and audio sub-diversity systems can use the same diversity antenna system, but each will require its own signal processor module. Similar types of mobile TV systems are common in both Europe and Japan, but to date they have not been widely accepted by the U.S. motoring public.

39.9 MOBILE TELEPHONE ANTENNAS

In 1974, the FCC allocated two 20-MHz bands in the 800 to 900 MHz region for cellular telephone use. The rapid growth in the use of cellular telephones has resulted in both of these bands being increased by an additional 5 MHz. The cellular system was designed to operate as a full-duplex system requiring simultaneous transmission in both the downlink direction (from the tower to the cell phone) and uplink direction (from the cell phone to the tower). To avoid interference between transmit and receive channels, a 45-MHz guard band was allocated between them, as listed in Table 39-2. This cell phone technology was followed by the addition of the Personal Communication System (PCS) in the United States and the Global System for Mobile Communication (GSM), which is the de facto wireless telephone standard in Europe. Wideband Code Division Multiple Access (W-CDMA) is a new 3G global cellular technology that is presently being launched into commercial service.

Dual-band phones operate in two separate frequency bands such as cellular and PCS (for North America), or GSM 900 and GSM 1800 (for Europe, Asia, etc.). Tri-band phones operate in cellular, PCS, and GSM 1800 (for North America, with limited use in Europe, Asia, etc.), or GSM 900, GSM 1800, and PCS (for Europe, Asia, etc., with limited use in North America). Finally, quad-band phones operate in all four of the mobile bands (cellular, GSM 900, PCS, and GSM 1800), permitting their use on a global basis.

Shown in Figure 39-18 are some typical geometries for cell phone mast antennas. A short mast antenna (i.e., height $\leq \lambda/4$) is commonly mounted on the vehicle roof to achieve good gain performance and near omnidirectional radiation/reception patterns in the azimuth plane. However, pattern characteristics of these short antennas are strongly dependent on the sheet metal of the vehicle. A short mast mounted near the center of the roof will have best gain and near omnidirectional patterns. As the mast antenna is moved near the edge of the roof, its gain can decrease and radiation/reception patterns become directional. To help avoid car body effects, a collinear antenna can be used with a $\lambda/2$ vertical antenna element positioned above and connected to a helical-coil positioned above and connected to a $\lambda/4$ mast antenna element. The collinear antenna is generally considered to be independent of a ground plane and is commonly used as an on-glass mounted antenna where its increased height will raise its top element above the roof line of the vehicle, providing an unobstructed azimuth view. A low-impedance adapter is used to couple the RF energy from the antenna through the glass window to the radio coaxial cable.²⁸ Antenna specifications as supplied by automobile manufacturers generally require a gain similar to that of a center roof-mounted $\lambda/4$ mast with omnidirectional radiation/reception patterns (within \pm a few dB) in the azimuth plane. Diversity reception techniques are being investigated to improve mobile telephone reception.²⁹

TABLE 39-2 Land Mobile Telephone Systems

System	Coverage area	Uplink (MHz)	Downlink (MHz)
Cellular	North America	824–849	869–894
GSM 900	Europe	880–915	925–960
GSM 1800	Europe	1710–1785	1805–1880
PCS	North America	1850–1910	1930–1990
WCDMA	World wide	1920–1980	2110–2170

FIGURE 39-18 Typical cellular telephone mast antennas

The requirement by vehicle manufacturers for multiband antenna systems (i.e., with an aesthetically pleasing appearance) has motivated the development of a family of meander-line antennas. These antennas are basically mast antennas designed with a meander-line pattern³⁰ to effectively increase their electrical length to a near resonance condition while limiting their overall physical height to be less than $\lambda/4$ (see Figure 39-19 and Delphi's web site³¹). These types of antennas have been designed using a genetic algorithm technique and will generally require a matching circuit.

Multiband planar inverted F antenna (PIFA) technology has been investigated for vehicle mobile communication purposes. Although these type antennas have been used successfully in mobile telephones and laptop computers, their physical size and on-vehicle directional patterns have not met OEM requirements.

39.10 GPS ANTENNAS

The Global Positioning System (GPS) uses 24 satellites placed in six orbital planes (four satellites in each) that are equally spaced and inclined at a 55-degree angle relative to the equatorial plane of the earth. The altitudes of these satellites are such that they repeat the

FIGURE 39-19 Multiband vehicle antenna system (Courtesy of Delphi)

same orbit trace over the earth's surface about every 24 hours. This provides a GPS user with potentially five to eight usable satellites from any point on the earth's surface. Each satellite transmits a right-hand circularly polarized (RHCP) signal at a carrier frequency of 1575.42 MHz. This signal is modulated with a unique Pseudo Random Noise (PRN) code within a 1-MHz bandwidth. The PRN code is used to identify which satellite generated a particular GPS signal. These signals are then used to mathematically determine a receiver's position (longitude, latitude, and elevation) by determining its distance from at least four satellites (i.e., using measured time delays) and applying triangulation techniques. The fourth distance is required to determine a precise-time variable that is used in the solution process (x , y , z , and t). The Standard Positioning Service (SPS) is specified to provide accuracies of better than 13 m (95 percent) in the horizontal plane, 22 m (95 percent) in the vertical plane, and 40 ns (95 percent) in time.³² The use of Differential GPS (DGPS) techniques can improve positioning accuracy to within a few meters.

An automobile GPS antenna should be compact, lightweight, reliable, low cost, and easily integrated into the automobile production process. Its beamwidth needs to encompass the greater portion of the hemisphere above the earth's surface (i.e., omnidirectional reception). An example of a GPS antenna pattern is shown in Figure 39-20. The roof is the best mounting location for this type of antenna because it is the highest point on the automobile, providing an unobstructed view of the upper hemisphere, a nearly horizontal mounting surface, a relatively safe site from damage, and easy access for maintenance purposes. The antenna should be kept several inches from the edge of the roof, thereby reducing edge diffraction effects to acceptable levels. If the vehicle has a sunroof, the antenna should be

FIGURE 39-20 Example of an elevation pattern for a GPS antenna

kept several inches from the edges of both the roof and sunroof. Other possible mounting locations include the uppermost central region of the windshield, uppermost central region of the rear window, trunk lid, instrument (dash) panel, and rear packaging shelf. However, these mounting locations were determined to be less desirable in that they generally have an adverse impact on the pattern characteristics of the antenna (e.g., signal blockage effects).

The design process for a GPS antenna begins with an “off-vehicle” phase where the proposed antenna is mounted and tested on a flat 1-m-diameter ground plane. This phase is followed by an “on-vehicle” testing phase to validate that the antenna does meet the requirements of the vehicle manufacturer. If the antenna does not meet these requirements, the design process is repeated. Each vehicle manufacturer has developed its own set of on-vehicle antenna requirements. These on-vehicle antenna requirements are considered proprietary information and must be obtained directly from the manufacturer. Generally, these require a minimum passive antenna gain of 2 dBic in the zenith direction ($\theta = 0^\circ$), and -10 dBic for an elevation angle of 10° ($\theta = 80^\circ$). A low-noise amplifier (LNA) is integrated into the base of the GPS antenna to compensate for cable loss and improve the noise figure (NF) at the input port of the receiver. The LNA generally has a gain between 15–35 dB and NF about 1 dB.

Microstrip Patch Antennas

The microstrip patch antenna has become the most popular type of GPS antenna because of its low profile, small footprint, conformability to vehicle surfaces, manufacturability, physical robustness, and low cost. A typical microstrip antenna consists of a very thin conductive patch ($t \ll \lambda_0$), thin low-loss ceramic substrate ($h \ll \lambda_0$, $h \gg t$, and $\epsilon_r \approx 20$), and finite ground plane. Its RF characteristics include a high Q (quality factor), narrow bandwidth, maximum gain in the zenith direction, and near hemispherical patterns. The theory and design principles for this antenna are extensively reported in the literature,³³ and only a brief overview of its operating principles will be presented.

Insight into the operating principles of the microstrip antenna can be achieved by using either a transmission-line model or cavity model. The transmission-line model is used to view the patch as consisting of two orthogonal low-impedance transmission lines with slot apertures at each of their ends. Each orthogonal line has a length of $\lambda_g/2$ (where λ_g is the wavelength in the dielectric material) creating a phase difference of 180° between its paired apertures, thereby achieving maximum gain in the zenith direction. Circular polarization is achieved by setting the phase difference between the two orthogonal transmission lines to be 90° . This phase difference is obtained by selecting the appropriate geometry for the conductive patch, dielectric substrate, and/or feed system. In a similar manner, the cavity model can be used to view the patch as a dielectric-loaded cavity with dominant resonant TM_{010} and TM_{001} modes as shown in Figure 39-21.

FIGURE 39-21 Mode configurations for a microstrip patch antenna

FIGURE 39-22 Typical circularly polarized patch antennas

The bottom-fed coaxial cable connection is a commonly used feed system for patch antennas. Its center conductor is attached to the patch element and its outer shield is attached to the ground plane. An example of a circular polarized patch antenna is shown in Figure 39-22a with a dual trimmed corner patch element and an x_1 offset-feed point. Another example is shown in Figure 39-22b with a single trimmed corner substrate and an x_1 and y_1 offset-feed point.

The design process for the patch element (i.e., its composition, substrate shape, and patch shape) must take into account the electrical characteristics of the vehicle panel on which it is to be mounted (see Figure 39-23 and Reference 34). A sheet metal panel will act as an extended ground plane and affect the RF characteristics of the patch. In addition, edge diffraction effects of the sheet metal panel can have a significant impact on the resulting antenna pattern in regions of low signal levels (i.e., in the form of a ripple pattern being superimposed on the antenna pattern). A patch mounted on a sloped surface will have its patterns tilted in the direction of the sloped surface. These and other antenna-vehicle interactions must be taken into account during the final design and testing phase of the patch antenna.

Shown in Figure 39-24 is a commercially available GPS patch antenna along with its RF characteristics when mounted on a 70-mm-square ground plane.³⁵ The patch design must take into account the dielectric loading of its radome and/or window glass (i.e., if attached to the inside surface of a vehicle window). The patch shown in Figure 39-24 has a 5-MHz frequency offset that allows for the loading effect of its radome. The narrow bandwidth of the patch antenna is commonly used as an effective filter to block RF noise and EMI (electromagnetic interference) signals before they reach the LNA circuit.

Quadrifilar Helix Antennas

The quadrifilar helix (QFH) antenna is recognized as possibly the best GPS antenna, and was the first antenna used for this purpose. The quadrifilar antenna has been investigated for the past several decades, and its characteristics are well known.³⁶⁻³⁸ It has a cardioid-shaped conical pattern, a low front-to-back pattern ratio, and good circular polarization characteristics. It consists of four equally spaced wires that are wrapped around a cylindrical surface, forming four equally spaced helices. A four-way equal signal combiner with relative phases of 0° , 90° , 180° , and 270° is used to connect these helices to the antenna feed port.

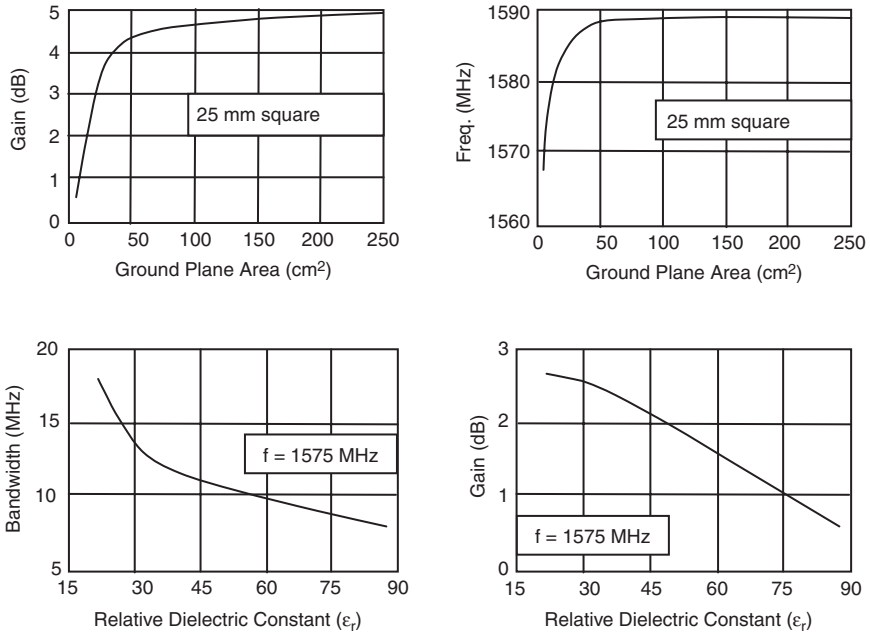

FIGURE 39-23 Relationships between physical and RF properties of a patch antenna (Courtesy of Spectrum FSY Microwave)

This antenna can be viewed as two bifilar helix antennas that are physically rotated 90° from each other and fed in phase quadrature. The lengths of its helix elements are an integer multiple of a quarter wavelength ($\lambda/4$) at its resonant frequency. Its low-backlobe characteristic allows it to be operated with or without a ground plane.

The design process for this antenna involves selecting a height, diameter, and pitch angle to obtain desired gain, pattern shape, and impedance. Resonant $1/4$ -turn, $1/2$ -turn, and 1-turn quadrifilar helix antennas generate cardioid-shaped patterns for all axial lengths and diameters. The element ends of the $1/4$ - λ antenna are open-circuited while those of the $1/2$ - λ and 1- λ antennas are short-circuited (see Figure 39-25). Antenna elements with more than one turn and/or small axial length-to-diameter ratios will have degraded pattern shapes and higher polarization axial ratios. Shown in Figure 39-26 is experimental data demonstrating the relationship of the beamwidth, axial ratio, and front-to-back pattern ratio versus axial length.³⁷

Listed in Table 39-3 are the cylindrical dimensions for three $1/2$ -turn, $1/2$ - λ -long antenna geometries designed to operate at 1.575 GHz.³⁸ The process for selecting antenna radius, pitch angle, and height is very time consuming without the use of an EM computer program. The method-of-moments technique was

TABLE 39-3 Fraction Turn Volute Descriptions

	Axial Length (λ)	Volute Radius (cm)
Antenna 1	0.20	1.60
Antenna 2	0.27	1.39
Antenna 3	0.35	1.04

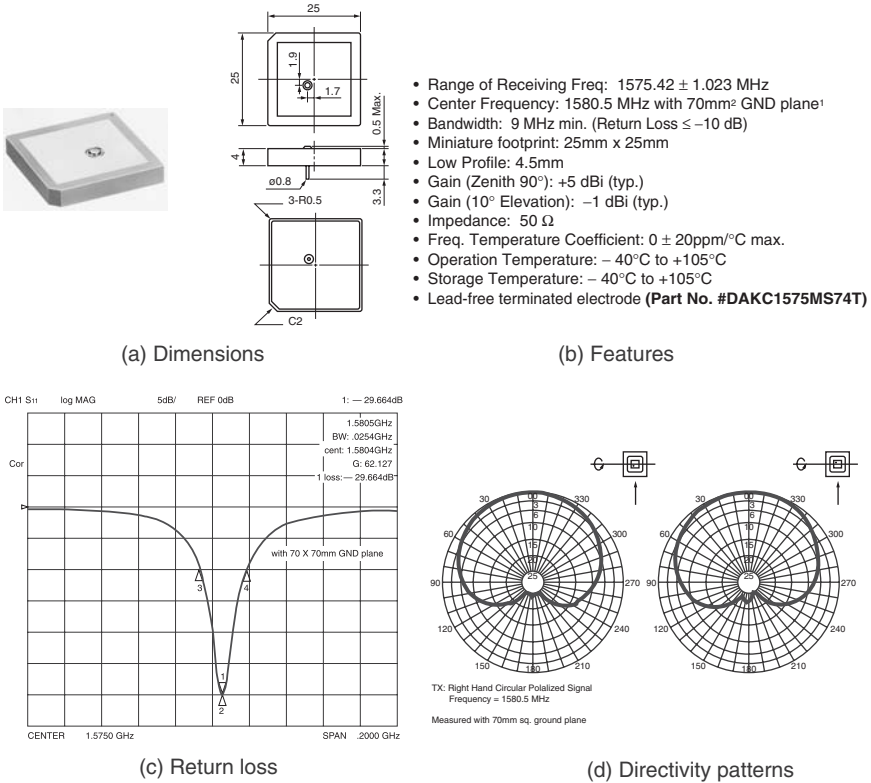

FIGURE 39-24 GPS dielectric patch antenna (Courtesy of Toko America, Inc.)

used to compute the radiation properties for these antennas, and the resulting data is shown in Figure 39-27.

The four-way equal signal combiner with relative phases of 0° , 90° , 180° , and 270° is a critical component for this antenna. One design approach is to use a feed combiner consisting of multiple 90° drop-in hybrid couplers (available in discrete and chip forms). However, the insertion loss for this type of feed is about 0.75 to 1.25 dB,³⁹ which is considered to be unacceptable for both GPS and SDARS applications. Another feed approach that avoids this high insertion loss and has a lower cost is a pair of microstrip power dividers with one feed branch $\lambda/4$ longer (i.e., 90° phase shift) than the other branch. This type of feed system was found to be much more efficient, having an insertion loss of 0.2 to 0.4 dB. Another feed approach is to use two bifilar antennas with one resonant just above and the other just below the desired resonate frequency of

FIGURE 39-25 Quadrifilar helix antenna

FIGURE 39-26 Quadrifilar helix experimental data: solid lines in (b) indicate peak axial ratio over the entire hemisphere in front of helix; dashed lines indicate peak axial ratio over the 3-dB beamwidth of helix pattern (after C. C. Kilgus³⁷ © IEEE 1969)

the combined quadrifilar helix antenna. These bifilar antennas have equal gains at the desired resonate frequency of the combined quadrifilar helix antenna, but with relative phase shifts of $+45^\circ$ and -45° , respectively. Although the quadrifilar helix antenna is a very good antenna for satellite reception, its cost and size are significant disadvantages.

Dielectric-Loaded Quadrifilar Helix Antennas

The dielectric-loaded quadrifilar helix antenna is an emerging technology consisting of copper tracks deposited onto a high-dielectric ceramic cylinder and individually laser trimmed for optimum antenna performance.⁴⁰ The dielectric cylinder is 18-mm long with a diameter of 10 mm and a relative dielectric constant of about 40. The antenna is formed by two quadrature-phased bifilar helical loops of slightly different lengths to achieve two slightly different offset resonant frequencies (see Figure 39-28). The longer bifilar helix has a lower resonant frequency to create an inductive input impedance with a phase angle of $+45$ degrees at 1.57542 GHz, and the shorter bifilar helix has a higher resonant frequency to create a capacitive input impedance with a phase angle of -45 degrees at the same 1.57542 GHz frequency. These helices are positioned so that they are orthogonal to each other, and fed by a four-way equal signal combiner located at the top of the cylinder. The antenna currents travel around the helices to the rim of an integral sleeve balun that effectively isolates the antenna from the unbalanced coaxial feed cable. This balun technique creates a balanced antenna condition that significantly reduces the near field proximity

FIGURE 39-27 Computed amplitude and phase response patterns for the $\lambda/2$ quadrifilar helix at 1575.42 MHz with axial length = 0.20λ (—), 0.27λ (---), and 0.35λ (---) (after J. M. Tranquilla and S. R. Best³⁸ © IEEE 1990)

FIGURE 39-28 GPS dielectric quadrifilar helix antenna (Courtesy of Sarantel)

effects between the antenna and GPS receiver. Contained in Figure 39-29 is a list of its specifications and a representative reception pattern. The dielectric-loaded QFH is used in handheld GPS devices and is presently being investigated for vehicle application.

39.11 SDARS ANTENNAS

The Satellite Digital Audio Radio System (SDARS) was placed into service in 2001 to provide its customers with a large number of digital quality radio channels on a nationwide basis (i.e., for the continental United States). It consists of two service providers (XM Radio, Inc. and Sirius Satellite Radio, Inc.), each with multiple digital radio satellites supported by a network of complementary terrestrial repeaters. SDARS satellites transmit left-hand circularly polarized (LHCP) signals, while terrestrial repeaters transmit vertically polarized signals. Each provider uses different satellite configurations, repeater networks, and antenna requirements (see Table 39-4 and the literature⁴¹⁻⁴³).

Specifications

Frequency:	1575.42MHz \pm 2MHz
Polarization:	RHCP
Gain:	-2.8dBic (zenith typical w/o ground plane)
Efficiency:	27% (total); 50% (hemispherical)
Beamwidth:	> 120° (typical)
Axial Ratio:	< 1.5 (zenith typical)
VSWR:	< 2:1 (typical)
Impedance:	50 Ω
Op. Temp.:	-40 to +85°C
Overall Dim.:	10mm diameter x 22mm length

Radiation Pattern (dBic, Free Space, No Ground Plane)

FIGURE 39-29 Specifications and pattern for GPS dielectric quadrifilar antenna (Courtesy of Sarantel)

TABLE 39-4 SDARS Performance Requirements

	Parameter	XM	Sirius
Satellite	Frequency (MHz)	2332.5–2345	2320–2332.5
	Polarization	Left-hand circular	Left-hand circular
	Gain (dBi)*	+2–+4	+2–+4
	Elevation coverage (deg.)	20–60	25 – 90
	LNA gain (dB)	32	36
	LNA noise figure (dB)	0.7–1.2	0.7

	Elevation coverage (deg.)	0	0
	LNA gain (dB)	30	28
	LNA noise figure (dB)	1.5	2

*For an antenna placed at the center of a 1-m-diameter ground plane

XM has two transmitting geostationary satellites, with each assigned to operate in two of four subfrequency bands about its 2.33875 GHz center frequency (see Figure 39-30). The two transmitting satellites have their orbit tracks located over the equator at 85° and 115° west longitudes with an orbiting radius of 43,000 km. Elevation angles of reception (i.e., in the southerly direction) vary from 60° for the southernmost region of the U.S. to 20° for the northernmost region. Tall buildings, overpasses, tunnels, leafy trees, and other obstacles can significantly “block” these signals. To help mitigate this signal blockage, a network of up to 1500 terrestrial repeaters, operating in two subfrequency bands, are distributed throughout the U.S. (primarily in major cities). These repeaters receive signals from the satellites and retransmit them as vertically polarized signals after appropriate demodulation and remodulation. Satellite signals are modulated using QPSK (Quadrature Phase Shift Keying) while terrestrial signals are modulated using OFDM (Orthogonal Frequency Division Multiplexing). An XM radio can receive signals from three sources: one from each satellite and another from a terrestrial repeater. These signals contain the same program content but travel along different paths. An XM receiver will continuously monitor these signals and use spatial, time, and frequency diversity techniques to obtain best reception.

Sirius has three satellites in an inclined elliptical orbit with a radius varying from 30,300 to 53,500 km. The elevation angle for reception is greater than 57° for at least one of the three satellites. The higher reception angles result in fewer signals being blocked by tall buildings and other obstacles. Each satellite is assigned to operate in one of two subfrequency bands about its 2.32625 GHz center frequency (see Figure 39-30). Only two of the three satellites are active at any one time, to avoid in-band interference. Each satellite will spend approximately 16 hours within its U.S. footprint, with at least one of these satellites always providing service. Once an active satellite is no longer capable of providing nationwide service, it is deactivated and its assigned signal is handed off to another satellite that is reactivated as it enters the U.S. service area. To help mitigate signal blockage, a network of up to 150 terrestrial repeaters, operating in a third subfrequency band, are primarily located in major U.S. cities. A Sirius radio can receive signals from three sources: two from satellites and another from a terrestrial repeater. A Sirius radio continuously monitors these signals, and applies spatial, time, and frequency diversity techniques to obtain best signal reception.

FIGURE 39-30 SDARS frequency allocation

An SDARS automobile antenna is required to have good omnidirectional patterns for both high (celestial) and low (terrestrial) elevation angles. In addition, these antennas must be aesthetically pleasing (i.e., very low profile or preferably hidden), low cost, lightweight, and easily integrated into the vehicle production process. The roof is the best mounting location for the antenna because it is the highest point of the vehicle, providing an unobstructed view of the upper hemisphere, a nearly horizontal mounting surface, a relatively safe site from damage, and easy access for maintenance purposes. The antenna should be located a minimum distance of several inches from the edge of the roof edge in order to reduce diffraction effects to acceptable levels. If the vehicle has a sunroof, the antenna should be kept at a distance of several inches from the edges of the roof and sunroof. Other possible mounting locations include the uppermost central region of the windshield, uppermost central region of the rear window, trunk lid, instrument (dash) panel, and rear packaging shelf. However, these mounting locations were determined to be less desirable in that they generally have an adverse impact on the pattern characteristics of the antenna (e.g., signal blockage effects).

Dual antenna systems (one for celestial reception and another for terrestrial reception) are commonly used to meet the requirements of both the service providers and vehicle manufacturers. The most common satellite antenna is the microstrip patch, and the most common terrestrial antenna is the monopole. Service providers state their antenna requirements in terms of an antenna mounted on a 1-m-diameter ground plane, while vehicle manufacturers state their antenna requirements in terms of an antenna mounted on the intended vehicle. The antenna characteristics for these two mounting conditions can be significantly different. A more detailed discussion of the effects of a finite (1 m diameter) ground plane and its appropriate edge geometry is contained in M. Daginnus et al.⁴⁴ In addition, the low-level signal environment that an SDARS receiver system must operate in requires the use of LNAs (see Table 39-4) to compensate for cable loss and to improve SNR for both satellite and terrestrial reception.

Satellite Antennas

The antenna technologies that were reviewed in Section 39-10 for GPS antennas (i.e., microstrip patch, quadrifilar helix, and dielectric quadrifilar helix antennas) are applicable to SDARS antennas and will not be repeated in this section. As is the case for the GPS antenna, the microstrip patch antenna has become the most popular type of SDARS automobile antenna because of its low profile, small footprint, conformability to vehicle surfaces, manufacturability, physical robustness, and low cost. However, the quadrifilar helix antenna is considered to have better reception characteristics, followed by the bent crossed-dipole antenna.

Bent Crossed-Dipole Antenna

One technique for generating a hemispherical circularly polarized antenna pattern is to place two $\lambda/2$ dipoles above a ground plane and at right angles to each other. These dipoles are fed with signals of equal amplitude but shifted in phase by 90° . The resulting E -plane and H -plane patterns for each dipole have beamwidths (relative to zenith) of 60° and 120° , respectively.⁴⁵ This difference in beamwidths results in low axial ratios for only a few degrees about the zenith. One technique to correct this deficiency is to use bent crossed-dipole antennas that will increase the beamwidth of the E -plane pattern.³⁹ An example of a bent crossed-dipole antenna is shown in Figure 39-31a with its measured and simulated patterns shown in Figure 39-31b. The feed system for this antenna consists of a microstrip power divider, with one arm being $\lambda/4$ longer for the required 90° phase difference.

Terrestrial Antennas

The terrestrial antenna generally takes the form of a simple monopole antenna. In one application, the monopole is positioned along the axis of a quadrifilar helix antenna.⁴¹ In another application, the monopole is located at the center and along the normal axis of a microstrip patch antenna (i.e., extending from the patch base, through an access channel cut into the ceramic material, and out the top). In another application, four electrically short ($\lambda/8$) monopoles are placed symmetrically around the bent crossed-dipole antenna as shown in Figure 39-31. This monopole arrangement forms a terrestrial antenna array, with signals from these monopoles being combined using a microstrip feed assembly. The low height associated with satellite patch antennas allows the use of much smaller terrestrial antennas (e.g., meander-line antenna, dielectric mast antenna, etc.).

PIFAs are commonly used in handheld cell phones⁴⁶ and have been investigated for use as a vehicle SDARS terrestrial antenna. However, their on-vehicle RF characteristics and various physical attributes have significantly limited their potential use as a vehicle antenna.

FIGURE 39-31 SDARS bent crossed-dipole antenna with reception patterns (*Courtesy of Receptec, Inc.*)

The gain for the terrestrial antenna should be greater than -1.0 dBi in the azimuth plane ($\theta \approx 90^\circ$). However, a number OEMs have begun using the patch antenna for both satellite and terrestrial reception. They have determined that the slight loss in terrestrial gain is offset by lower cost and improved aesthetics.

39.12 EMERGING TECHNOLOGIES

Table 39-5 lists a number of emerging automobile telecommunication technologies. Although ZigBee, Bluetooth, and WiFi use the same frequency band and appear to be similar, they are designed for considerably different applications:

- ZigBee for control, monitoring, automation, sensors, etc.
- Bluetooth for mobile phones, headsets, MP3s, PDAs, notebooks, etc.
- WiFi for wireless local area networks (WLANs)

The ZigBee technology is capable of using radio node devices to form mesh networks, where each node can relay information to its neighboring nodes. If a node malfunctions, one or more of its neighboring nodes can reroute communication around the disabled node, providing a robust communication network.

Bluetooth and WiFi technologies use a central hub-and-spoke distribution network that channels communication to its radio devices. Bluetooth offers automatic network configuration and service discovery that makes the establishment of the network almost transparent at distances up to 10 m. WiFi operates much like a mobile phone, providing fast connection from anywhere within its coverage area. It connects computer devices to its network at distances up to 100 m. WiMAX is similar to WiFi but is intended to support a metropolitan-wide wireless network capable of handling thousands of users. It provides high-throughput broadband connections over long distances (with a maximum range of about 30 miles). WiMAX has much promise with its established global standards, high throughput, high reliability, and low-cost services.

TABLE 39-5 Emerging Vehicle Telecommunication Technologies

Application	Frequency Band (GHz)
ZigBee	2.402–2.480
Bluetooth	2.402–2.480
WiFi - IEEE 802.11a	5.150–5.350
WiFi - IEEE 802.11a	5.725–5.825
WiFi - IEEE 802.11b	2.410–2.462
WiFi - IEEE 802.11g	2.410–2.462
WIMAX - IEEE 802.16	2–11
DSRC - IEEE 802.11p	5.850–5.925
Mobile Satellite TV	12.2–12.7
Automobile radar	24 & 76

Dedicated Short Range Communications (DSRC) is a short-to-medium-range wireless system specifically designed for automobile use. This system is being developed to support a wide range of vehicle-to-vehicle and vehicle-to-roadside communications. It will complement the mobile telephone by supporting new communication systems that require time-critical responses and/or high data-transfer rates. It will operate in the 5.850 to 5.925 GHz band and have a range of up to 1000 m. Some proposed applications include electronic toll, electronic parking, warning of an approaching emergency vehicle, cooperative adaptive cruise control, intersection collision avoidance, etc.

Mobile satellite TV is another wireless system being investigated for automobile use. Satellite TV operates in the frequency band from 12.2 to 12.7 GHz (Ku-band) and requires a rather large circularly polarized receiving antenna with a beamwidth of less than 1 degree. The standard TV satellite dish is too big and bulky to be placed on a moving vehicle, and would require some means to keep it pointed at the satellite as the vehicle maneuvers through traffic. The high operating frequency necessitates that the satellite TV antenna be mounted on the roof, or possibly the trunk lid, to avoid signal blockage by the structure of the vehicle. To overcome the dish size limitations, the vehicle antenna should have a "flat" plate geometry with mechanical and/or electronic scanning capability. Proposed mobile TV antennas have not been able to meet the physical size, weight, and cost requirements of vehicle manufacturers. Mobile satellite TV systems are commercially available as an aftermarket or add-on accessory item, but these are currently too heavy, bulky, and costly (e.g., a few inches in height and about 30 inches in width) for common vehicle use.

Automobile radar is another area that is being investigated. Potential applications include collision warning (with autonomous braking), headway distance warning (HDW), adaptive cruise control (ACC) equipped with stop and go, blind spot detection (BSD), pre-crash detection for smart airbags, and parking aid (PA) systems. These radar systems generally operate in the Ka- (e.g., 24 GHz) and W-band (e.g., 76 GHz). Their distance capabilities vary from 2 m up to 150 m with antenna beamwidths from less than $\pm 4^\circ$ up to $\pm 45^\circ$. Antenna geometries include a single beam, dual beam, and multiple beams with mono-pulse, mechanical, and electronic scanning capabilities. It has been suggested that automotive radar frequencies may move above 100 GHz in a continuing effort to shrink the physical size of the antenna.

39.13 ANTENNA MEASUREMENTS

Over the past several decades, automobile manufacturers have had to develop their own antenna measurement techniques for characterizing vehicle antennas. This process started with the AM band and was later expanded in the mid-1960s to include FM. In the early 1980s, an R&D automobile antenna range was built to investigate new automobile antenna technologies and determine range requirements for antenna pattern measurements.²¹ A decade later, a much larger and more accurate range was built with the capability of measuring AM, FM, RKE, and cell phone antennas (see Figure 39-32). This quasi-far-field facility was designed to measure vehicle antennas in an RF environment similar to fringe reception conditions. At about the same time, a number of other automobile manufacturers and antenna suppliers built in-house ranges using their own range requirements. Over the following years, it was determined that there are significant discrepancies in the data measured by these ranges, with no consensus as to what data set is correct. In an effort to resolve these discrepancies, an industry/government effort was established to conduct an in-depth RF evaluation of the large outdoor range shown in Figure 39-32, and make appropriate recommendations to improve the accuracy and reduce the uncertainties of its measured data. This study revealed that the in-ground turntable had a significant adverse impact on the uniformity of the electromagnetic

FIGURE 39-32 Far-field antenna facility (*Courtesy of General Motors*)

field just above the turntable surface. Recommendations were made for developing new measurement procedures to improve accuracy, enhance repeatability, and reduce uncertainties of its measured data to within stated error limits.^{47,48}

The introduction of automobile satellite antennas has generated a need for a different type of antenna range capable for measuring vehicle antenna patterns that encompass the greater portion of the hemisphere above the earth's surface (see Figures 39-29 and 39-31). It was determined that a hemispherical near-field antenna test facility was required to make this type of antenna measurement. A near-field system samples the amplitude and phase of the electromagnetic field along a predetermined surface very close to and surrounding the antenna under test. This near-field data is then used to determine its corresponding far-field patterns. For an automobile satellite antenna, the sampling surface is a hemisphere with a radius that is sufficiently large to encompass the entire vehicle. Two basic near-field systems are currently available: an outdoor near-field range (see Figures 39-33 and 39-34 for two examples of this type of system), and an in-door (anechoic chamber) near-field range (see Figure 39-35).

The outdoor near-field range generally consists of an in-ground turntable, a radome, and a single-probe "gantry arm" near-field system.⁴⁹ This near-field system has a wide operating bandwidth (FM band up to the mm band), but its single-probe setup requires several hours to complete measurements for a GPS or SDARS antenna.

(a) Far-field range

(b) Near-field range

FIGURE 39-33 Outdoor near-field antenna facility with radome (*Courtesy of Nippon Antenna Co., Ltd.*)

FIGURE 39-34 Outdoor near-field antenna facility with radome (Courtesy of Hirschmann Car Communication, Inc.)

The indoor near-field range consists of an anechoic chamber, a turntable, and a multiprobe arc near-field system.⁵⁰ The multiprobe arc has a 6-meter radius with 103 dual-polarized probes located every degree along its length. The system (including the dual-polarized probes) has an operating bandwidth from 400 MHz to 6 GHz, and is capable of multiple-frequency and/or antenna operation. Its normalized pattern directivity ($D_n = |D(\theta, \phi)/D_{\max}|$) error is less than

(a) Near-field range

(b) Multifrequency elevation patterns for a rear roof-mounted SDARS antenna

FIGURE 39-35 Anechoic chamber near-field antenna facility (Courtesy of General Motors)

+/- 0.25 dB for relative pattern levels from 0 to -5 dB, and less than +/- $0.1 \times (-D_n)$ dB for pattern levels from -5 to -30 dB. Peak gain measurements are repeatable to within a few tenths of a dB, and inter-laboratory data comparisons (with an outside RF laboratory) demonstrated a correlation to within 1.0 dB. Major advantages of this facility are its accuracy, repeatability, and speed. The multiple dual-polarized probes allow the system to complete pattern measurements in 5 minutes (limited by the rotational speed of the turntable) instead of the several hours require for the single-probe system.

40.1 INTRODUCTION

The design of antennas used for aircraft differs from other applications. Special consideration must be given to the environment to which the antenna is exposed, interaction of the aircraft with the antenna performance characteristics, safety-of-flight, and regulatory requirements.

Aircraft antennas must be designed to withstand severe static and dynamic stresses. Antennas for high speed aircraft must be designed aerodynamically, to limit physical stress on the antenna and limit degradation of the aircraft's flight characteristics. Triboelectric charging of the airframe surfaces by dust or precipitation particles, known as p static, gives rise to corona discharges. These discharges may produce extreme electrical noise, especially when the location of the antenna is such that there is strong electromagnetic coupling to the discharge point. In transmitting applications, corona discharge from the antenna element may limit the power-handling capacity of the antenna. Also, special consideration must frequently be given to the protection of aircraft antennas from damage due to lightning strikes.

The size and shape of the airframe play a major role in determining the impedance and radiation pattern characteristics of an antenna. The type of antenna used in a given application will often depend on the size of the airframe relative to the wavelength. In the case of propeller-driven aircraft and helicopters, the motion of the blades may give rise to modulation of the radiated signal. Through careful placement of the antenna on the aircraft, optimum electrical performance characteristics can be achieved.

While the types of antennas and their locations on an aircraft are influenced by the previous factors, the most important consideration is safety-of-flight. Structural failure of the antenna cannot significantly endanger personnel aboard the aircraft or critical aircraft components (such as propellers, jet engines, wings, flaps, and so on). Redundant systems are installed to ensure the aircraft has at least a minimum level of functionality for safe flight. The type and number of systems required include voice and identification communications for air traffic control as dictated by national and international governments and organizations. The following table shows an example of the types of the avionics systems required for large aircraft.

System Description	Quantity	Frequency	Polarization	Function
ADF	1-2	190-1750 KHz	Vertical	Automatic Direction Finding
HF Voice	1-2	3-25 MHz	Horizontal	Long Range Communication
VHF Voice (FM)	1	30-76 MHz	Vertical	Communication with Air Traffic Control
Marker Beacon	1	75 MHz	Horizontal	Instrument Landing System
VOR/Localizer	2	108-118 MHz	Horizontal	Bearing/Instrument Landing System
VHF Voice (AM)	2	118-152 MHz	Vertical	Civil Aviation
UHF Voice	2	224-400 MHz	Vertical	Military
Glide Path	1	329-335 MHz	Horizontal	Instrument Landing System
DME/TACAN	2	962-1214 MHz	Vertical	Navigation Distance and Bearing
ATC Transponder/IFF	2	1030/1090 MHz	Vertical	Traffic Control/Identification
GPS	1	1525-1585 MHz	RH Circular	Navigation
Radar Altimeter	1	4.2-4.4 GHz	Horizontal	Navigation/Ground Proximity
Weather Radar	1	9.375 GHz	Horizontal	Navigation/Weather Avoidance

40.2 LOW-FREQUENCY ANTENNAS

The wavelengths of frequencies below about 2 MHz are considerably larger than the maximum dimensions of most aircraft. Because of the inherently low radiation efficiency of electrically small antennas and the correspondingly high radio-frequency (RF) voltages required to radiate significant amounts of power, nearly all aircraft radio systems operating at these lower frequencies are designed so that only receiving equipment is required in the aircraft.

Radiation patterns of aircraft antennas in this frequency range are simple electric or magnetic dipole patterns, depending upon whether the antenna element is a monopole or a loop. The pattern produced by a small monopole antenna will always be that of a simple dipole regardless of location; the orientation of the equivalent-dipole axis with respect to the vertical will depend upon location. A small antenna element placed on the airframe would respond to vertical, longitudinal, and transverse field components, indicating that the dipole moment of the antenna-airframe combination has projections in all three directions. Since the aircraft surface is small in terms of square wavelengths, it is appropriate to employ the method of moments (MOM) to assess pattern performance.¹⁻³ This technique is discussed in Section 40.9.

The sensitivity of low-frequency (LF) antennas is customarily expressed in either of two ways, depending upon whether the antenna is located on a relatively flat portion of the airframe such as the top or bottom of the fuselage or at a sharp extremity such as the tip of the vertical stabilizer. In the first case, it can be assumed (at least when the antenna element is small relative to the surface radii of curvature) that the antenna performs as it would on a flat ground plane, except that the incident-field intensity which excites it is greater than the free-space incident-field intensity because of the field fringing produced by the airframe. The effect of the airframe on antenna sensitivity can be expressed by the ratio of the local-field intensity on the airframe surface to the free-space incident-field intensity. For a vertically polarized incident field (which is the case of primary importance in LF receiving-antenna design), this ratio is designated as F_v and is called the *curvature factor for vertical polarization*. Measurements can be performed to determine the equivalent dipole tilt angle and the factor F_v .

Effective height and capacitance data for antennas installed in locations for which this method is applicable are usually obtained by measurements or calculations for the antenna on a flat ground plane. The effective height (for vertically polarized signals) of the antenna installed on the airframe is then estimated by multiplying the flat-ground-plane effective height by the factor F_v appropriate to the installation. On the other hand, the capacitance may be assumed to be the same as that determined with the antenna on a flat ground plane. The presence of a fixed-wire antenna on the aircraft may have a significant effect on F_v . Because of the shielding effect due to a wire, LF antennas are seldom located on the top of the fuselage in aircraft which carry fixed-wire antennas.

Flat-ground-plane data for a T antenna are shown in Figure 40-1. The capacitance curves shown apply to an antenna made with standard polyethylene-coated wire. The standard is a 0.052-in- (1.32-mm-) diameter conductor and a 0.178-in- (4.52-mm-) diameter polyethylene sheath. Two antennas of this type are frequently located in close proximity on aircraft having dual automatic-direction-finder (ADF) installations. The effects of a grounded T antenna on h_e and C_a of a similar nearby antenna are shown in Figure 40-2. To determine the significance of capacitance interaction it is necessary to consider the Q 's of the input circuits to which the antennas are connected and the proximity of the receiver frequencies.

Sensitivity data for a flush antenna and a low-silhouette antenna consisting of a relatively large top-loading element and a short downlead are shown in Figures 40-3 and 40-4, respectively.

FIGURE 40-1 Effective height and capacitance of a T antenna

The antenna dimensions shown in these figures are not indicative of antenna sizes actually in use, but are rather the sizes of the models used in measuring the data. Both h_e and C_a scale linearly with the antenna dimensions.

A rule-of-thumb design limit for flush antennas may be derived on the basis of a quasi-static analysis of LF antenna performance. If any electric dipole antenna is short-circuited at its feed terminals and placed in a uniform electrostatic field with its equivalent-dipole axis aligned parallel to the field, charges of $+q$ and $-q$ will be induced on the two elements of the antenna. It may be shown that the product of the LF parameters h_e and C_a is related to the induced charge by the equation

$$h_e C_a = q/E \quad (40-1)$$

where h_e and C_a are expressed in meters and picofarads, respectively, q is expressed in pico-coulombs, and the incident-field intensity E is expressed in volts per meter. The quantity q/E is readily calculated for a flush cavity-backed antenna of the type shown in Figure 40-3, at least for the case in which the antenna element virtually fills the cutout in the ground plane. In this case, the shorted antenna element will cause practically no distortion of the normally incident field, and the number of field lines terminating on the element will be the same as the number which would terminate on this area if the ground plane were continuous. The value of q/E is hence equal to $\epsilon_0 a$, where $\epsilon_0 = 8.85 \times 10^{-12}$ F/m and a is the area of

FIGURE 40-2 Shielding effect of one T antenna on another

FIGURE 40-3 Design data for a flush low-frequency antenna

the antenna aperture in square meters. For a flush antenna with an element that nearly fills the antenna aperture the result is

$$h_e C_a = \epsilon_0 a \quad (40-2)$$

The line labeled “theoretical maximum $C_a h_e$ ” in Figure 40-3 was calculated from Eq. 40-2. With practical antenna designs, there will be regions of the aperture not covered by the antenna element, so that some of the incident-field lines will penetrate the aperture and terminate inside the cavity. As a result, the induced charge q will be smaller than that calculated previously, and the product $h_e C_a$ will be smaller than the value estimated from Eq. 40-2.

FIGURE 40-4 Design data for a heavily top-loaded low-frequency antenna with flat-plate top loading

FIGURE 40-5 Rotor modulation for a low-frequency receiving antenna on an idealized helicopter model

The helicopter presents a special antenna-design problem in the LF range as well as in other frequency ranges because of the shielding and modulation caused by the rotor blades. Measured curves of F_v , obtained with an idealized helicopter model to demonstrate the effects of different antenna locations along the top of the simulated fuselage, are shown in Figure 40-5. The MOM also may be used to compute rotor modulation effects. See Section 40.9 for MOM details.

It is characteristic of the rotor modulation of LF signals that relatively few modulation components of significant amplitude are produced above the fundamental rotor modulation frequency (which is equal to the number of blade passages over the antenna per second). This fundamental frequency is of the order of 15 Hz for typical, three-blade, single-rotor helicopters. It should be noted that new sidebands will be generated about each signal sideband and about the carrier. It is thus not a simple matter to predict the effects of rotor modulation on a particular system unless tests have been made to determine the performance degradation of the airborne receiver due to these extra modulation components.

ADF Antennas

The ADF system, which determines the direction of arrival of the signal by rotating its loop antenna about a vertical axis until a null is observed in the loop response (Figure 40-6), is subject to bearing errors because of the difference in direction of the local

FIGURE 40-6 ADF loop antenna on aircraft

FIGURE 40-7 (a) Bearing-error curve for $a_{zz}/a_{yy} = 2$; (b) The maximum bearing error and the true bearing at which the maximum bearing error occurs as functions of a_{zz}/a_{yy}

incident magnetic fields. The relationship between the true and the apparent directions of the signal source is given by the equation*

$$\tan \phi_t = \frac{a_{xx}}{a_{yy}} \tan \phi_a \quad (40-3)$$

where ϕ_t and ϕ_a are respectively the true and the apparent bearings of the signal source. A curve of the bearing error ($\phi_t - \phi_a$) as a function of ϕ_t with the ratio $a_{xx}/a_{yy} = 2$ is shown in Figure 40-7a. Figure 40-7b shows graphs of the maximum bearing error $|\phi_t - \phi_a|$ and the value of ϕ_t (in the first quadrant) at which the maximum bearing error occurs as functions of the ratio a_{xx}/a_{yy} .

Survey data showing the coefficient a_{xx} and the maximum bearing error for loop antennas along the top and bottom centerline of a DC-4 aircraft are shown in Figure 40-8. The ADF loop has a 180° uncertainty in null location due to its figure eight pattern. An auxiliary sense antenna is used to resolve the null uncertainty via amplitude comparison. The ADF system is calibrated after installation to achieve proper performance.

The automatic-direction-finder loop antenna is normally supplied as a component of the ADF system, and the problem is to find a suitable airframe location. The two restrictions which govern the selection of a location are (1) that the cable between the loop antenna and receiver be of fixed

FIGURE 40-8 Low-frequency loop-antenna survey data for a DC-4 aircraft, showing maximum bearing error and sensitivity coefficient for transverse polarization for top and bottom centerline locations

* The ratio of local magnetic field intensity on the airframe surface to the incident magnetic field intensity is designated as a_{xx} for the case in which the incident field is transverse to the line of flight (the signal arrives from the front or rear of the aircraft). It is designated as a_{yy} when the incident field is along the line of flight (the signal arrive from the side of the aircraft).

length, since the loop and cable inductances form a part of the resonant circuit in the loop amplifier input, and (2) that the maximum bearing error which the system can compensate be limited to about 20° . As can be seen from the bearing-error data in Figure 40-7, positions on the bottom of the fuselage forward of the wing meet the minimum bearing-error requirements on the aircraft type for which the data are applicable (and on other comparable aircraft). Such positions are consistent with cable-length restrictions in most cases since the radio-equipment racks are usually just aft of the flight deck.

Bearing-error compensation is accomplished in some ADF systems by means of a mechanical compensating cam.⁴⁻⁵ Standard flight-test procedures⁴⁻⁶ are generally used in setting the compensating cams. In some loop designs⁷ electrical compensation is achieved by modifying the immediate environment of the actual loop element.

Unlike the loop antenna, the sense antenna must be located within a limited region of the airframe for which the equivalent-dipole axis is essentially vertical. This ensures accurate ADF performance as the aircraft passes over or near the ground station to which the receiver is tuned.⁸

A typical flush ADF sense-antenna installation is illustrated by the C-141 aircraft.⁹ The antenna, in this case, is a cavity built into the upper fuselage, fairing just aft of the wing crossover. It was decided during the design phase to use the Bendix ADF-73 automatic-direction-finder system, which to some extent determined the sense-antenna requirements. The basic antenna requirements were (1) antenna capacitance of 300 pF, (2) a minimum quality factor of 1.4, and (3) a radiation-pattern tilt angle between 0 and 10° downward and forward. Figure 40-9 shows the patterns of the dual sense antenna.

For the C-141, the electrical center of the aircraft (pattern tilt angle of zero) was initially located through radiation-pattern measurements by using a small model configuration; a tilt-angle change was noted when the feed point for the cavity ADF antenna was moved. A zero tilt angle was obtained, and it was found that an approximate 10-in (254-mm) movement of the feed point aft produced a $+10^\circ$ tilt angle. Since a tilt angle of 0 to 10° is required, the measurements permitted selection of an optimum feed point ($+5^\circ$ tilt). Figure 40-9 shows the yaw, pitch, and roll radiation patterns obtained with the optimum antenna feed point.

The Rockwell/Collins DF-206A automatic direction finder (ADF) system is unique in that the DFA-206A antenna consists of a combined sense and loop antenna assembly. The sense antenna input is used as the reference input and is coupled to a low-pass filter. The low-pass filter removes the high-frequency interference. The two loop antennas are physically oriented 90° apart, and the resulting signal strengths are related to the direction of the antennas in relation to the transmitting station.

The antenna is a self-contained unit that may be located on either the top or the bottom of the aircraft. This unit is housed in a 16.5-in-long, 8.5-in-wide, and 1.75-in-thick teardrop designed to mount flush with the aircraft fuselage. It should be located as near the centerline

FIGURE 40-9 Voltage radiation patterns for the C-141 ADF sense antenna

of the aircraft as possible to reduce unsymmetric quadrantal error and near the wing root to obtain the best station-crossing indication. Unlike previous ADF systems, the length of the interconnecting cables between the antenna and receiver is neither limited nor critical. However, short cable runs are preferred to reduce the exposure to ground currents and interfering fields within the airframe.

40.3 HIGH-FREQUENCY COMMUNICATIONS ANTENNAS

Aircraft antennas for use with communications systems in the 2- to 30-MHz range are required to yield radiation patterns which provide useful gain in directions significant to communications. Also, impedance and efficiency characteristics suitable for acceptable power-transfer efficiencies between the airborne equipment and the radiated field are needed. A receiving antenna that meets these requirements will deliver to the input of a matched receiver atmospheric noise power under noise field conditions, which is many times greater than the input-circuit noise in the communications receiver. When this is the case, no improvement in signal-to-noise ratio can be achieved by further refinement of the antenna design. Since the transmitting mode of operation poses the more stringent requirements, the remainder of the discussion of HF antennas is confined to the transmitting case. Sky-wave propagation is always an important factor at these frequencies, and because of the rotation of polarization which is characteristic of reflection from the ionosphere, polarization characteristics are usually unimportant. Thus, the effective antenna gain can be considered in terms of the total power density. At frequencies below 6 MHz, ionosphere (and ground) reflections make almost all the radiated power useful for communication at least some of the time, so that differences between radiation patterns are relatively unimportant in comparing alternative aircraft antennas for communication applications in the 2- to 6-MHz range. In this range, impedance matching and efficiency considerations dominate. For frequencies above 6 MHz, pattern comparisons are frequently made in terms of the average power gain in an angular sector bounded by cones 30° above and below the horizon.

In the 2- to 30-MHz range, most aircraft have major dimensions of the order of a wavelength, and currents flowing on the skin usually dominate the impedance and pattern behavior. Since the airframe is a good radiator in this range, HF antenna design is aimed at maximizing the electromagnetic coupling to the airframe. The airframe currents exhibit strong resonance phenomena that are important to the impedance of antennas which coupled tightly to the airframe.

Wire Antennas

Wire antennas, supported between the vertical fin and an insulated mast or trailed out into the airstream from an insulated reel, are reasonably effective HF antennas on lower-speed aircraft. Aerodynamic considerations limit the angle between a fixed wire and the airstream to about 15° . This means that fixed-wire antennas yield impedance characteristics similar to moderately lossy transmission lines, with resonances and antiresonances at frequencies at which the wire length is close to an integral multiple of $\lambda/4$. Figure 40-10 shows the input impedance of a 56-ft (17-m) fixed-wire antenna on a C-130 Hercules aircraft. Lumped reactances connected between the wire and the fin produce an effect exactly analogous to reactance-terminated lossy transmission lines. The average directive gain of these antennas in the sector $\pm 30^\circ$ relative to the horizon (for example, the fraction of the total radiated energy that goes into the second, bounded by the cones 30° above and below the horizontal plane)

FIGURE 40-10 Impedance of the C-130E right-hand long-wire antenna

remains near 60 percent from 6 to 24 MHz. The efficiency of wire antennas is not high because of resistance loss in the wire itself and dielectric loss in the supporting insulators and masts. The resistance of commonly used wires is of the order of $0.05 \Omega/\text{ft}$ at 4 MHz. The RF corona breakdown threshold of fixed-wire antennas is a function of the wire diameter and the design of the supporting fittings. To minimize precipitation static, a wire coated with a relatively large-diameter sheath of polyethylene is frequently used, with special fittings designed to maximize the corona threshold. Even with such precautions, voltage breakdown poses a serious problem with fixed-wire antennas at high altitudes. Measurements indicate that standard antistatic strain insulators have an RF corona threshold of about 11 kV peak at an altitude of 50,000 ft (15,240 m)¹⁰ and a frequency of 2 MHz. Such an insulator, placed between the vertical stabilizer and the aft end of the open-circuited antenna, would go into corona at this altitude if the antenna were energized with a fully modulated AM carrier of about 150 W at 2 MHz.

Probe Antennas

A variation of the isolated-cap antenna is the probe or bullet-probe antenna. The radiation-pattern and impedance-resonance effects of the empennage, fuselage, and wings also affect probe antennas. The marked advantage of the probe antenna over the tail-cap antenna lies in the relative ease of incorporation into the structure of the aircraft empennage. The C-141 bullet-probe antenna shown in Figure 40-11¹¹ makes use of a portion of the structural intersection of the horizontal and vertical stabilizers in the T-tail configuration. The antenna is composed of the forward portion of the aerodynamic bullet with a probe extension. The plastic isolation gap in the bullet extends forward 11 in (279 mm), and the overall length of the antenna including the isolation band is 112 in (2845 mm). The maximum structural gap width was 13 in (330 mm), and the minimum gap width to withstand RF potentials was 3 to 4 in (76 to 102 mm). To obtain maximum airframe coupling, a maximum resistive component is required at the lowest expected resonant frequency. This resonance occurred at 2.4 MHz, which corresponds to a half-wavelength resonant condition caused by the wing-tip-to-horizontal-stabilizer-tip distance. Another parameter considered was the capacitive reactance of the antenna at 2.0 MHz. This reactance had to remain below 1000 Ω if existing couplers were to be used. This resulted in

FIGURE 40-11 Impedance curves for the C-141 aircraft forward bullet-probe antenna¹¹

a gap width of 11 in for satisfactory performance. Figure 40-14 shows the impedance curves for the C-141 forward bullet-probe antenna.

A solid bulkhead was installed just aft of the isolation band for two reasons: (1) the metallic bulkhead acts as an electrostatic shield between the antenna and other metallic objects, and (2) the antenna tuner will mount on the bulkhead. Connection to the antenna is made through a lightning arrester which protrudes through the bulkhead into the gap area. The lightning arrester has a birdcage terminal which plugs into a flared tube, which is tied electrically to the probe and metal portions of the forward bullet.

Shunt or Notch High-Frequency Antennas

Shunt- and notch-type HF antennas are becoming increasingly popular on modern high-speed aircraft because of drag reduction and higher reliability. The basic difference in the shunt and notch configurations is the ratio of length to width of the cutout (dielectric) portion of the aircraft. Figure 40-12 shows the basic configurations.¹²

The shunt or notch antenna is a kind of transmission line that uses the vertical stabilizer or wing to feed the remainder of the aircraft. It can be located at various points on the airframe, but since it functions as an inductive coupler, it should be located at a point of low impedance or high current. The shunt-fed loop current causes the airframe itself to act as the antenna. The particular portion of the airframe supporting the current path is a function of the frequency and physical lengths of the parts of the airframe involved. For example, the wing-tip-to-horizontal-tip half-wavelength resonance on the C-5

FIGURE 40-12 Basic configuration of the C-130 notch high-frequency antenna¹²

FIGURE 40-13 Impedance of the shunt-fed HF notch antenna on the C-130 aircraft¹²

aircraft occurs at approximately 2.5 MHz. The coupler feed point should always be located at the end of the shunt feed closest to the center of the aircraft.

The design of the antenna involves first finding a suitable location for the dielectric area and then arranging the dimensions of the shunt feed and dielectric area to provide an antenna that can be efficiently matched to $50\ \Omega$ with a relatively simple antenna coupler. Guidelines to observe are as follows: (1) The first choice for location on the airframe from a radiation-pattern and impedance standpoint is the root of the vertical stabilizer. An alternative is the wing root, but in this case the radiated vertically polarized energy is reduced. (2) The antenna coupler should be connected to the shunt feed near the stabilizer or wing root to provide maximum efficiency. (3) The dielectric material used to fill the opening should have low-loss characteristics. (4) The exact size and shape of the dielectric area is not a critical design parameter, but the dielectric area should be as deep as possible for maximum coupling to the airframe. Radiation efficiency is generally proportional to the dielectric area.

To avoid the need for a complicated antenna-tuning network, the antenna reactance at 2.0 MHz should be no less than $+j18\ \Omega$, and ideally parallel resonance should occur between 20 and 30 MHz. Series resonance should be completely avoided, and antenna reactance should be no lower than $-j100\ \Omega$ at 30 MHz. To ensure good coupling to the airframe, the parallel component of the antenna impedance should be less than $20,000\ \Omega$.

Figure 40-13 shows the shunt-fed notch antenna for the C-130 aircraft. A portion of the dorsal and a portion of the leading-edge fairing are combined to yield a notch in the root of the vertical stabilizer. The total distance around the notch is approximately 160 in (4064 mm), or slightly smaller than the ideal periphery of approximately 200 in (5080 mm). This was necessary because of interference with the leading-edge de-icing system. The impedance curve for this antenna is shown in Figure 40-14.

A unique application of the shunt-fed HF antenna is found on the Lockheed Jet Star aircraft.¹³ Figure 40-14 is a sketch of the antenna. The antenna is fed from a coaxial feed on the upper surface of the wing, where a 32-in (813-mm) piece of phosphor-bronze stranded cable connects the center conductor to the leading lower edge of an aft-mounted engine nacelle. Excellent omnidirectional patterns are obtained, and the impedance is tuned by using an off-the-shelf coupler inside the pressurized area of the fuselage.

FIGURE 40-14 Shunt-fed HF notch-antenna configuration on the Lockheed JetStar¹³

40.4 UNIDIRECTIONAL VERY-HIGH-FREQUENCY ANTENNAS

The marker-beacon and glide-slope equipments require relatively narrowband antennas with simple patterns directed down or forward from the aircraft. This combination of circumstances makes the design of these antennas relatively simple. Both flush-mounted and external-mounted designs are available in several forms.

Marker-Beacon Antennas

The marker-beacon receiver operates on a fixed frequency of 75 MHz and requires a downward-looking pattern polarized parallel to the axis of the fuselage. A standard external installation employs a balanced-wire dipole supported by masts. The masts may be either insulated or conducting. Low-drag and flush-mounted designs are sketched in Figure 40-15. The low-drag design is a simple vertical loop oriented in the longitudinal plane of the aircraft. The feed line is inductively coupled to the loop, which is resonated by a series capacitor, and the antenna elements are contained in a streamlined plastic housing. The flush design is electrically similar, but in this case the structure takes the form of a conductor set along the longitudinal axis of the open face of a cavity. To achieve the desired impedance level, the antenna conductor is series-resonated by a capacitor and the feed point tapped partway along the antenna element.

FIGURE 40-15 Typical marker-beacon antennas

FIGURE 40-16 Protruding glide-slope antennas

Glide-Slope Antennas

The glide-slope receiver covers the frequency range from 329 to 335 MHz and requires antenna coverage only in an angular sector 60° on either side of the nose and 20° above and below the horizon. This requirement can be met by horizontal loops or by vertical slots. Because of the narrow bandwidth, the antenna element need not be electrically large. Two variations on the loop arrangement are sketched in Figure 40-16. Configuration *a* is a simple series-resonant half loop which can be externally mounted on the nose of the aircraft or within the nose radome. A variation of this antenna has two connectors for dual glide-slope systems. Configuration *b*, which is similar to the cavity-marker-beacon antenna of Figure 40-16, is suitable for either external or flush mounting.

40.5 OMNIDIRECTIONAL VERY-HIGH-FREQUENCY AND ULTRAHIGH-FREQUENCY ANTENNAS

In the frequency range in which the airframe is electrically large, the achievement of omnidirectional patterns, such as those used for short-range communications, is complicated by airframe effects. Since very-high-frequency (VHF) and ultrahigh-frequency (UHF) antennas of resonant size are structurally small, the required impedance characteristics can be achieved with fixed matching networks. Shadowing and reflection by the airframe result in major distortions of the primary pattern of the radiating element.

The tip of the vertical fin is a preferred location for omnidirectional antennas in the VHF and UHF range because antennas located there have a relatively unobstructed view of the surrounding sphere. At these frequencies the mean chord of the fin is approximately 10 wavelengths and the principal effect of the airframe on the radiation patterns is a sharply defined optical shadow region. At the lower end of this frequency range and on smaller aircraft, the effect of the airframe on the patterns is more complicated. Deep nulls in the forward quadrants can occur because of the destructive interference between direct

radiation and radiation reflected from the fuselage and wings. The latter contribution is more important for small aircraft since the ground plane formed by the surface of the fin tip is now sufficiently small enough to permit strong spillover of the primary pattern, which also can create lobing in the transverse-plane pattern. In this frequency range, the null structure is strongly influenced by the position of the radiating element along the chord of the fin, and careful location of the antenna along the chord may result in improvements in the forward-horizon signal strength.

UHF/VHF Antennas for Vertical Polarization

The monopole and its variants are the most commonly used vertically polarized VHF and UHF aircraft antennas. The antenna typically has a tapered airfoil cross section to minimize drag. Simple shunt-stub matching networks are used to obtain a voltage standing-wave ratio (VSWR) below 2:1 from 116 to 156 MHz.

The basic configuration of an all-metal VHF blade antenna is shown in Figure 40-17. This antenna employs a shunt-fed slot to excite the blade. The advantage of this configuration is its all-metal construction, which provides lightning protection and eliminates p static. Figure 40-18 shows a low-aerodynamic-drag sleeve monopole for the 225- to 400-MHz UHF communications system. The cross section is diamond-shaped, with a thickness ratio of 5:1. A feature of this antenna¹⁴ is the introduction into the impedance-compensating network of a shunt stub such that its inner conductor serves as a tension member to draw the two halves of the antenna together. In addition to providing mechanical strength, this inner conductor forms a direct-current path from the upper portion of the antenna to the aircraft skin, thereby providing lightning-strike protection.

Figure 40-19 is a broadband monopole/blade antenna matched through a pair of shunt blocks and a series feed with a capacitive section of semirigid coax. The shunt blocks are similar to L/R shunts and are ferrite-based for a gain of -24.5 dBi. There is an abrupt drop-off of antenna performance below 30 MHz.

A number of monopole designs have been developed for installation on a fin in which the top portion of the metal structure has been removed and replaced by a suitable dielectric housing. Various other forms of vertically polarized UHF and VHF radiators have been designed for tail-cap installation. The pickax antenna, consisting of a heavily top-loaded vertical element, has been designed to provide a VSWR of less than 3:1 from 110 to 115 MHz with an overall height of $15\frac{1}{2}$ in (393.7 mm) and a length of 14 in (355.6 mm).

UHF/VHF Antennas for Horizontal Polarization

There are three basic antenna elements which yield omnidirectional horizontally polarized patterns: the loop, the turnstile, and the longitudinal slot in a vertical cylinder of small diameter. All three are used on aircraft, and all suffer from a basic defect. Because they must be mounted near a horizontal conducting surface of rather large extent (i.e., the top or bottom surface of the aircraft), their gain at angles near the horizon is low. The greater the spacing from the conducting surface, the higher the horizontal gain. For this reason, locations at or near the top of the vertical fin are popular for horizontally polarized applications, particularly for the VHF navigation system (VOR) which covers the 108- to 122-MHz range.

FIGURE 40-17 Basic configuration of an all-metal VHF blade antenna

FIGURE 40-20 *E*-slot VOR antenna for the L-1011 aircraft (after L. Schuchman et al¹⁸ © IEEE 1989)

Figure 40-20 shows an *E*-fed cavity VOR antenna designed into the empennage tip of the L-1011 aircraft.¹⁵ The antenna system consists of a flush-mounted dual *E*-slot antenna and a stripline feed network mounted on the forward bulkhead of the cavity between the two antenna halves. The antenna halves are mirror-image assemblies consisting of 0.020-in- (0.508-mm-) thick aluminum elements bonded to the inside surface of honeycomb-fiberglass windows. The feed network consists of a ring hybrid-power-divider device with four RF ports fabricated in stripline. The two input ports for connecting to the antenna elements are out-of-phase ports. The two output ports connect to separate VOR preamplifiers. The operating band of the antenna is 108 to 118 MHz with an input VSWR of less than 2:1 referred to 50 Ω . Radiation coverage is essentially omnidirectional in the horizontal plane. The principal polarization is horizontal with a cross-polarization component of more than 18 dB below horizontal polarization. The antenna gain is 3.6 dB below isotropic at band center. Figure 40-21 shows the principal-plane voltage radiation patterns.

Figure 40-22 is a single half-loop antenna which is commonly installed on each side of the vertical stabilizer. The installed two-half-loop antenna system is basically a forced-fed balanced loop. The electrical equivalent is a single loop with a single feed with no intervening ground plane. The feed points are 180° out of phase to create a circuitous current flow with cancellation in the plane of the vertical stabilizer. Matching is achieved through one inductive and one capacitive shunt, and the feed gap is joined through a capacitive feed.

FIGURE 40-21 Voltage radiation patterns for the *E*-slot VOR antenna on the L-1011 aircraft (after L. Schuchman et al¹⁸ © IEEE 1989)

40.6 OMNIDIRECTIONAL L-BAND FREQUENCY ANTENNAS

The monopole and its variants are also commonly used for vertically polarized L-Band aircraft antennas. The antenna designs used for VHF and UHF frequencies can be scaled down to resonate at higher frequency ranges. Flush-mounted antenna designs are also possible since antenna dimensions are small enough to fit between aircraft structural elements.

The basic flush-mounted vertically polarized element for fuselage mounting is the annular slot,¹⁶ which can be visualized as the open end of a large-diameter, low-characteristic-impedance coaxial line. As seen from the impedance curve of Figure 40-23, such a structure becomes an effective radiator only when the circumference of the slot approaches a wavelength. The radiation patterns have their maximum gain in the plane of the slot for very small

FIGURE 40-24 Radiation patterns of an annular-slot antenna and a quarter-wave stub on a $2\frac{1}{2}$ -wavelength-diameter circular ground plane

slot diameters only, and they yield a horizon gain of zero for a slot diameter of 1.22.¹⁷ This pattern variation is illustrated in Figure 40-24. For these reasons and to minimize the structural difficulty of installing the antenna in an aircraft, the smallest possible diameter yielding the required bandwidth is desirable.

Again, the design for a UHF annular-slot antenna can be scaled down for use at L-Band. Consider a UHF broadband design for the 225- to 400-MHz band. The minimum practical diameter, considering construction tolerances and the effect of the airframe on the impedance, is about 24 in (610 mm). This is a rather large hole to put in an aircraft fuselage and is why this type of antenna is typically used at L-Band frequencies and higher. A VSWR under 2:1 across the 225- to 400-MHz band can be obtained with this diameter and a cavity depth of 4.5 in (114.3 mm). Figure 40-25 shows a design by A. Dörne together with its approximate equivalent circuit. In the equivalent circuit the net aperture impedance of the driven annular slot and the inner parasitic annular slot is shown as a series resistance-capacitance (RC) circuit. The annular region 1, which is coupled to the radiating aperture through the mutual impedance between the two slots, and the annular region 2, which is part of the feed system, are so positioned and proportioned that they store primarily magnetic energy. The inductances associated with the energy storage in these regions are designated as L_1 and L_2 in the equivalent circuit. The parallel-tuned circuit in the equivalent circuit is formed by the shunt capacitance between vane 3 and horizontal disk 4, together with the shunt inductance provided by four conducting posts (5) equally spaced about the periphery of 4, which also serve to support 4 above 3. From this element inward to the coaxial line, the base plate is cambered upward to form a conical transmission-line region of low characteristic impedance. A short section of low-impedance line is added external to the cavity to complete the required impedance transformation.

FIGURE 40-25 Annular-slot antenna for the 225- to 400-MHz band and its equivalent circuit

40.7 GPS ANTENNAS

The deployment of the Global Positioning System (GPS) “promises unprecedented worldwide, all-weather navigation capabilities when fully implemented in the 1990s.”¹⁸ The GPS system certainly provides general navigation functions and may be extended for Category 1 through 3 landings by the use of Differential GPS (DGPS) techniques.^{18,19} This technology is currently being evaluated, as seen in “Comments on Alternatives to the Microwave Landing System (MLS).”¹⁹ The GPS satellite transmits information on two frequencies: L_1 at 1575.42 MHz and L_2 at 1227.6 MHz. The L_1 frequency carries a code known as the *C/A code* and a *P-code*. The L_2 frequency carries only the P-code, which is controlled by the Department of Defense and is encrypted for use of classified military users.²⁰ Thus GPS antennas are required for both civil and military applications.

In order to obtain maximum position accuracy, a field of view which encompasses four satellites is required. In general, this dictates a near-hemispherical antenna pattern with a coverage extending from near the horizon to the zenith. However, the ideal antenna pattern would maximize horizon gain at the expense of zenith gain due to geometry considerations. That is, the satellites at the horizon are at the maximum range. The GPS satellite transmits right-hand circular polarization. Therefore, a linearly polarized antenna can be employed with a 3-dB gain-loss penalty. Although maximum gain is desirable, low antenna gain is compensated for by the processing gain inherent in the GPS code. Typical GPS antenna gains range from -7.5 to -3 dBci at the horizon to 0 to 4 dBci at zenith, depending on the antenna utilized. For civilian applications, the typical antennas consist of crossed slots, spirals, annular slots, microstrip quadrafilers, helices, and microstrip patches. The patch antennas typically consist of stacked patches which are tuned to the two frequencies. These antennas are categorized as fixed reception pattern antenna (FRPA). For military applications, which may utilize adaptive null steering to counter interfering jamming signals, a controlled reception pattern antenna (CRPA) may be used. These antennas are typically microstrip patch arrays which are capable of adaptive beam forming.

40.8 ALTIMETER ANTENNAS

The radio altimeter, which operates at 4300 MHz, requires independent downward-looking antennas for transmission and reception. Proper operation requires a high degree of isolation between the transmitting and receiving elements. Horn antennas were originally used, but microstrip patch antennas are most commonly used today due to their smaller size, weight and structural modification requirements.

40.9 ANTENNA PERFORMANCE AND AIRCRAFT INTERACTION

Several techniques are used in characterizing the impedance and radiation pattern characteristics of an antenna installed on an aircraft. Scale model testing has historically been the most common method used for radiation pattern measurements. Full-scale measurements are expensive, require enormous facilities, and are therefore usually employed only in large budget government programs. Computer simulations have matured with the growth in processing power and are widely used today. All of these techniques can be used to predict the aircraft's effects on antenna performance, including modulation of the radiated signal due to motion of the blades in the case of propeller-driven aircraft and helicopters.

Scale Model Pattern Measurements

Using scale models overcomes many of the difficulties associated with radiation pattern measurements. The distance to the far-field can be reduced so that a reasonably sized indoor or outdoor pattern range can be used. A properly designed range can manipulate the model of the aircraft with the antenna to get the desired pattern measurements and provide a controlled environment to help eliminate unwanted reflections from the ground and surrounding objects or allow their removal through signal processing techniques. When developing a scale model, if the aircraft and antenna are reduced in size by a given scaling factor, the frequency and conductivity must be increased (multiplied) by that same factor. The accuracy of the model in terms of detail and electrical parameters depends on the frequency of operation, location of the antenna relative to the detailed parts, and required accuracy of the pattern performance predictions.

Most external antennas are located on the top or bottom centerline of the fuselage in order to maintain symmetry of the radiation patterns. Pattern coverage in such locations is limited by the airframe shadows. Figure 40-26 shows the scale model patterns for a monopole on the bottom centerline of a one-fifth scale C-141 model. Since the aircraft is one-fifth scale, the frequency measured is five times greater and the monopole is designed to resonate at 1000 MHz. It is apparent that coverage is limited to the hemisphere below the aircraft. Antennas on the top of the fuselage yield patterns confined to the upper hemisphere, with a null aft owing to the shadow cast by the vertical stabilizer. In many applications, as for example in scheduled-airline operations, these pattern limitations are acceptable.

The deep lobing in the roll-plane pattern of Figure 40-26 is due to reflections from the strongly illuminated engine nacelles. In some locations, similar difficulties are encountered because of reflections from the wing flaps when they are extended. Shadows and lobing also occur due to extended landing gear and can be troublesome for bottom-mounted antennas.

Full-Scale Pattern Measurements

If a full-scale version of the aircraft and antenna can be accommodated by an antenna pattern range, detailed performance characteristics can be measured. For example, the VOR navigation system is particularly vulnerable to the modulation effects of a helicopter rotor. Angular-position information is contained in a 30-Hz modulation tone which corresponds closely to the third harmonic of the fundamental blade-passage frequency on a typical helicopter. In Figure 40-27, two VOR antenna installations on an H-19 helicopter are shown with the horizontal-plane radiation patterns.

FIGURE 40-26 Voltage radiation patterns of a 1000-MHz monopole on the bottom of a C-141 aircraft

FIGURE 40-27 Two VOR-antenna locations on the H-19 helicopter and horizontal-plane radiation patterns

The fine structure on these patterns shows the peak-to-peak variation in signal amplitude due to passage of the rotor blades. The percentage of modulation of the signal received on the horizontal loop antenna is seen to be lower than that received on the ramshorn antenna. This is due partly to the shielding afforded the loop by the tail boom and partly to the fact that the loop antenna has inherently less response to scattered signals from the blades because its pattern has a null along its axis while ramshorn antenna receives signals from directly above it very effectively.

Method-of-Moments Analysis of Low-Frequency and High-Frequency Antenna Patterns

The method of moments (MOM)¹⁻³ is a computer analysis method which can be employed to determine the radiation patterns of antennas on aircraft and missiles. A discussion of this technique is beyond the scope of this handbook, but user-oriented computer programs are available.²¹⁻²³

The method of moments is based upon a solution of the electromagnetic-wave-scattering integral equations by enforcing boundary conditions at a number N of discrete points on the scattering surface. The resulting set of equations is then solved numerically to determine the scattered fields. This is typically accomplished by modeling the surface as a wire grid for which the self- and mutual impedances between the wires can be calculated. This technique, for a set of N wire elements that represent the aircraft as shown in Figure 40-28, results in an $N \times N$ impedance matrix. For a given antenna excitation, inversion of the $N \times N$ matrix yields the solution for the wire currents and hence the radiated fields of the antenna-aircraft system.

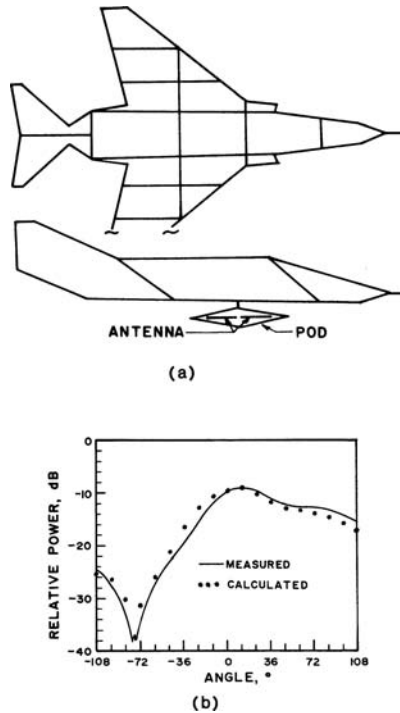

FIGURE 40-28 MOM wire-grid analysis of low-frequency aircraft antenna patterns: (a) MOM wire-grid model of an RF-4C aircraft; (b) MOM calculated roll-plane pattern for a pod-mounted dipole array on the RF-4C aircraft (after J. J. Wang and C. E. Ryan²⁴ © IEEE 1977)

Computer programs which implement this technique for wire scatterers^{1,21-24} and for surface patches^{25,26} have been written. Supercomputers can handle matrixes on the order of 10,000 by 10,000 elements, and continuing technology advances will permit larger matrixes to be solved. Also, several MOM codes for personal computers (PCs) are available.^{22,23} These codes will become increasingly useful as the computing capability of PCs increases. The number of wire or patch elements which must be employed to ensure a convergent numerical solution varies as a function of the particular code implementation. Typically, a wire element less than $\lambda/8$ in length must be used so that $1\lambda^2$ surface patch requires a square wire-grid model containing 144 wires. Thus it is seen that as the surface area increases, the required matrix increases roughly as the square of the area which, in practice, restricts the MOM to electrically small- to moderate-sized geometries. Codes based on body-of-revolution approximations are also available²⁵ and are particularly applicable to missiles.

A wire-grid model which was used for the pattern analysis of a pod-mounted high-frequency (HF) folded-dipole array antenna on an RF-4C aircraft is shown in Figure 40-28. An MOM code employing piecewise, sinusoidal basis functions^{1,24} was used to calculate the roll-plane patterns for the array. These results are compared with measured data in Figure 40-28.

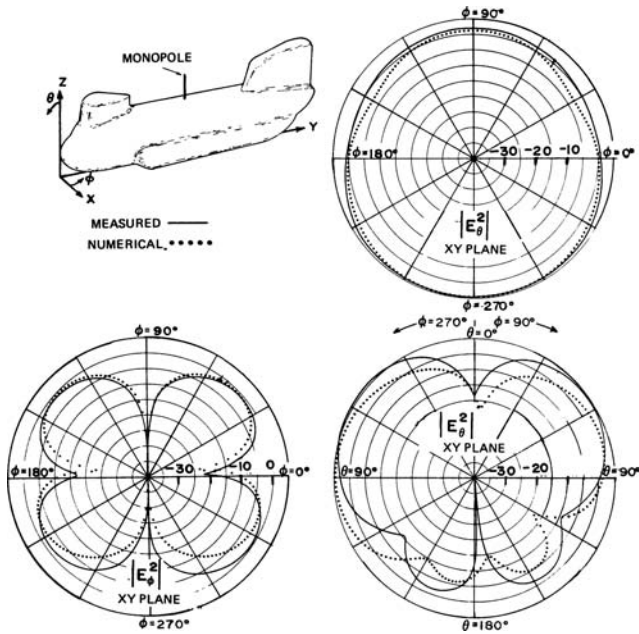

FIGURE 40-29 MOM surface-patch-calculated patterns for the CH-47 helicopter (after D. L. Knepp and J. Goldhirsh²⁷ © IEEE 1972)

A surface-patch method has also been employed to analyze the patterns of antennas on helicopters.²⁷ In this analysis, the helicopter surface was subdivided into a collection of curvilinear cells, which employed 94 surface-patch cells, is shown in Figure 40-29 for the pitch and yaw planes. Generally, good results were obtained for this complex-shaped airframe. Also, we note that, by representing the helicopter rotor blades as wires, the rotor effects on the patterns can be computed.

For some LF applications, a simplified stick model of an aircraft may be sufficient.²⁸ A model of an aircraft is shown in Figure 40-30. The fuselage, wings, and empennage can be represented by either single or multiple thin wires if their maximum electrical width

FIGURE 40-30 MOM calculated voltage patterns for a blade antenna (tilted monopole) on a stick model aircraft

is approximately less than $\lambda/10$. Figure 40-12 shows a calculated result for a monopole mounted on a stick model, and the effects of the fuselage and wings can be seen by comparison with the unperturbed-monopole pattern.²⁹

GTD Aircraft Antenna Analysis

The MOM technique is limited to surfaces which are relatively small in terms of square wavelengths. However, as the frequency increases and the surface becomes large in terms of square wavelengths, the propagation of electromagnetic (EM) energy can be analyzed by using the techniques of geometrical optics. For example, if an incident field is reflected from a curved surface, ray optics and the Fresnel reflection coefficients yield the reflected field.

The geometrical theory of diffraction (GTD) uses the ray-optics representation of EM propagation and incorporates both *diffracted rays* and *surface rays* to account for the effects of edge and surface discontinuities and surface-wave propagation. In the case of edge diffraction, the diffracted rays lie on a cone whose half angle is equal to the half angle of the edge tangent and incidence vector. For a general curved surface, the incident field is launched as a surface wave at the tangent point, propagates along a geodesic path on the surface, and is diffracted at a tangent point toward the direction of the receiver. Each of these diffraction, launching, and surface propagation processes is described by appropriate complex diffraction and attenuation coefficients which are discussed in the literature.³⁰ In practice, these coefficients are implemented as computer algorithms which can be used as building blocks for a specific analysis.

In the GTD analysis, the received far- or near-zone field is composed of rays which are directly incident from the antenna, surface rays, reflected rays, and edge-diffracted rays. Also *higher-order effects* such as multiple reflections and diffractions can occur. Several computer models have been implemented to perform the required differential-geometry and diffraction calculations.³¹⁻³³ It is anticipated that these methods will become more user-oriented and powerful with the advent of increasingly sophisticated computer-graphics systems.

Figure 40-21 shows a model of a missile composed of a conically capped circular cylinder with a circumferential-slot antenna.³⁴ In this case, the radiated field is due to direct radiation from the slot, surface rays which encircle the cylinder, and diffracted rays from the cone-cylinder and cylinder-end junctions and from the cone tip. The computed results shown in Figure 40-31 were obtained by employing the solution for a slot on an infinite circular cylinder to represent the direct- and surface-ray fields and by computing the diffracted fields from the junctions and tip as corrections to the infinite-cylinder result. The principal-plane pattern shown is in agreement with measured data, and comparable results have been obtained for the off-principal planes.³⁵

An analysis due to Burnside et al.³¹ approximates the fuselage as two joined spheroids, and the wings and empennage are modeled by arbitrarily shaped flat plates. In addition, the engines can be modeled by finite circular cylinders. Figure 40-32 shows a result obtained from this analysis of a $\lambda/4$ monopole on a KC-135 aircraft for the roll plane. J. R. Mantz and R. F. Harrington²⁵ present a complete 4π -sr plot for a monopole on a Boeing 737 aircraft. The results, which compare well with measured data, illustrate the accuracy of the GTD analysis for VHF and UHF antennas.

It should be noted that a complete GTD model may not always be required for an engineering assessment of antenna performance. For example, if wing reflection and blockage effects are dominant, one can use a simpler model consisting of two submodels: a submodel for an antenna on a finite (or perhaps an infinite) cylindrical fuselage and a flat-plate submodel for the wings.³³ In this case, the antenna-on-cylinder pattern results are used as the antenna illumination for calculation of the wing blockage, reflection, and diffraction.

D. Burnside et al³¹ © IEEE 1975)

The computer analysis of aircraft interference effects on scanning array antenna patterns is a subject of much interest to those working in the field of large airborne antenna arrays. Experience indicates that such analyses employing the geometrical theory of diffraction (GTD) are feasible and cost-effective. The emphasis in the technology is the use of large-aperture, low-frequency (UHF to S-band) arrays installed on large airframes such as the C-5A or B747 aircraft. Techniques usually considered are scale-model measurements, full-scale measurements, and computer simulation of the array antennas on airframes. Computer-simulation techniques have a considerable advantage from a cost standpoint over the other two options. The computer-simulation technique is a very useful tool for determining the proper array location on the airframe and the frequency sensitivity to airframe effect on radiation patterns. Wing, engine nacelles, and empennage structure in the near field of large arrays can cause devastating effects on the sidelobe structure of a well-designed array antenna. Once the airframe and the array are simulated on the computer, it is a simple matter to relocate the array on the airframe and compute the resulting pattern. While the pattern computation is very central process unit (CPU) time-intensive, it is still more cost-effective to move the array on the computer than to move the array on the full-scale aircraft or scale model.

A collection of plates and cylinders is used to model the airframe, including the empennage, wing, engine nacelles, and engine pylons. Each element in the array antenna is assumed to be a separate source controllable in amplitude and phase, allowing the use of aperture-distribution tapering and simulated electronic scanning of the beam to a desired angle.

This technique allows the computation of three parameters to help with the evaluation of antenna performance on the airframe. They are the two-way integrated sidelobe-to-mainlobe (SL/ML) ratio in decibels, the rms sidelobe level in decibels, and the 3-dB beamwidth in degrees. To calculate the SL/ML ratio, the sidelobes and mainlobe are sampled at 1° increments and integrated. The integrated sidelobe power (two-way) is divided by the integrated mainlobe power (two-way). One of the great strengths of this computer-analysis technique is the user's ability to disassemble the airframe, when desired, for identifying the primary contributor to a particular sidelobe or cross-polarized component of the radiation patterns.

The computer code used to compute phased-array antenna radiation patterns is a modified version of the "Numerical Electromagnetic Code—Basic Scattering Code" (version 3.19) developed by the Ohio State University ElectroScience Laboratory.^{36,37} It uses the geometrical theory of diffraction (GTD) to determine the total field at a given observation point. Several basic geometric shapes can be used to model scattering objects. They are arbitrarily oriented flat plates, perfectly conducting finite elliptic cylinders, elliptic cone frustum sections, and finite composite ellipsoids. These objects should have a minimum dimension of one wavelength, and the accuracy increases as the object size in wavelengths increases. The required accuracy of the scattering model also depends on the direction of the mainbeam, while broad-beam antennas require greatest accuracy in the part of the model near the antenna.

The GTD code was used to analyze a rotodome array installed on the S3 aircraft, as shown in Figure 40-33. The 28-in by 228-in array is composed of 32 columns spaced 7.125 in by 4 rows spaced 7.0 in. A 50-dB Taylor ($n = 6$) aperture distribution was chosen for the horizontal plane and a 30-dB Taylor ($n = 4$) aperture distribution was chosen for the vertical plane. The free-space azimuth plane pattern, shown in Figure 40-34, has a 3-dB beamwidth of 4.75° in the horizontal plane at 900 MHz. When this array is installed in the rotodome above the S3 airframe, the resulting pattern for a 45° look angle from the nose of the aircraft is shown in Figure 40-35. The integrated two-way SL/ML ratio for the free-space radiation pattern is -91 dB. When the array is installed on the S3 airframe, the SL/ML ratio is -71.6 dB. This parameter is indicative of how severe the competing sidelobe clutter might be in a radar application. The acceptability of this much sidelobe degradation would be determined by the radar designer.

41.1 INTRODUCTION

Antennas are widely used as part of passive remote sensing systems for inferring the physical properties of planetary atmospheres and surfaces¹ as well as related applications such as all-weather vision for aviation and imaging through materials for security. Radiometer antennas are similar in type to those used for active systems such as radars and telecommunications links but differ primarily in requiring extreme efficiency and stability. In the case of radar and telecommunications antennas, signal variations of order 0.1 dB or more due to antenna losses and pattern uncertainties may be tolerable. In radiometry the tolerable level of variation imparted by the antenna is often a hundred times (or more) smaller, approaching a level of tens to hundreds of microBels ($1 \mu\text{B} = 10^{-5} \text{ dB}$). This extreme level of stability is required to permit the radiometer system to distinguish thermal fluctuations of order $\sim 0.1 \text{ K}$ or smaller against a background radiation intensity of tens to hundreds of Kelvins.

We can further distinguish between two types of radiometer antennas: those used for Earth remote sensing and those used for radioastronomy. In Earth remote sensing the radiometric system observes a distributed target of large angular extent and relative warmth in temperature. For example, ocean brightness temperatures in the microwave bands are of order 120 K, while land surfaces can be 200-300 K or more.¹ Hence, antenna systems for downward-looking radiometric systems must have small, close-in sidelobes out to the angles where the surface brightness diminishes. In radio astronomy the natural sources (planets, stars, galaxies, and quasars) are of such limited angular extent that they are effectively point sources. In addition, they are immersed in a cold sky of several degrees Kelvin.²⁻³ Techniques such as interferometry are regularly used in radio astronomy to improve resolution at the expense of high sidelobes, and have recently been adopted for remote sensing of atmospheres and surfaces in downward-viewing Earth remote sensing systems.

Owing to the above, radiometer antenna design requires much more precise consideration of antenna performance parameters than most antenna engineers are accustomed to. For example, main beam efficiency, antenna losses, antenna stability, antenna physical temperature, and scanning considerations are extremely important, as are directional gain, sidelobe levels, mismatch, and polarization. In this chapter we include an extended section on basic radiometer principles, along with a description of basic radiometer system types in present or proposed use on spacecraft and aircraft, as well as a discussion of the basic radiometer antenna types commonly in use.

41.2 BASIC PRINCIPLES

For microwave remote sensing applications, the radiometer antenna is used with a very sensitive receiver for detecting and providing a measurement of the electromagnetic radiation intensity received within the solid angle subtended by the antenna beam. The received radiation can originate from a variety of sources, including emission from atmospheric gases and hydrometeors, land, snow, ice, or ocean surface contributions, and the cold cosmic background. The radiation field can undergo scattering from both hydrometeors and the surface. Properties of the atmosphere such as temperature, moisture, and cloud water content influence the radiation intensity within the antenna beam.⁴⁻⁷ Depending upon knowledge of the roughness and dielectric properties of the surface and the relationship of the dielectric properties to the physical properties of the surface, indirect or remote measurements of these properties are feasible.

FIGURE 41-1 Typical radiometer observation geometry in microwave remote sensing

The received power detected by the radiometric system is

$$P_{\text{rec}} = \int_{f-\frac{B}{2}}^{f+\frac{B}{2}} \frac{hf}{(e^{hf/kT_A} - 1)} df \approx kT_A B \quad (41-1)$$

where $k = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant, $h = 6.63 \times 10^{-34}$ J-s is Planck's constant, B is the radio frequency bandwidth of the receiver in Hz, and T_A is the antenna temperature in Kelvins. The rightmost side of Eq. 41-1 is the Rayleigh-Jeans approximation that holds for frequencies $f \ll kT_A/h$.

Antenna Temperature

The antenna temperature, stated in a manner suppressing polarization and presuming use of the Rayleigh-Jeans approximation,¹ is given by

$$T_A = \frac{\int_0^{2\pi} \int_0^\pi f(\theta, \phi) T_B(\theta, \phi) \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^\pi f(\theta, \phi) \sin \theta d\theta d\phi} \quad (41-2)$$

where $f(\theta, \phi)$ is the radiation pattern of a perfect plane-polarized antenna and $T_B(\theta, \phi)$ is the brightness temperature of the scene observed by a radiometer antenna with the same polarization. A typical scenario for which the antenna is pointed toward a surface is given in Figure 41-1. Here, T_{sky} is the downwelling sky radiation in the specular direction and includes thermal radiation emitted by the atmosphere and from the cosmic background. The brightness temperature observed by the radiometer antenna is the sum of the brightness temperature T_{Bs} emitted by the surface and the energy from the sky radiation scattered by the surface in the specular direction. This brightness temperature $T_B(\theta, \phi)$ is given by

$$T_B(\theta, \phi) = T_{Bs} + |R_s|^2 T_{\text{sky}} \quad (41-3)$$

where $|R_s|^2$ is the reflection coefficient for the air-surface interface and for the polarization of interest.

¹ More precisely, the antenna temperature is derived by integrating the spectral density $\frac{hf}{e^{hf/kT_B(\theta, \phi)} - 1}$ against the antenna pattern over all angles, then inverting this integrated power P according to the function $\frac{hf}{k \ln \left(\frac{hf}{P} + 1 \right)}$.

The emissivity of the surface is given by

$$\epsilon_s = 1 - |R_s|^2 \quad (41-4)$$

and the brightness temperature T_{Bs} is related to the physical surface temperature T_s by the relation

$$T_{Bs} = \epsilon_s T_s \quad (41-5)$$

From Eqs. 41-3, 41-4, and 41-5

$$T_B(\theta, \phi) = (1 - |R_s|^2) T_s + |R_s|^2 T_{sky} \quad (41-6)$$

It is emphasized that these equations do not consider the polarization properties of the antenna and the surface. These properties are discussed in the next subsection.

Polarization

To include the effects of polarization in the expression for antenna temperature, we must consider both the polarization properties of the radiation field and of the antenna itself. For Earth remote sensing, the polarization of the radiation field is described using the Stokes parameters as defined in terms of a simple polarization basis associated with the direction of observation and the surface normal. Consider the coordinate system of Figure 41-2 where the direction of the antenna beam is along (θ, ϕ) relative to a fixed Cartesian coordinate system with the z-axis pointing toward the zenith direction. Let the unit vector \hat{k} point along this direction toward the antenna. Then the unit vectors \hat{v} and \hat{h} are defined as follows:

$$\hat{h} = \frac{\hat{k} \times \hat{z}}{|\hat{k} \times \hat{z}|} \quad \hat{v} = \hat{h} \times \hat{k} \quad (41-7)$$

In general the radiation field propagating along \hat{k} toward the antenna consists of a statistical distribution of plane waves with complex electric field components in both the \hat{v}

FIGURE 41-2 Polarization of a radiometer antenna with regard to the surface and sky scene

and \hat{h} directions: $\bar{E} = E_v \hat{v} + E_h \hat{h}$. It is possible to fully characterize this distribution of complex field amplitudes using four parameters that describe the powers in the vertical and horizontal polarizations along with the complex correlation between the amplitudes in these two polarizations:

$$\begin{aligned} I &= \frac{1}{2\eta} \left(\langle |E_v|^2 \rangle + \langle |E_h|^2 \rangle \right) \propto T_{BV} + T_{BH} \\ Q &= \frac{1}{2\eta} \left(\langle |E_v|^2 \rangle - \langle |E_h|^2 \rangle \right) \propto T_{BV} - T_{BH} \\ U &= \frac{1}{\eta} \operatorname{Re} \langle E_v E_h^* \rangle \propto T_{BU} \\ V &= \frac{1}{\eta} \operatorname{Im} \langle E_v E_h^* \rangle \propto T_{BV} \end{aligned} \quad (41-8)$$

where $\langle \rangle$ denotes statistical expectation for waves filtered over a small solid angle $d\Omega$ and small frequency interval df , and $\eta = 377\Omega$ is the impedance of free space. These are the four Stokes parameters⁸ for the radiation field. It can be easily shown that $I^2 \leq Q^2 + U^2 + V^2$. Natural surfaces generate upwelling radiation fields with values of I and Q in the range of a hundred Kelvin or more. It has recently been established⁹ that anisotropic surfaces, for example, ocean waves, generate values of U and V of up to a few Kelvins.

To determine the contribution of the four Stokes parameters to the received power it is useful to consider the antenna's gain matrix, defined by analysis of the polarized far-field components of the antenna's radiated field when used as a transmitter:

$$G_{ij}(\theta, \varphi) = \lim_{r \rightarrow \infty} \frac{2\pi r^2 E_i(r, \theta, \varphi) E_j^*(r, \theta, \varphi)}{\eta P_T} \quad (41-9)$$

where P_T is the transmitted power and the subscripts i, j are either \hat{v} (vertical) or \hat{h} (horizontal) field components defined relative to a unit vector in the $-\hat{k}$ direction. The response of the antenna to the Stokes parameters is thus precisely as follows:

$$P_{\text{rec}} = \int_{f-\frac{B}{2}}^{f+\frac{B}{2}} \iint_{4\pi} \left[A_{vv} \left(\frac{I+Q}{2} \right) + \operatorname{Re}\{A_{vh}\}U + \operatorname{Im}\{A_{hv}\}V + A_{hh} \left(\frac{I-Q}{2} \right) \right] d\Omega df \quad (41-10)$$

where $A_{ij}(\theta, \varphi) = \frac{\lambda^2}{4\pi} G_{ij}^*(\theta, \varphi)$ are the effective area matrix elements of the antenna associated with each gain matrix element.¹⁰ Accurate characterization of the antenna gain matrix can be used to properly interpret received power signals in terms of the four Stokes parameters, although good cross polarization isolation (of -30 dB or better) is usually the best way to separate measurements of each of these parameters. Further discussion of this subject is found in later sections of this chapter.^{9,10}

It is useful to note that for many surfaces^{6,11} T_{BH} and T_{BV} have properties such that $T_{BH} - T_{BV} \approx 0$ out to 20° to 30° incidence. Hence, if a narrow-beam low-sidelobe antenna is used for near-nadir observations, the antenna temperature as given in Eq. 41-10 will be largely independent of the polarization of the radiometer antenna. For the antenna designer, the message at this point is rather clear. A radiometer antenna must be designed so that

sidelobes, cross-polarization lobes, and backlobes do not pick up unwanted contributions. Common design parameters for comparing radiometer antennas are the beam efficiency and the cross-polarization index.

Beam Efficiency

The beam efficiency of an antenna is defined as

$$BE(\theta_1) = \frac{\text{power radiated in cone half-angle } \theta_1}{\text{power radiated in } 4\pi \text{ sr}} \quad (41-11)$$

or

$$BE(\theta_1) = \frac{\int_0^{2\pi} \int_0^{\theta_1} f(\theta, \phi) \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^{\pi} f(\theta, \phi) \sin \theta d\theta d\phi} \quad (41-12)$$

It should be noted that polarization is not considered in Eq. 41-12 for simplicity, but will be included later. One can observe from Eqs. 41-11 and 41-12 that to relate one antenna to another in terms of beam efficiency the choice of the angle θ_1 must be made in a standard manner. A common choice for θ_1 is the angle between the main beam axis and first pattern null. Another choice for comparing antennas, such as the wide angle corrugated horn or the multimode horn in which the first null is poorly defined, is to use the criterion for θ_1 as $2\frac{1}{2}$ times the half angle of the 3-dB beamwidth.

The beam efficiency of aperture antennas with non-uniform aperture amplitude distributions has received much attention. Curves comparing one aperture distribution to another are readily available.¹²⁻¹⁴ Examples of the impact of various aperture distributions upon beam efficiency are shown in Figure 41-3 for rectangular and circular apertures as a function of the dimensionless parameter $U = ka \sin \theta$. For uniform circular and rectangular amplitude distributions the first several sidelobes cause pronounced ripples in the beam-efficiency curves, and values of $BE = 95\%$ are not achieved even for large values of U . For more tapered distributions the beam efficiency rises to large values rapidly and independently of aperture shape.

This characteristic of ideal aperture distributions for large beam efficiency is consistent with reduction of wide-angle sidelobes through tapering.^{12,14} Indeed, some antennas such as the multimode, exponential, and corrugated horns have very low sidelobes and backlobes and hence excellent beam efficiencies. Reflector antennas are also sometimes used in radiometry, although in this case the overall beam efficiency is influenced by feed spillover, cross-polarization, and blockage in addition to aperture illumination taper and reflector-surface roughness. These properties will be discussed later on.

The effects of polarization on beam efficiency can be described by the quantity BE_{dp} for the direct (versus cross) polarization:

$$BE_{dp} = \frac{\text{power within angle } \theta_1, \text{ direct polarization}}{\text{total received power, both polarizations}} \quad (41-13)$$

Stated in equation form

$$BE_{dp} = \frac{P_{\theta_1, dp}}{P_{dp} + P_{op}} \quad (41-14)$$

FIGURE 41-3 Comparison of beam efficiencies for rectangular and circular apertures with various aperture distributions

where P_{dp} is the total power received in the direct polarization and P_{op} is the total power received in the orthogonal polarization. The effect of the orthogonal-polarization energy therefore is to decrease the direct-polarization beam efficiency of the antenna. A cross polarization index (CPI) can be defined as¹⁵

$$\text{CPI} = BE_{dp} \frac{P_t}{P_{op}} \quad (41-15)$$

For example, for $BE_{dp} = 85$ percent and on the assumption that the antenna has the property $P_{op}/P_t = 26$ dB, the cross-polarization isolation index is 25 dB.

The significance of cross-polarization levels in a radiometer antenna can be vividly demonstrated by reviewing the earlier discussion on polarization resulting in Eq. 41-10. The brightness temperature of a particular scene is polarization- and angle-dependent. In general, except at near-nadir angles, the brightness temperature of a given surface will be different for vertical and horizontal polarizations. To demonstrate the effect of cross-polarization upon the radiometric measurement of a scene the curves in Figure 41-4 are presented. The bias error ΔT_A in this figure is the error in brightness temperature produced by the integrated cross-polarized lobes observing the surface. This approximation is valid for only narrow-beam antennas in which emission from the surface at a given polarization is constant over $2\frac{1}{2}$ times the 3-dB beamwidths

FIGURE 41-4 Effect of antenna cross-polarization power on radiometer bias as a function of scene polarization difference temperature

of the antenna. For precision measurements of ocean temperature in which accuracies of 0.3 K or better are desired, values of cross-polarization energy less than 28 dB are required.

Stray Radiation

For narrow-beam antennas, $T_B(\theta, \phi)$ is relatively constant over the main beam, and Eq. 41-2 can be written as

$$T_A = T_B(\theta, \phi)BE_{\theta_1} + \frac{\int_0^{2\pi} \int_0^\pi f(\theta, \phi)T_B(\theta, \phi) \sin \theta d\theta d\phi}{\int_0^{2\pi} \int_0^\pi f(\theta, \phi) \sin \theta d\theta d\phi} \quad (41-16)$$

If the assumption that $T_B(\theta, \phi)$ is constant in the second term of Eq. 41-16 is made, this equation may be written as

$$T_A = T_B(\theta, \phi)BE_{\theta_1} + T_B(\theta, \phi)[1 - BE_{\theta_1}] \quad (41-17)$$

The second term in Eq. 41-17 is the so-called stray radiation contribution. For radioastronomy and some Earth remote sensing applications, the near-in and relatively far-out sidelobes observe cold sky surrounding the main beam, thus justifying the assumptions made in Eq. 41-17. For radioastronomy applications the design emphasis must be placed

on minimizing contributions from backlobes which point toward the warm earth. For Earth remote sensing applications, the close-in and wide-angle sidelobes observe brightness temperatures in the same range as the main beam (100–270 K), while in many configurations the backlobes point to the cold sky. Concepts such as stray radiation are useful in that they provide a bound on the ultimate accuracy of the T_A measurement. Simplistic forms to compute stray radiation such as Eq. 41-17 should be avoided unless great care has been exercised to understand the amplitude and angular distribution of brightness temperatures in the scene.

Ohmic and Reflection Losses

The ohmic losses in the antenna will modify the apparent temperature observed by the radiometric system by the relation⁶

$$T_a = (1 - \epsilon_L) T_A + \epsilon_L T_0 \quad (41-18)$$

where T_a is the apparent antenna temperature of a source whose antenna temperature (observed without loss) is T_A , T_0 is the physical temperature of the antenna, and ϵ_L represents the fractional power loss in the antenna.

The significance of physical losses in the antenna upon the absolute accuracy of remotely sensed surface properties can be seen using the following example. Assume that the antenna physical temperature is that of room temperature, for example, $T_0 \approx 300$ K. Typical ocean and land scenes exhibit (lossless) antenna temperatures between 100 and 300 K. Using this information, the effect of antenna losses upon measurement accuracy is given in Figure 41-5. For some ocean-temperature applications ($T_A \approx 102$ K), absolute

FIGURE 41-5 Effects of losses upon scene antenna temperature

accuracies of 0.3 K or smaller are of importance. Hence, very small losses (≤ 0.005 dB) are of significance. For antennas in which losses are significant, this loss must be stable, well characterized, and the physical temperature of the antenna known to high precision so that the added emission can be treated as a known bias. For example, a Potter horn built for a precision S-band radiometer⁶ exhibited an acceptably stable loss of ≤ 0.1 dB. Studies of corrugated and multimode horns¹⁶ indicate small but significant losses when these are used as radiometric antennas. To ensure stability in calibration, antennas may be enclosed in thermally stable boxes with very low loss radomes.

The effect of mismatch at the input to the radiometer upon the observed antenna temperature can be expressed as⁶

$$T_a = (1 - \rho)[(1 - \epsilon_L)T_A + \epsilon_L T_0] + \rho T_R \quad (41-19)$$

where ρ is the reflection coefficient of the antenna and T_R is the microwave temperature seen looking into the receiver. The effects of small mismatches are very important for precision measurements. Stability of this mismatch will allow one to treat this error as a bias. Again, as in the case of physical loss, the thermal stability of the antenna impedance is important.

Calibration

Calibration is performed by stimulating the input of a radiometer with known temperatures and then identifying the system response parameters. The gain and offset of a radiometer system are subject to significant drift compared to the typical required brightness precision. Accordingly, calibration of the entire radiometer system, including the antenna, is desired to compensate for such variations. Three common methods of calibration are shown in Figure 41-6. The steerable-antenna method (see Figure 41-6a) requires that the radiometer antenna be able to be periodically pointed toward a cold reference source such as space (ideally the galactic pole) to provide a measurement of system gain. The antenna can also be pointed at a warm reference, such as a thermally stable lake, in order to obtain a second calibration point for determination of both gain and offset. References can also be microwave blackbody targets at distinct temperatures, for example, a porous microwave absorber located in a container filled with liquid nitrogen. This type of load is commonly used in laboratory calibration and for pre-flight calibration of airborne radiometers, provided that the radiometers have been designed to be very stable over long periods of time. The emission characteristics of such blackbody targets must be well understood.¹⁷ Accurate calibration requires that the references have temperatures that bound the range of variation of scene antenna temperature.

For applications where the antenna cannot be steered toward references, a switchable two-antenna technique (see Figure 41-6b) can be used although variations in system response due to differences between the two antennas must be determined. Another disadvantage of this scheme are switch losses that might change as a function of time, depending upon the switch technology and method

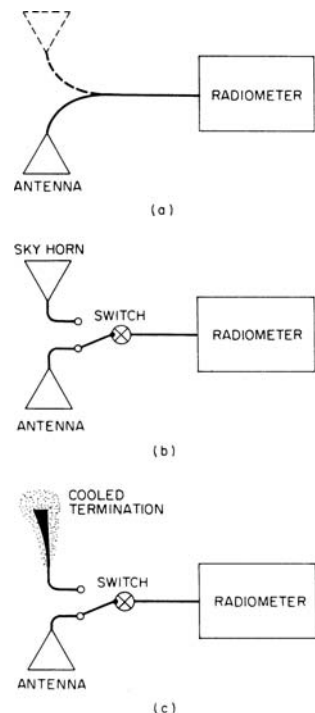

FIGURE 41-6 Radiometer calibration methods: (a) steerable antenna, (b) reference antenna and switch, and (c) cooled termination and switch

of thermal control. The third method (see Figure 41-6c) uses cooled terminations and has the advantage of not requiring a separate or movable antenna. This technique is very useful for systems in which rapid internal calibration is necessary.¹⁸ Cooled terminations can be fabricated either using Peltier effect coolers or by connecting to the input of a low noise amplifier. Use of two switches and a pair of terminations at two distinct temperatures permits determination of both gain and offset. Of course, switch losses are common to the methods in Figure 41-6b and c.

Calibration must be performed often enough to identify significant variations in gain and offset. The time stability of the radiometer components, which depends to a great extent on thermal stability, determines the required maximum calibration period. End-to-end calibration of fully polarimetric radiometers has been demonstrated.^{19,20}

41.3 SYSTEM PRINCIPLES

Radiometer Types

A variety of radiometer architectures have been used for radio astronomy and Earth remote sensing (for example, Hidy et al⁶). Four basic types commonly in use are described in simplistic block-diagram form in Figure 41-7.

The simplest of these is the total-power radiometer shown in Figure 41-7a. The output voltage of this radiometer, which is not modulated, can be expressed as

$$V = G(T_A + T_N) \quad (41-20)$$

where T_A is the antenna temperature, T_N is the system noise temperature referred to the antenna input terminals, and G is the power gain of the receiver system. The total power radiometer can resolve a change in scene temperature in a dynamic system of

$$\Delta T = \frac{T_B + T_R}{\sqrt{B\tau}} \quad (41-21)$$

where

- T_B = brightness temperature of the scene, K
- T_R = effective receiver noise temperature, K
- B = predetection bandwidth, Hz
- τ = integration time, s

The absolute accuracy of this system is dependent upon the stability of the radiometer after calibration using hot and cold references. Use of state-of-the-art receiver technology and precision thermal regulation can usually result in accuracies of better than ~1 K over reasonable periods of time. For spaceborne radiometers the calibration of this system is improved by spinning the spacecraft antenna so that cold sky is observed during each revolution, as in the calibration method of Figure 41-6a. This spinning-antenna system is equivalent to the signal-modulated Dicke-switched radiometer discussed next, except that the switching circulator is eliminated and the modulation frequency is reduced.²¹

Another commonly used radiometer type is the Dicke switched radiometer²² of Figure 41-7b. The advantage of the Dicke radiometer is that variability of the noise from the receiver T_N is eliminated so that the output voltage is given by

$$V = G[T_A(1 - \epsilon_s) - T_{\text{ref}}(1 - \epsilon_R) + (\epsilon_s - \epsilon_R)T_0] \quad (41-22)$$

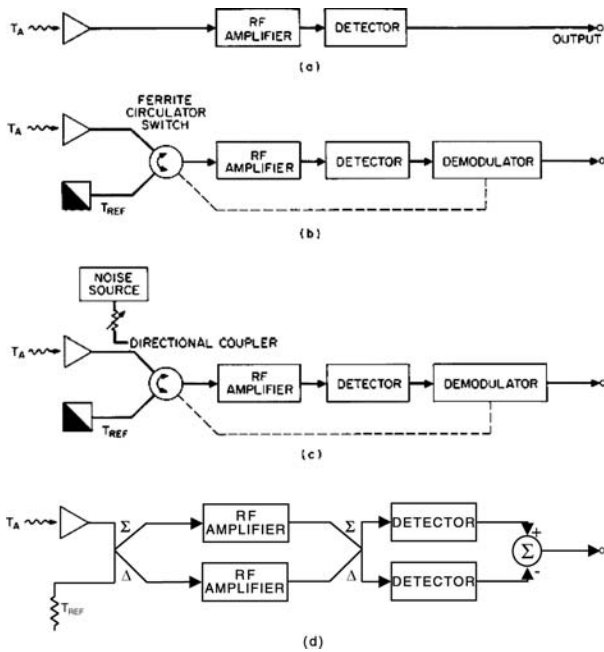

FIGURE 41-7 Simplified diagram of basic radiometer types (after Hidy et al⁶): (a) Total power radiometer; (b) Dicke switched radiometer; (c) Noise-injection switched radiometer; (d) Differential radiometer

where ϵ_s and ϵ_r are the ohmic losses in the signal and reference arms and T_0 is the physical temperature of the radiometer components. Provided that T_{ref} is maintained close to T_A , the system gain variations have less of an impact on overall accuracy than for a total power system. However, the rms integration noise is twice as large. A variation on the Dicke switched radiometer is the noise injection signal-modulated type shown in simplified form in Figure 41-7c. The noise injection method eliminates gain instability by permitting noise power to be added or subtracted to the reference input of the radiometer based on negative feedback. Various methods of performing this variable noise injection include use of variable calibrated attenuators and pulse-width noise switching. Variable-height pulse modulation of a noise diode feedback circuit can also be employed.⁶ A digital version of the noise-injection modulated radiometer has been devised and analyzed²³ and implemented.²⁴

A fourth type of radiometer is the differential radiometer²⁵ shown in Figure 41-7d. This system is based on a sum-difference hybrid combiner, dual amplifier chains, and a correlator stage formed from a second sum-difference combiner. It has the decided advantages of a differential response as in Eq. 41-22 but also that amplifier noise and gain fluctuation noise are reduced in the output. However, it requires two amplifier and detector chains, and is thus more expensive. For the differential radiometer the integration noise is $\sqrt{2}$ times that of the total power radiometer.

Radiometric Imaging Systems

The most common radiometer system in Earth remote sensing is the cross-track imaging type depicted in Figure 41-8a. Imaging on a spacecraft or aircraft is usually achieved by

FIGURE 41-8 Ground spot patterns of cross-track scanned radiometer-antenna systems

uni- or bidirectional scanning of a reflector/antenna/feed system relative to a stable moving platform. Imaging radiometers provide wide-swath coverage of the surface or atmospheric scene. The spatial resolution of the scanning system is limited by antenna size, which in turn is limited by the size of aircraft ports or launch vehicle fairings. When finer spatial resolution is required, large deployable antennas that are limited in scan rate and required to spin with the radiometers as a single unit can be employed. Owing to the combination of scan rate and spacecraft velocity, a single-beam radiometer antenna of the scanning type may not produce contiguous resolution cells on the surface at the beginning and end of each rotation, and may offer only a small amount of integration time per sample. To produce contiguous coverage, a whiskbroom radiometer antenna system can be employed as in Figure 41-8b. Here each beam in the whiskbroom requires an independent antenna port and radiometer.²⁶ The beam patterns can be produced by multiple feeds in a single reflector system.

As even larger radiometer antennas are required to obtain better surface resolution, physical motion to obtain wide swath coverage may not be possible. To provide swath-width coverage without mechanical scanning a pushbroom radiometer system can be used, as in Figure 41-8c. In this design an independent radiometer is connected to each of several antennas with adjacent beams. Regular sampling of the pushbroom beam produces a surface radiometric brightness temperature map.

A mechanically scanned beam can be implemented by pointing a feed horn in the direction of platform motion and rotating a reflector tilted at 45° to this axis about this axis. This simple cross-track scanned system is used in a number of airborne and low-Earth orbiting (LEO) spaceborne systems, for example the NOAA Advanced Microwave Sounding Unit (AMSU).²⁷ Reference sources can be readily viewed during the scan cycle for calibration. Two disadvantages are that the surface spot size changes throughout the scan (being smaller at nadir) and the polarization basis of the feedhorn rotates throughout the scan. A conical scanning system resolves these problems by providing constant incidence angle and fixed polarization basis throughout the scan, but requires the radiometer to rotate with the reflector antenna. A scheme for electronically rotating the polarization basis of a radiometer has been demonstrated to permit the radiometer to be fixed to the platform while maintaining polarization alignment with the Earth throughout the scan.⁹ Airborne systems have been built to provide both conical and cross-track scanning.²⁸

Because of requirements to distinguish signals from parameters such as salinity and temperature for the ocean, or clouds and water vapor for the atmosphere, multiple frequencies are commonly required to be integrated into scanning,¹⁶ whiskbroom, or pushbroom radiometric systems. Such multifrequency systems are usually designed as multiple feeds with a single main reflector. Combining frequencies in a single broadband corrugated horn is feasible over nearly 2:1 bands with low-loss properties and also for

bands of approximately odd harmonics (for example, 3:1, 5:1). A very broadband horn with over 5:1 bandwidth has been designed and used in space with a scanning system.²⁹ This antenna, however, exhibits large losses which must be compensated as large bias errors.

41.4 RADIOMETER ANTENNA TYPES

Horns

A straightforward design for a moderate-beamwidth (10° to 30°) radiometer antenna is the electromagnetic horn; however, because of the requirement for high beam efficiency (and, therefore, for low sidelobes) specialized horn designs are necessary for radiometer applications. Radiometer horn antennas are designed so that the normally high E -plane sidelobes are reduced to an acceptable level by aperture field tapering. The H -plane sidelobes (typically -23 dB) are already low enough to achieve a sufficiently high beam efficiency for moderate beamwidths, although they can be further reduced by tapering. Tapering can be accomplished using several techniques. The simplest is to utilize multiple modes³⁰ in the radiating-horn aperture to provide sidelobe cancellation in the far-field pattern. The higher-order modes are excited by a step or sudden change in the cross section of the waveguide or horn taper. The bandwidth of a multimode or dual-mode horn is limited to a few percent because of the difference between the modal phase velocities in the tapered waveguide horn section. However, a shortened version³¹ of the Potter horn can exhibit good pattern characteristics over a bandwidth approaching 10 percent. The performances of the square multimode horn and the conical dual-mode horn are quite similar.

For radiometer applications requiring a larger bandwidth and low sidelobes the class of corrugated horns³² is attractive. As with the multimode-type horn, the purpose of the corrugated-horn design is to reduce the normally high E -plane sidelobes by tapering. This is accomplished by designing the corrugations so as to decrease the current along the corrugated wall, thus producing a tapered (approximately cosine) E -plane aperture field distribution. This tapered distribution can be maintained over a bandwidth approaching 2:1 but is usually limited to the operating bandwidth of the feed waveguide. Multiple bands of odd harmonic order can be implemented using the same corrugations.

Another type of horn which shows promise as a wideband radiometer antenna is the exponential horn with a specially flared aperture.³³ A similar wideband horn is one which is flared like a trumpet.³⁴ The design approach of these wideband horns is to eliminate sharp discontinuities and provide a smooth transition between the horn modes and free space.

Beam-efficiency calculations are given in Figure 41-9 for a circular aperture with a radial aperture distribution equivalent to that of the TE_{11} -mode H -plane distribution and with a quadratic phase taper, as being representative of the beam efficiencies obtained from radiometer horns. The figure also illustrates that, in order to achieve high beam efficiencies, the horn must be designed for small phase taper, either by decreasing the horn flare angle or by using a phase-correcting aperture lens.

FIGURE 41-9 Effect of aperture phase taper on beam efficiency for a conical corrugated or dual-mode horn

Feed-Reflector Systems

For radiometer applications requiring narrow beamwidths or multiple bands, reflector antennas are more appropriate since highly tapered reflector illuminations can yield the much lower sidelobes necessary for high beam efficiency. The feed elements should be designed for spillover minimization, which represents additional beam-efficiency degradation. Aperture efficiency is generally a secondary concern for radiometers. The reflector surface must be constructed precisely (usually a machined and possibly polished surface is required) to minimize loss in beam efficiency due to statistical roughness.

The overall beam efficiency for a reflector antenna can be expressed as

$$BE = BE_s BE_f BE_\delta \quad (41-23)$$

where BE_s is the main beam efficiency obtained by integration of the reflector secondary pattern, neglecting the back radiation, BE_f is the spillover beam efficiency of the feed evaluated at the angle of the edge illumination, and BE_δ is the beam efficiency due to reflector surface roughness. Calculations of beam efficiencies BE_s for a circular aperture with raised quadratic and raised quadratic squared distributions are presented in Figures 41-10 and 41-11 and representative of reflector illuminations with edge tapers of -20 , -10.5 , -8 and -6 dB. The dashed curve for uniform illumination is included for reference. Figure 41-12 shows the effect of edge taper on the spillover efficiency BE_f . The calculations are for a conical dual-mode horn with no phase error as being typical of feed patterns used in horn-reflector radiometer antennas. The reduction in beam efficiency BE_δ due to reflector-surface roughness can be obtained from the analysis of Ruze³⁵ as

$$BE_\delta = BE_s \exp(-\delta^2) + \Delta BE \quad (41-24)$$

where $\delta = 4\pi\sigma/\lambda$, σ is the rms surface roughness, and ΔBE is a correction term which accounts for the nonzero correlation length c of the surface error. Specifically,

$$\Delta BE = \exp(-\delta^2) \sum_{n=1}^{\infty} (\delta^{2n}/n!) [1 - \exp(-(uc/D)^2/n)] \quad (41-25)$$

where D is the antenna diameter and $u = ka \sin \theta_l$ with θ_l defined as in Eq. 41-11. Figure 41-13 is a plot of the reduction factor versus rms surface roughness and correlation length. It should

FIGURE 41-10 Beam efficiency for a circular aperture with parabola-on-a-pedestal distribution

FIGURE 41-11 Beam efficiency for a circular aperture with a parabola-on-a-pedestal-squared distribution

be noted from Eq. 41-24 that for beam efficiencies greater than 90 percent the reflector surface should be $\lambda/50$ or smoother.

An additional concern for offset reflectors is the cross-polarization level, which can complicate the interpretation of antenna temperature data as discussed earlier. The cross-polarization for reflectors decreases for larger focal length to diameter ratios and smaller offsets;³⁶ however, these parameters must be optimized to minimize feed and spar blockage effects. The BE_s curves in Figures 41-10 and 41-11 neglect the effects of feed and strut blockage. Indeed, these effects cannot be treated simply as an aperture blockage as in gain calculations, and the secondary pattern beam efficiency BE_s therefore should be recomputed with the wide-angle scattering from feed and spars included.

FIGURE 41-12 Feed beam efficiency factor for a reflector antenna

Phased Arrays

Phased arrays have been successfully employed as radiometer antennas^{37,38} when beam scanning is required or volume constraints indicate that an array is the appropriate antenna type. High beam efficiency is obtained through amplitude tapering within the feed distribution network. In the design of feed networks for radiometer array antennas, internal line losses must be minimized. If line losses are not excessive, stabilization of the losses through temperature control can be used in combination with calibration techniques to correct the radiometric temperature data. Resistors and terminations within the feed network should be avoided or used with discretion, since noise emitted by such components into the receiver could desensitize and confound the radiometric measurement.

Microstrip Patch Radiometer Antennas

Although the ohmic efficiency of microstrip antennas is not high, arrays of microstrip patch antenna elements are attractive for airborne radiometry due to their potential for conforming to arbitrary surface shapes.³⁹ Accordingly, it can be expected that as feed and coupling techniques for improving main beam efficiency and thermal measurement and compensation techniques improve, the use of microstrip antennas in radiometry will become more widespread.

41.5 RECENT DEVELOPMENTS AND TRENDS IN RADIOMETRY

Overview

Several major developments in radiometry and radiometer antennas have occurred in the areas of

FIGURE 41-13 Beam-efficiency factor of a random rough surface reflector

precision radiometric imaging and sounding and interferometry for Earth applications. Two particularly important applications of radiometry are polarimetric imaging of the Earth for ocean wind direction sensing and geostationary microwave imaging and sounding. These radiometric techniques rely on state-of-the-art radiometer antennas or systems of antennas.

Spaceborne Imaging Radiometers

Since the launch of the Scanning Multichannel Microwave Radiometer (SMMR)²⁹ system in 1978, the scientific and operational value of microwave imagery for measuring Earth surface parameters such as soil moisture, sea surface temperature, snow water equivalent, sea ice concentration, and atmospheric parameters such as precipitable water vapor, rain rate, and cloud liquid water has been well established. Conical microwave imaging is performed using a rotating offset parabolic reflector antenna with $\sim 55^\circ$ incidence angle scanned about a vertical axis. The resulting conical scan provides a polarization basis that coincides with the Earth's natural basis⁹ provided that the feedhorn and radiometers also rotate with the scan. Examples of such systems include SMMR, the DMSP Special Sensor Microwave/Imager (SSM/I),⁴⁰ the JAXA Advanced Microwave Scanning Radiometer (AMSR-E) on board the NASA EOS Aqua spacecraft,⁴¹ the Tropical Rainfall Measuring Mission (TRMM) Microwave Imager,⁴² and the U.S. Navy's WindSat polarimetric imaging sensor.⁴³ These systems use either closely spaced arrays of multi-polarization feedhorns or multiband multipolarization feedhorns to achieve nearly coincident beams at several frequency bands. The selected bands are located at key transmission window or absorption line frequencies that collectively span over a decade in bandwidth. These sensors provide dual polarization imagery, while the WindSat sensor also has provided the first fully polarimetric (four Stokes parameter) imagery from space.

The SSM/I system consists of a seven-channel, four-frequency, linearly polarized microwave radiometer system operating at 19.3, 22.2, 37.0, and 85.5 GHz.⁴⁰ This system was launched into low Earth orbit and travels at a velocity of 6.58 km/s at an altitude of 833 km. The SSM/I Earth coverage in a single day is shown in Figure 41-15. The scanning antenna depicted in Figure 41-14 is an offset reflector fed by a multifrequency corrugated horn.

FIGURE 41-14 SSM/I scan geometry (after Hollinger et al⁴⁴ © IEEE 1990)

FIGURE 41-15 SSM/I Earth coverage of SSM/I in a 24-hour period. Shaded areas are not observed in this time period (after Hollinger et al⁴⁴ © IEEE 1990).

A similar corrugated horn at low-frequency bands was used on the SMMR system. The SSM/I feed horn has a flare angle of 58° , giving an equivalent edge taper of about 17 dB for all frequencies. The SMMR horn (Figure 41-16) used a set of ring-loaded corrugations. This horn design has been modified to include straight-sided grooves of alternating depth. Multifrequency performance is achieved by coupling waveguides at various points along the feed waveguide and/or horn body. Filters were placed in the various waveguide ports to minimize multiband coupling. These remarkable feedhorns were designed by Dr. K. A. Green and have significant losses of 0.5 to 0.7 dB, depending on operating band.

Geostationary Microwave Imaging and Sounding

Microwave imaging of the Earth from geostationary orbit offer the unique possibility of tracking storms, weather fronts, and hurricane rainbands that are hidden to infrared and optical sensors by clouds and at the time scales at which these weather systems naturally evolve (~15 minutes or less). However, the high orbital altitude presents unique engineering challenges in designing an efficient multiband radiometer antenna with extremely narrow beams and a low mass-and-power scanning mechanism. One such design utilizes a 2-meter diameter main parabolic reflector and moveable Cassegrain subreflector to provide a rapid scan of its beams over a portion of the Earth's disk.⁵⁵ The entire antenna slews at a slow rate so as to permit imaging over the entire disk with little momentum transfer to the host platform. The five-band GEostationary Microwave (GEM) radiometer provides a 3-dB subsatellite spatial resolution of ~16 km at the highest of its sounding frequencies (424 GHz), and progressively lower resolution but higher radiometric sensitivity at its lower frequencies (380, 183, 119, and 55 GHz). To maintain high main beam efficiency, the subreflector is limited to scanning a range of ~0.3° around the antenna boresite. Geostationary imaging of the earth in microwave bands is also being studied using synthetic aperture interferometry⁵⁶ with the potential advantage of implementing a system having no moving parts.

42.1 INTRODUCTION

Antenna angle tracking systems have a variety of forms dependent on their application. System applications that use broad coverage antennas can have either no antenna tracking requirements or modest pointing requirements, such as the case in terrestrial relay designs. Other applications require very precise closed loop systems in order for high gain antennas to satisfy high angular accuracy requirements. Generally, antenna tracking systems are required when the uncertainty in the signal direction exceeds a small fraction of the antenna's beamwidth. This requirement derives from the need to maintain alignment of the antenna's peak gain level with the signal's direction to avoid signal loss. The boresight axis of the antenna is coincident with the antenna's peak gain level. At the outset, it is well to distinguish between *antenna pointing*, which is the capability to position the antenna's boresight axis towards a given direction (for example, an azimuth and elevation value), and *antenna tracking*, which is quite different. Antenna tracking is the capability to align the antenna's boresight axis (the one that intersects the peak gain level of the antenna's pattern) with the signal direction and then follow any variations in that direction. Thus, pointing is a static quantity whereas tracking is a dynamic quantity.

The system applications for antenna tracking include communication and radar systems. While both system applications share some commonality in techniques and implementations for antenna tracking, their requirements differ. Communication system signals generally have well-known directions of arrival for the signals and the received signal levels are generally well behaved with little variation in received power levels. By contrast, radar systems typically must detect potential targets, a phase generally referred to as *search and acquisition*, and then locate detected targets not only in the angular coordinates of interest using the angle tracking techniques discussed here, but also in the target's range and Doppler coordinates. Further, the received radar signal level typically has a large dynamic range, as the aspect angle between the radar and target changes.

A hierarchy of antenna tracking techniques exists. In some cases, the signal direction is stationary and antenna pointing rather than tracking is required. A common example is the user direct broadcast antennas that require only a simple pointing alignment. The simplest antenna tracking technique results when variations in the signal direction are known or predictable to an uncertainty that is a small fraction of the antenna's beamwidth. In this case, the antenna position can be simply commanded to follow known changes in the signal's directions, a technique known as *program track*. Program track is an example of an open loop tracking design, as is another technique referred to as *step track*, which when commanded, validates and updates correct antenna tracking. Closed loop antenna tracking techniques also exist, and two distinct techniques, conical scan, and monopulse systems, are described. These closed loop techniques continuously measure the signal's direction of arrival. The measured signal directions are an input to the antenna's control system, which commands the antenna to dynamically follow changes in the signal's direction. The closed loop techniques involve more than the antenna's RF design, and they include the means of pointing to and following the signal's directional variations using a positioner and control system. These features mechanically and/or electronically align the antenna's main beam with the signal direction in response to estimates of the signal direction derived from the antenna's response. As the antenna tracking system becomes more complex, test techniques to verify the performance of the antenna tracking design become more stringent, and such system testing is also discussed.

42.2 TRACKING REQUIREMENTS

The requirements for antenna tracking depend on the system's application. Communication system applications require maintaining signal alignment within a specified accuracy. Commonly, alignment within one-tenth of the antenna's beamwidth limits the signal loss to about 0.1 dB lower than the peak antenna gain level on the boresight axis. Radar systems have a more stringent requirement than signal loss and seek to determine the target's location with as much angular accuracy as possible. Generally, an angular accuracy of one-twentieth of the antenna's beamwidth or better is achieved by tracking radars. The selection of the antenna tracking design depends on the uncertainty of the signal direction relative to the antenna's boresight axis containing the peak gain level of the main beam. Commonly, the antenna's tracking accuracy normalized to the antenna's beamwidth¹ is the measure of performance. This tracking accuracy is the one sigma angular uncertainty normalized to the antenna's beamwidth. Error budget projections using the rss sum of the one sigma error component values and the algebraic sum of the mean components are used to quantify antenna tracking performance. It should be recognized that tracking accuracy does not have an absolute angular limit independent of the antenna's beamwidth. The tracking accuracy limit is a fractional part of the antenna's beamwidth.

Communication Systems

Antenna tracking is commonly required for larger ground terminal antennas used in satellite communication system applications. Satellite pointing directions are determined from the user location on the earth and the satellite's ephemeris, which describes the satellite's orbital motion. For geostationary satellites that maintain a fixed location above the earth's surface, the changes in the signal's direction is minimal and a slight figure eight motion over a day's time is encountered. The magnitude of this figure eight motion about the equatorial plane depends on how well the satellite is stationkept for maintaining its position on the equatorial plane and for compensating for orbital perturbations. The size of the figure eight is controlled by occasional satellite thruster adjustments. Satellites in other orbital configurations move in predictable trajectories described by the satellite's ephemeris and typically require positioners and antenna tracking systems to follow the dynamics of the satellite's trajectory.

The satellite communication application illustrates the variety of requirements for antenna tracking systems. Broad beamwidth antennas used with geostationary satellites require little more than antenna pointing alignment to limit signal loss, and a variety of such antennas for very small antenna terminals (VSAT) applications are commonly used. Positioning for these designs range from a fixed alignment to simple positioners that can be commanded to point the antenna to different satellites in the geostationary satellite belt. Antennas for other orbital configurations require more capable positioners that can follow the satellite's trajectory. The dynamic requirements of these positioners increase with reduced satellite altitude. Still more capable positioners are required for high data rate systems where the gain performance of a larger aperture is required for link closure. Such antennas can require open loop or closed loop antenna tracking design dependent on the antenna's beamwidth. Larger antennas are typically subject to pointing perturbations by wind unless they are protected by a radome. When unprotected by a radome, closed loop antenna tracking is generally required to compensate for wind disturbances.

The tracking accuracy requirement for communication systems limits signal loss resulting from antenna boresight misalignment. This loss depends on the antenna's main beam pattern and the sensitivity to misalignment relative to the antenna's boresight axis. Typical values

FIGURE 42-1 Pattern loss with boresight misalignment for communication systems

in Figure 42-1 illustrate the required tolerance of the signal loss to antenna misalignment, and they indicate a 1/10 beamwidth misalignment results in about a 0.1 dB signal loss. Antenna tracking is principally concerned with the antenna's pattern close to the main beam's boresight axis. A convenient means for determining this sensitivity assumes the shape of the antenna's high level portion of the main beam follows a Gaussian function at the higher gain levels. This is a good assumption for practical antennas that is used in this discussion. The pattern variation around the main beam peak, normalized to its peak gain level (voltage), is given by

$$F(\theta) = \exp(-K(\theta/\theta_{hp})^2)$$

where θ is the angular variation of the pattern in one plane, θ_{hp} is the half power beamwidth of the actual antenna, and $K = 1.3816$ as determined by evaluating the pattern at its half power point. This expression can be refined by using analytic projections of the actual antenna pattern predicted by commonly available computer codes or measured values of the actual antenna.

Larger antenna diameters that are not protected by radomes are susceptible to tracking disturbances caused by wind gusts. When the antenna aperture is buffeted by wind, the resulting torques disturb the antenna positioner system, producing antenna pointing errors. Thus, maintaining antenna pointing under wind loading depends in part on the torque capabilities of the positioner drives. Analysis techniques to determine antenna tracking errors caused by wind disturbances² have been developed and address the statistical disturbances of the antenna pointing as a function of the wind conditions. Ultimately, the wind torques are sufficient to potentially damage the antenna positioner and/or antenna, and vendor recommendations advise placing the antenna in a *stow* (pointing straight up); a position that minimizes the wind torque. Finally, vendors also specify a survival wind velocity in the stow position. When systems have high availability requirements, antenna radomes are typically used and the antenna is protected from wind-induced antenna pointing errors. The radome cost is offset in part by the reduced antenna structural and weather protection requirements and the torque requirements of the positioner drive.

Radar Systems

Radar systems³⁻⁴ can be broadly separated into *search radars* and *tracking radars*. Search radars look for potential targets and the antennas follow a fixed angular scan pattern. A typical example is airport surveillance radars that continuously scan both in azimuth and in range searching for aircraft. A time history of the radar returns defines the trajectory of the detected aircraft. Tracking in this case is really an open loop process. A plan position indicator (PPI) indicates target location in an azimuth direction and the radial distance from the indicator center is proportional to the target range. The time history of targets resulting from the persistence of this screen displays the trajectory of the aircraft target.

Search radar performance depends on the power aperture product of the radar, and therefore cost considerations favor low frequency operation. Tracking radars, on the other hand, gather more details regarding detected targets and the dimensions of tracking radar resolution include range, Doppler resolution, and, of interest in this discussion, target location in angular coordinates. Tracking radars generally operate at higher frequencies than search radars and use coherent radar waveform processing techniques to obtain improved resolution in comparison to search radars. The angular resolution of the target benefits from narrow antenna beamwidths, while Doppler resolution benefits from both the high frequency and coherent processing of narrow bandwidth waveforms. Finally, range resolution is achieved by processing wide bandwidth radar waveforms. In operation, narrow bandwidth and wide bandwidth radar waveforms are alternatively used to obtain range and Doppler resolution, respectively. In some cases, dual frequency radars are configured to provide search capability at the lower frequency and tracking capabilities at the higher frequency. A wide diversity of radar designs, with varying requirements for angle tracking, also exists.

Requirements for radar angle tracking differ from communication system requirements. Radar angle tracking strives to locate the angular coordinates of the detected target with as much precision as possible. Radar angle tracking requirements are more complex than antenna tracking requirements for communication systems, not only because radar systems generally require higher angular accuracy, more rapid acquisition times, greater dynamics in signal direction, and a dynamic range in received signal levels, but because the variation of the target aspect angle relative to the radar presents varying RCS (Radar Cross Section) levels from the target. This variation is received at signal level, and typically requires simultaneous signal reception of the main beam, azimuth, and elevation tracking beams commonly referred to as three-channel processing. In contrast to the one-tenth beamwidth accuracy typical for communication systems, the goal for radar angle tracking accuracy often exceeds one-twentieth of the antenna's beamwidth. Precision tracking radar systems typically use a large antenna at high frequencies to obtain narrow antenna beamwidths, high Doppler sensitivity, and sufficient waveform bandwidth for range resolution performance. They also use closed loop antenna tracking techniques to accurately measure the target location in angular coordinates.

Other issues for radar systems can arise. In some applications, multiple target tracking calls upon the radar to sequentially monitor the trajectories of several targets. Such monitoring requires rapid repositioning of the antenna beam. Antennas using reflector designs would require rapid mechanical motion to respond to multiple targets, and the time necessary to reposition and reacquire the targets may become excessive. In this case, the cost of array antenna technology may be justified by rapidly revisit targets with the array's electronic agility of beam positioning. The array technology has a limited scan volume over which the array's antenna gain can be maintained, and wider angular coverage typically requires separate array antennas covering different angular sectors so that radar system performance is not limited by array antenna beam scanning limitations.

Angle tracking at low elevation angles⁵ is problematic because of antenna multipath interaction and an image of the target being created by smooth surfaces such as water. Typically, at low elevation angles where the radar beam intercepts the terrain, the radar receives signals from both the actual target and its image. (The radar tends to track towards the horizon.) In such cases, operation at a sufficiently high frequency allows the terrain to be diffuse rather than specular. Higher frequency operation generally results in a narrow beamwidth antenna, and the minimum elevation position is kept above the terrain by one quarter of the antenna's beamwidth. Higher frequency operation also permits using sufficient waveform bandwidth to resolve the target from multipath and terrain images. These are effective techniques for maintaining angle tracking performance at low elevation angles.

Radar systems for terminal guidance applications have errors resulting from the target scattering properties. At long ranges, the accuracy of angle tracking is limited by S/N (Signal to Noise ratio). At close ranges to the target, scattered returns from different portions of the target can be resolved; typically, the radar is also in the near field of the radar target. As the radar approaches the target, the phasing between the different scattering centers comprising the target response varies, and this phasing results in different indicated target positions. This phenomenon is referred to as target "glint" and is the limiting error source for target tracking at close ranges. One treatment⁶ of this problem analyzes the balance point based on the target's scattering characteristics. This balance point is a centroid of the target tracking and dynamically moves as the individual scattering terms coherently combine in and out of phase; depending on the phasing, the radar alignment can be outside of the target dimensions. This treatment addresses the scattering mechanisms of the actual target by analytic means. A second approach⁷ examined the statistical behavior of measured tracking responses and proposes such statistical modeling in addressing glint issues. The statistics for a given target geometry, aspect angle, and radar frequency are required. Both of these approaches have instilled debate.⁸⁻⁹ Wide bandwidth radar waveforms can be effective in reducing this error source because the phasing effects between target scattering centers is decorrelated over the bandwidth.

In other applications, a tracking beacon is used on the target. The beacon has both receive and transmit antennas connected to a transponder, which amplifies the received radar signal. In contrast to skin tracking from the target's geometry, beacon tracking has some distinct advantages. Generally, amplification within the beacon provides a higher level return signal than the target itself reducing the performance requirements of the radar and/or increasing the radar's detection range. Additionally, the beacon return depends on the beacon's transmit antenna pattern, so that the radar's received signal has a better behaved variation with aspect angle changes than the skin return from the vehicle that generally has a lobe structure. Beacon operation is beneficial in satellite launch vehicle applications, for example, where tank separations and other events require the radar to determine the appropriate portion of the vehicle to track. In addition, the beacon also affords the opportunity to modulate other data onto the beacon return, providing trajectory, health, and other telemetry data. In some cases, the beacon translates the incident frequency both to provide additional isolation between the beacon's transmit and receive antennas and to separate the radar's receive signal from surrounding clutter returns in the normal radar response.

42.3 OPEN LOOP ANTENNA TRACKING

The most straightforward antenna tracking techniques are open loop designs. The open loop tracking technique follows the functional block diagram in Figure 42-2. The antenna is pointed using a positioner or in the case of an array steered to a nominal beam direction.

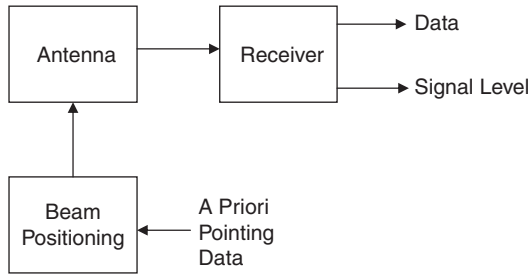

FIGURE 42-2 Functional diagram for open loop tracking

The receiver provides an indication of the received signal strength. The antenna beam is repositioned following *a priori* information. If the knowledge of the antenna's boresight axis positioning and the uncertainty of the pointing information corresponds to a small fraction of the antenna's beamwidth, such open loop methods can be quite effective and inexpensive to implement. The signal level can be the output of a carrier tracking loop or an AGC voltage. Two types of open loop tracking techniques are described: program track and step track.

The simplest form of antenna tracking is where the antenna's angular position is simply commanded to follow the time variation of the signal's direction, a technique referred to as program track. This technique relies on a known antenna location and orientation and the time history of the signal direction relative to the antenna's location. A common application is direct broadcast satellite services where the antenna is commanded to move from one satellite to another. The angular positions of the satellites defined by their ephemeris values and the antenna's location are known. This information provides the azimuth and elevation coordinates required to command the antenna to point to the selected satellite. Another application for relatively broad beamwidth antennas is meteorological satellites in a polar orbit. The satellite's trajectory is known and the antenna location is also known. This information allows the calculation of the time history of the required antenna positioning. The combination of the terminal's location, its orientation relative to level and true north, and time of day suffice to provide acceptable performance.

Step Track

While program track by itself is acceptable in many applications, another open loop tracking technique is useful in validating correct antenna tracking. This process is referred to as step track¹⁰ and involves pointing the antenna at its nominal position, commanding equal angular offsets in opposite directions, and then measuring the received signal power at these locations. If the nominal position is correct when the antenna is displaced in equal and opposite directions, the same signal power level is received. The operation of the step track technique is illustrated in Figure 42-3, where the nominal beam pointing is indicated, and the displaced beam pointings to both the left and right are also indicated. An example signal direction is indicated in the figure, and the pattern levels for the nominal and displaced beams are apparent. For this example, the signal direction is slightly removed from the boresight axis. If the antenna is moved in the vicinity of this point, small changes in signal level are observed and significant measurement accuracy is required to relocate the antenna to the peak gain value on axis. By contrast, the displaced beam positions result in significantly different signal levels.

FIGURE 42-3 Step track operation

This difference in signal power levels allows the calculation of the angular correction needed to align the antenna with the signal direction. Assuming the Gaussian pattern representation, the angular correction θ_e can be easily computed from the amplitude imbalance¹⁰ at the two angular offsets using

$$\theta_e = -(\theta_{hp}^2 / 4K \theta_o) \ln R$$

where θ_{hp} is the antenna's half power beamwidth, θ_o is the angular offset from the antenna's boresight axis, K has been previously defined for the Gaussian function pattern approximation, and R is the amplitude ratio of the signal power at the two angular offsets. This process is repeated in the orthogonal plane.

In practice, step track validation of antenna tracking accuracy can be performed at regular intervals or by monitoring the received signal power (with an AGC output, for example), to determine whether or not an adequate power level is being received. For example, the antenna's pointing might be perturbed by wind gusts reducing the received signal power. Under this condition, step track can be used to decide if antenna realignment is appropriate. Another example is when a narrow beamwidth antenna tracks the stationkeeping variations of a geosynchronous satellite. Orbital perturbations result in geostationary satellites following a figure eight variation, centered on the equatorial plane over a 24-hour period. This movement is limited by correcting the satellite movement, a process referred to as stationkeeping. In this case, step track may be used to sample the figure eight movement at a discrete number of times over a 24-hour period. Because this motion repeats, the sampled points can be used to correct program tracking values.

In applying step track, the choice of the angular offsets, referred to as θ_o , must be made. This choice impacts the angular accuracy of the measurement. Small angular offsets have small reductions in signal power because the antenna pattern near the beam peak is relatively flat and high accuracy is required to measure signal level differences. Larger angular offsets experience more angular slope in the antenna pattern but the S/N (signal to noise ratio) is reduced which can increase measurement uncertainty. Thus, an optimum

value exists for the angular offset. A general expression¹⁰ for the step track accuracy σ_θ is given by

$$\sigma_\theta/\theta_{hp} = -(\theta_{hp}^2/2K\theta_o) \sigma_A$$

where σ_A is the one sigma accuracy with which the received signal amplitude can be measured. If the principal limitation of measuring the signal amplitude is S/N and that accuracy is $1/(2S/N)^{1/2}$, the accuracy becomes

$$\sigma_\theta/\theta_{hp} = k/(S/N)^{1/2}$$

where k is plotted in Figure 42-4. Notice that the tracking accuracy improves with increasing angular offset as a consequence of the increased slope of the main beam—until the reduced S/N limits the accuracy. An optimum value (minimum k) occurs at a pattern level of -4.3 dB. However, this is a broad optimum and in practical systems, different choices may be made. For example, most communication systems operate with a margin relative to threshold requirements as measured by bit error rate (BER) performance. In practice, the angular offset might be selected based on the signal margin requirements so that the data fidelity is maintained during tracking verification. It is important to recognize that the angular accuracy is limited by more factors than S/N considerations. For step track, positioner pointing errors and backlash, encoder quantization, and signal amplitude variations are other limitations. For this technique and others, it is important to construct an error budget incorporating all of the error sources specific to the applications to determine the overall accuracy of the design.

The step track antenna tracking technique as described has the assumption that the signal's direction remains fixed over the measurement interval. In some cases, this assumption is not valid, when, for example, tracking a polar satellite. Recently, the step track technique has been extended for this case and this extended technique is referred to as *rate corrected step track*.¹¹ One problem is the ability to sample the angular offsets while the signal direction changes in a known fashion, such as the case of satellite signals. In this case, the angular offsets are along the track and across the track of the trajectory rather

FIGURE 42-4 Step track accuracy coefficient versus angular offset (after R. B. Dybdal¹⁰ © IEEE 1998)

than repositioning the antenna in azimuth and elevation directions. An examination of the trajectory of a polar satellite reveals relatively small dynamics occurring at the rise and set of the satellite; the principal dynamics of the trajectory occur when the satellite is at the higher elevation angles of its trajectory. By using step track verification initially at the lower elevations, the ephemeris and antenna tracking can be corrected. The cross track motion centers the antenna on the trajectory, while the antenna beam location in the track direction is determined either by moving the antenna ahead and behind to identify the beam peak location or by moving the antenna ahead and slowing it to let the satellite drift through the main beam peak. As a practical matter, the satellite's orbital drag slows the satellite in orbit resulting in a time offset. Motion outside of the orbital plane requires perturbations other than drag. Thus, outdated ephemeris generally requires a time offset.

A second problem is the initial acquisition of the satellite as it clears the horizon; the multipath at low elevation angles limits tracking performance. The time required for initial acquisition is important because the goal is to collect as much data as possible during the time that the satellite is in view. To reduce the effects of multipath for step track operation, it is recommended that the antenna boresight be initially positioned above the horizon by about one quarter beamwidth, and azimuth motion be used to center the beam on its trajectory. As the satellite elevation angle increases, the satellite will drift through the main beam and the rate corrected step track can be initiated. By fixing the elevation angle, the phasing between the direct and multipath signal components tends to remain fixed.

These open loop tracking techniques are simple and cost-effective to implement. Such techniques are particularly useful for communication applications having a well-behaved signal power level. Their application to radar systems is limited by changes in the target's RCS levels during the signal sampling at the offset angular positions. Step track techniques are a useful means to verify the accuracy of program track in order to avoid excessive signal loss.

42.4 CLOSED LOOP ANTENNA TRACKING

Closed loop antenna tracking techniques require an antenna that has the means to dynamically measure the received signal's direction and a control system that can position the antenna based on the measured signal direction. The functional diagram in Figure 42-5 showing closed loop tracking differs from Figure 42-2's diagram for open loop tracking in several respects. The antenna must provide the capability for continuously measuring the

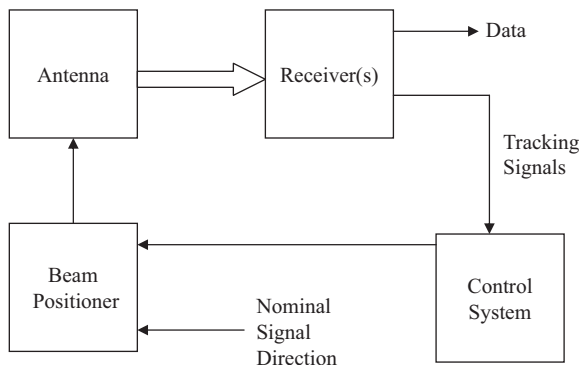

FIGURE 42-5 Functional diagram for closed loop tracking

received signal's direction in the form of a tracking signal. This directional information then provides an error signal that serves an input to the control system. By minimizing the error signal, the antenna is dynamically aligned with the signal direction. In operation, the antenna requires some *a priori* estimate of the signal directions and, for reasons that will be discussed, the uncertainty required in this *a priori* estimate is on the order of the antenna beamwidth. This *a priori* information can come from handover information from other systems or in the radar case, from target detection. Early closed loop tracking systems followed conical scan designs, while more recent designs favor monopulse designs. Closed loop antenna tracking techniques have been applied to both radar and communication applications.

Conical Scan

Conical scan designs¹ use a conventional antenna design and sense the signal direction by offsetting the boresight axis of the main antenna beam to coincide with a conical surface, and by rotating the antenna's boresight axis on the conical surface whose half angle corresponds to angular boresight offset. If the antenna is ideally aligned with the signal, the received signal strength is independent of the main antenna rotation on the conical surface. Antenna misalignment results in angular variation as the antenna's main beam traces its conical path. This angular variation has a sinusoidal form with its peak level occurring when the main beam is closest to the signal direction and a minimum level occurring when the main beam is farthest from the signal. A synchronous detector measures the received signal amplitude as the antenna beam traces its conical path. The amplitude variation increases with increasing antenna misalignment. The amplitude variation serves as an error signal for the control system, which operates by minimizing the amplitude variation. The magnitude of the amplitude variation increases with the magnitude of the misalignment. The azimuth angles of the maximum and minimum values (for example, the phase of the amplitude variation) indicate the direction to realign the antenna in order to reduce the amplitude modulation. In other words, the rotation axis of the conical scan should be repositioned in an azimuth direction from the highest value towards the lowest value.

Conical scan designs use a conventional antenna design and require mechanical motion to generate the conical scan pattern. For small antennas, such motion is commanded through the positioner drive. Larger antennas that have a dual reflector design generally offset and rotate the subreflector in order to generate the conical scan pattern with reduced mechanical rotation requirements, as compared to rotating the entire antenna. If conical scan is applied to array antennas, the beam rotation and repositioning is performed electronically. The angular accuracy for conical scan¹ is

$$\sigma_{\theta}/\theta_{hp} = 0.6/(S/N)^{1/2}$$

and is limited in part because the received signal is not aligned with the antenna's main beam peak gain level during tracking. Again, the angular accuracy is limited by error sources other than S/N , which must be addressed for specific applications. These error sources for conical scan include mechanical perturbations in the scan pattern and imperfect synchronization in the detection of the amplitude variation.

One problem with conical scan designs arises when the received signal amplitude fluctuates. This problem is particularly severe when the amplitude fluctuation rate is harmonically related to the conical scan frequency. Such variations in the received signal level result in a control system response that is unreliable. For communication systems requiring antenna tracking, the received signal level is generally well behaved. For radar systems, the received signal level depends on the target aspect angle relative to the radar, and changes in

the received signal level depend on the variation of the target's radar cross section (RCS) with aspect angle changes. This sensitivity to fluctuations in the received signal level limits the attractiveness of conical scan systems for radar applications.

An early variation of the conical scan design involves switching the antenna beam from one side of the boresight axis to the other side. This variation is referred to as sequential lobing, a technique that predates conical scan. Correct alignment results in the same amplitude at the switched positions, while misalignment results in different amplitudes. In early applications of sequential lobing, the control system was the operator. Sequential lobing has some features that are analogous to step track, but the lobing is performed continuously rather than being commanded at discrete time intervals like step track. Step track physically moves the antenna beam to off-axis position whereas sequential lobing electronically repositions the beams to off-axis positions. Like step track, sequential lobing is repeated in orthogonal planes. Like conical scanning, sequential lobing is susceptible to received signal amplitude fluctuations that limits tracking accuracy.

Monopulse Designs

Monopulse designs sense the signal direction by using two types of antenna patterns. One pattern is the conventional antenna response having a main beam aligned with the antenna's boresight axis and is used for data reception. The second pattern has a pattern null that is coincident with the antenna's boresight axis and is used for antenna tracking. The ratio of these two patterns, the tracking divided by the data pattern, yields a response that has a null on-axis and a linear slope (volts/volt/deg) for antenna misalignments from the boresight axis. This ratio is an error response and is the input to the control system for antenna beam positioning. The error response is the ratio of the tracking and data signals and results in the fundamental advantage of monopulse designs. Both the tracking and data signal levels can fluctuate with changes in the amplitude of the incident signal. However, their ratio is invariant with the incident signal fluctuations. Thus, monopulse designs are not limited by fluctuations in the received signal power. The term *monopulse* derives from the ability to obtain tracking information from a single radar pulse. True monopulse operation provides tracking information that is independent of signal fluctuations, unlike the sequential measurements made in other forms of antenna tracking.

Conceptually, antennas for monopulse operation¹² form the data and tracking patterns from two antenna beams symmetrically displaced from the antenna's boresight axis. When the two beams are added, an on-axis beam results. This beam is commonly referred to as the sum beam corresponding to the data pattern. When the two beams are subtracted, the pattern has a null on axis, and away from the axis, the beam is in phase with the sum beam in one direction and out of phase in the other direction. The two pattern responses using the Gaussian pattern assumption in Figure 42-6 illustrate typical pattern behavior. The ratio of the difference and sum beam is zero on axis, whereas near the axis it has a linear slope and is referred to as the *error response*, as illustrated in Figure 42-7. The error response follows the classic control system law in order to minimize the error that aligns the antenna with the difference pattern null. Since the peak of the data pattern is coincident with the error response null by design, minimizing the error response not only aligns the error response null with the signal direction, but also aligns the peak of the sum (data) pattern with the signal. Misalignment from the axis is measured by the error response magnitude and the sign of error indicates the direction towards the null.

The Gaussian pattern analysis can be used to derive the angular accuracy for monopulse systems.¹² This analysis assumes the two conceptual beams cross over at their half power point and it yields an angular accuracy given by

$$\sigma_{\theta}/\theta_{hp} = 0.51 \sigma_A$$

FIGURE 42-6 Monopulse sum and difference patterns

This analysis can be refined if the pattern data or error response of the actual antenna is available. Like step track, the angular accuracy depends on the ability to measure amplitude σ_A . Like step track, two limitations are S/N and positioning errors. Additionally, errors associated with the coincidence of the boresight axes of the sum and difference beams, the balance in the monopulse combining circuitry, and other factors need to be included in an error budget projection of tracking accuracy and also require quantification for specific designs. If S/N is the limiting factor in amplitude measurement accuracy, the monopulse accuracy becomes equal to

$$\sigma_{\theta}/\theta_{hp} = 0.361/(S/N)^{1/2}$$

Notice that the coefficient for the monopulse accuracy is smaller than those for conical scan or step track. Generally, monopulse tracking is more accurate than either conical scan or step track. However, the error budget limitations for the overall accuracy uncertainty differ

FIGURE 42-7 Monopulse error response corresponding to sum and difference patterns, as shown in Figure 42-6

in the three cases. In addition to the signal-to-noise issues, the monopulse errors include the balance of the feed circuitry, data and tracking pattern boresight coincidence, phasing errors, receiver tracking, and so on. This means that the individual error components in the uncertainty budgets must be addressed for all cases.

Monopulse designs require a more complex feed design than those used for open loop tracking, in order to produce the sum and difference beams. The problem of an optimum feed design has long been pursued. Early designs¹³⁻¹⁴ used multiple horns in the focal fields of the reflector to generate on-axis and off-axis beams, an approach that continues in radar designs. In radar applications, separate receivers are required for the sum, azimuth, and elevation difference beams so that measurements can be made simultaneously on both beam patterns. The multiple horn feed is also used in communication applications that does not have the same tracking sensitivity requirements as radar systems. Since communication systems generally have a well-behaved received signal level, the azimuth and elevation channels can be sequentially sampled and only a single tracking receiver is required. This approach is referred to as *pseudo-monopulse*. For communication applications, carrier recovery loops are often used to measure the incident signal amplitudes and the combination of a narrow bandwidth and averaging provide greater amplitude measurement accuracy than can be achieved from the signal alone. Accordingly, the difference channel antenna gain requirement can be lower than the sum channel requirement. One example for communication systems¹⁵ illustrates the integration of small feed apertures into the throat of a corrugated horn for tracking purposes.

Feeds using multimode excitations have developed more recently and are commonly used in communication applications. The communication application benefits from a well-behaved signal level in comparison to radar systems. Consequently, communication applications are often pseudomonopulse designs where the tracking signals are coupled onto the data signal and are sequentially sampled. This approach reduces the design complexity and the cost because separate tracking receivers and their amplitude balance requirements (each tracking receiver needs to produce the same output level for a given input signal level) are not needed. In practice, a dominant mode distribution in the feed provides the data or sum beam. A higher order waveguide mode sampled by a coupler supplies a tracking or difference pattern. The higher order mode has a null on axis as required for the tracking pattern. As the signal direction varies from the antenna boresight, the received signal level of the higher order mode increases, producing the linear variation from the null position required by the control system. The higher order waveguide modes, in addition to having an axial null, also have a phase progression with azimuth variations. When the dominant and higher order modes are combined, a peak level results when the two modes are in phase. The position of the peak level in azimuth is desired at quadrature points to provide the tracking response and then these quadrature points are sequentially sampled to determine the signal's azimuth position. If the amplitude is sampled at quadrature points using hybrid combining circuitry, azimuth and elevation difference channels are formed. In other cases, the magnitude and phase of the error response is measured. The magnitude indicates the magnitude to the boresight misalignment and the phase indicates the azimuth direction. In this case, the error response is a polar ρ and ϕ indication rather than an azimuth and elevation indication.

Three alternatives have been investigated to produce and process the dominant and higher order modes needed for monopulse operation. One approach¹⁶ uses multiple coupler arms to sample the higher order mode $TE_{2,1}$ circular waveguide modes. The waveguide section containing the higher order waveguide coupler supports the dominant $TE_{1,1}$ waveguide mode used for the sum signal. Eight $TE_{2,1}$ mode couplers are spaced in an azimuth direction around the circumference of the waveguide. These eight arms are combined through hybrid circuitry to produce azimuth and elevation tracking outputs. Another approach¹⁷⁻¹⁸ uses the $TM_{0,1}$ higher order circular waveguide mode and varies the azimuth angles where the

modes add in phase by using a phase shifter. This design uses four couplers spaced around the circumference of the multimode waveguide and then combines them with hybrids; an approach that has been demonstrated in wide bandwidth applications. A third approach¹⁹ uses a multiflare horn and a multimode coupler section and has a demonstrated high power transmitting capability. Orthomode junction couplers in the multimode section are used to sample the higher order tracking modes. The high transmit power capability in this case was obtained by combining four individual transmitters and the coupler design for the four transmitters was integrated into the feed design.

The tracking patterns obtained from the higher order waveguide modes and the data pattern obtained from the dominant mode must be coupled together in the pseudomonopulse design. The sequentially sampled tracking outputs provide an amplitude modulation on the data signal that is synchronously detected by the receiver. This detected amplitude modulation provides the input to the control system and the minimization of the amplitude modulation correctly aligns the antenna with the signal direction. One problem is that the path lengths through the tracking channels are generally longer than the straight path for the sum channel. Because of this, a “trombone” section is inserted into the sum path to equalize the path lengths between the data and tracking channels. This equalization of the group delay in the data and tracking channels is particularly important when polar ρ and ϕ processing is used. While a phase shifter can be used to equalize the phase, such an approach has a narrow bandwidth. When broad bandwidth antenna tracking is required, the phase shifter must be reset at discrete frequencies, if available for the broad bandwidth application.

The design issues for the multimode tracking techniques include the coupler that samples the higher order mode in a propagating section of the feed and the group delay differences between the sum and difference beams that result from their path length differences when these beams are combined together by a coupler. Couplers for the higher order modes are well demonstrated and the selection of the higher order mode to be used for tracking generally depends on the system's bandwidth requirement. This limitation results because the phase velocities of the dominant mode and higher order modes differ. The different group delay values of the sum and difference beams result in azimuth errors in the peak level of the dominant and higher order modes. These azimuth errors result in cross coupling degradation in tracking performance; for example, azimuth displacements produce indicated azimuth and elevation components. For narrow bandwidth applications, phase shifters can compensate for the group delay differences. For systems that operate at multiple frequencies, the phase shifter can be appropriately set for each of the bands. Such steps are not necessary if the waveguide lengths in the sum and difference channels can be equalized to produce the same group delay in both channels. By equalizing the group delays in the sum and difference channels, wide bandwidth operation can be achieved.

One problem with monopulse feed designs is their sensitivity to the polarization of the incident signal.²⁰ In polarization diverse signal environments, the feed response can lead to loss in tracking performance. For example, if the tracking channels of the feed are linearly polarized, the system will properly track circularly polarized signals of either sense with a polarization mismatch loss, but linearly polarized signals encounter difficulties when the polarization is cross-polarized to the design polarization of the feed. Because of the cross-polarization condition of the linearly polarized signal, the tracking signal does not measure a response and the system is without tracking information.

When the tracking channels of the feed are circularly polarized,²⁰ the system will properly track the design circular polarization with the proper design sense and all orientations of linear polarization with a polarization mismatch loss. However, the operation of the design when the system receives circular polarization of the wrong sense can actually become unstable. This instability results from the error response for cross-polarized signals. The error response for the design sense of circular polarization follows the standard response of having a null on axis and to first order a linear deviation as the antenna becomes misaligned

FIGURE 42-8 Error response for principal and cross polarization

from its boresight axis. Cross-polarized circular signals have an altogether different error response, having nulls in off axis positions corresponding to roughly the angular positions where the sum beam is roughly 10 dB below the beam peak. The error response differences between principal and cross polarizations are illustrated in Figure 42-8. The error response for the principal polarization case is well behaved and follows the desired linear behavior needed for the control system over a large fraction of the antenna's beamwidth. The error response for the cross polarized case has a much different behavior. Near the boresight axis, the error response peaks up and rapidly changes sign. This error response results in unstable tracking behavior as has been demonstrated.^{20,21} The dynamics of the antenna under such unstable operations are severe and the antenna tends to cone at an off axis position, probably where the error response nulls occur.

A technique²² has been devised to result in a tracking design that is independent of the signal's polarization for situations where the antenna must respond to a polarization diverse environment. The antenna is again configured for circularly polarized response for both senses of polarization. The tracking receiver is switched between both senses of circular polarization and the detected output for each polarization sense is summed to form an error response for the control system. If the received signal has the proper sense of the response being sampled, the proper error response is obtained. If the received signal has the wrong sense, the output is reduced in level by the polarization mismatch loss. The sum is dominated by the properly polarized response and the correct error response is routed to the control system. If the signal is linearly polarized, both the switched orthogonally polarized channels have the desired error response, albeit reduced by polarization mismatch. Such a design properly tracks both senses of circular polarization and linear polarization of any orientation.

A second problem is to make the sum channel independent of the signal's polarization, so that excessive polarization mismatch loss does not degrade signal reception. This is normally accomplished by combining the orthogonally polarized sum signal outputs with a diversity combiner. One configuration connects the two orthogonally polarized sum channels through a vector modulator, which combines the two channels in any arbitrary complex sum. Such diversity combining can be automated through an adaptive design. One approach examines the signal power differences for each polarization and combines the channels in both amplitude and phase in order to maximize the output signal power. A second approach uses a vector modulator that combines two signal paths in amplitude and phase. The modulator has two outputs, and by minimizing the signal power of one output through adjustment of amplitude and phase, the signal power is maximized at the second output.

Closed loop tracking dynamically follows directional changes in the received signal. These systems become necessary when the antenna's beamwidth is several times the uncertainty in the signal direction and accurate antenna pointing must be maintained. Such systems are more expensive than the open loop antenna tracking techniques. Part of the system expense lies with a more complex antenna feed design, because both data and tracking antenna patterns must be developed. Additional expense is incurred for the control system and the monitoring of the received signal levels. Radar systems must simultaneously sample the sum and two difference channels with three receivers to avoid degradation from received signal fluctuations. Communication systems generally have an easier and less costly implementation because the received signal level is well behaved. Thus, communication systems can sequentially sample a single receiver rather than multiple receivers and can effectively use averaging to maintain performance.

42.5 ACQUISITION ISSUES

Angle tracking techniques are successful when the received signal levels are sufficiently strong to allow detection. The process of aligning the antenna position with the signal is referred to as *acquisition* and assumes the system's receiver has an adequate signal level. Radar and communication systems again differ in the process of acquisition. The location of potential targets for radar applications is not known *a priori* and a search for the target must be undertaken. The location of potential targets for a tracking radar may be determined by handover information from a search radar or information regarding the target's trajectory may be known. Generally, tracking radars perform a limited search in the suspected target location, following a raster or spiral search pattern. The radar's range capability is a key requirement along with the target's radar cross section level. The radar search includes range and Doppler possibilities and an acquisition waveform may be used for coarsely determining the target's location. Radar target detection follows the usual issues of probabilities of detection and false alarm.

Communication systems are generally notified of the general signal direction and, as appropriate for the antenna's beamwidth, will conduct a limited search for the signal. Again, the antenna's beamwidth relative to the uncertainty of the signal direction dictates the need for a spatial search. Because the initial signal acquisition can often be done by acquiring the carrier component with the benefits of high sensitivity from a narrow bandwidth and averaging, the acquisition has greater sensitivity than the sensitivity needed to demodulate the data.

When extremely narrow beamwidth antennas are used, the spatial acquisition becomes more challenging. When very narrow antenna beamwidths are used, sometimes a separate, smaller acquisition antenna is used to provide a coarse determination of the signal's direction. While the gain of the smaller antenna is insufficient for data reception, the higher tracking sensitivity may still be able to obtain a coarse estimate of the signal direction to assist in acquiring the signal of the main antenna with its narrower beamwidth. A second approach²³ increases the acquisition field of view by using a cluster of antenna feeds in the focal region and individual tracking receivers on each feed. The spacing of these feeds is selected on the basis of the minimum required signal sensitivity, while a minimal number of additional feeds and tracking receivers can be selected to increase the acquisition field of view. The sensitivity of this approach is generally higher than using a separate, smaller acquisition antenna. Additionally, when one of the feeds acquires the signal, insight is provided to correctly align the antenna with the main beam from the knowledge of the pattern characteristics of the multiple beam of this design.

Antenna tracking techniques are limited to proper operation when the initial antenna positioning is within the main beam region. Away from this region, the anticipated tracking

response is not obtained. When narrow antenna beamwidths are used, the signal may be acquired with the signal arriving through the antenna's sidelobes. Three distinct techniques are available to verify the signal is aligned in the antenna's main beam rather than with an antenna sidelobe. One technique uses a separate smaller guard antenna. The guard antenna is selected so that this gain is comparable to the sidelobes near and adjacent to the antenna's main beam. A comparison of the signal level in the main and guard antennas are used to determine signal alignment. A single receiver can sequentially sample the signal level at the main and guard antennas. Separate receivers can simultaneously sample the received power levels, but the amplitude balance between separate tracking receivers, meaning both receivers have the same indicated output levels for the same input signal levels, must be maintained to produce reliable results. Signal injection through a coupler is one means to verify amplitude balance. If the main antenna signal level exceeds the guard antenna signal level, the signal is aligned with the main antenna's main beam and antenna tracking may be initiated. If the levels are comparable, a further search for main beam alignment is required.

A second technique²⁵ is based on the properties of the main antenna pattern and does not require a secondary guard antenna or tracking receiver. The angular width of the antenna's main beam is roughly twice the angular width of the antenna sidelobe. Measurement of the angular lobe width is used to distinguish main beam and sidelobe alignment. After the receiver has acquired, the antenna is commanded in angular offsets in order to measure the angular width of the lobe where the signal is received. This open loop commanding is similar to the operation of step tracking and if the location is determined to be the main beam, step tracking would be used for initial alignment. On the other hand, if this initial measurement indicates the smaller angular width of a sidelobe, the main beam is yet to be located. Open loop commands are then initiated to reposition the antenna to the next adjacent lobe position, and the angular width of this lobe is again measured. This process is repeated until the main beam is located. Insight into the pattern characteristics of the actual antenna is useful in applying this technique.

The third technique²⁵ applies to antennas having a monopulse capability. The error response has a linear response within the main beam and has high levels and a linear response having a different slope in the sidelobes, as shown in Figure 42-9. The error responses in this figure were determined by using $\sin X/X$ functions to obtain responses having a sidelobe structure. For the principal polarization, the error response follows the previously described behavior having a null on axis and a linear deviation away from the axis. This behavior persists over a significant portion of the main beam region and deviates from this response

FIGURE 42-9 Error response over wider angular range

beyond it. In the sidelobe region, a portion of the response also has a linear slope, but the slope in the sidelobe region exceeds the slope in the main beam region. These differences in the error response can be used to distinguish alignment in the main beam region from alignment in the sidelobe region.

Generally, tracking receivers for the amplitude modulation containing the tracking response saturate above a predetermined percent modulation. If the tracking receiver has a saturated output, the signal is not aligned in its linear region and again commanded offsets can be used to realign the antenna to a point having a linear response. When a linear region of the error response is obtained, slight angular offsets can be used to determine if the slope of the error response is that of the main beam region or a sidelobe. If the slope is in the sidelobe region, angular offsets can again be used to search for the main beam. Once main beam alignment is verified, antenna tracking can be initiated.

42.6 INTERFEROMETRIC SYSTEMS

Interferometric antennas derive their tracking information by determining the phase difference between separated antennas. Such systems are sometimes referred to as phase monopulse, because the tracking information can be obtained from a single pulse and the relative phase between antenna elements is independent of the received signal level.

The phase difference between interferometric elements¹² for a signal arriving at an angle θ , with respect to the boresight direction of the elements, equals

$$\Delta\phi = 2\pi (d/\lambda) \sin \theta$$

where d is the baseline separation between the phase centers of interferometric elements and λ is the operating wavelength as illustrated in Figure 42-10. By taking the derivative

FIGURE 42-10 Geometry of interferometer

of this expression and noting that the half power beamwidth of the interferometric lobes equals

$$\theta_l = 0.88\lambda/(d \cos \theta)$$

it can be shown that the angular accuracy of an interferometric pair equals

$$\sigma_\theta/\theta_l = 0.181 \sigma_\phi$$

where σ_ϕ is the phase measurement accuracy. Thus, the angular accuracy of an interferometer is normalized to the beamwidth of the interferometric pair and depends on the accuracy with which the relative phase between interferometric elements can be measured.

In practice, the relative phase between antenna elements can be measured in a modulo 2π sense. Generally the received signal strength for each interferometric element dictates the required antenna gain level. Accordingly, the separation between antenna phase centers exceeds several wavelengths, because the antenna apertures cannot physically overlap. Because the phase between elements can only be in a modulo 2π sense, the signal direction becomes ambiguous, having several potential values when the baseline between the interferometric elements are several wavelengths. Interferometric ambiguities can be eliminated only if the baseline between the antenna element is less than one-half wavelength, and the angular accuracy for such a spacing is generally unattractive. Therefore, a means must be devised to reliably select the correct signal direction from the possible locations corresponding to the phase ambiguities.

One approach¹² to the phase ambiguity problem applies to interferometers that use high gain antenna elements. If these interferometric antenna elements are configured with a monopulse capability, the monopulse estimate can be used to resolve the ambiguities of the interferometer as illustrated in Figure 42-11. Thus, this system design enjoys

FIGURE 42-11 Monopulse resolution of interferometric ambiguities (R. B. Dybdal¹² © IEEE 1986)

the angular accuracy of the interferometer, while the monopulse capability provides the means to resolve the interferometric ambiguities. A probability of correct ambiguity resolution has been derived based on the diameters of the interferometric antenna elements, the baseline between the elements, and the accuracy of the monopulse capability. For practical applications, it can be shown that a high probability of correct ambiguity resolution exists if the element baseline is limited to four to five times the antenna diameter. An attractive feature of this approach is that the results are independent of frequency. As the frequency increases, the monopulse accuracy also increases maintaining the probability of correct ambiguity resolution. Thus, such a design can be used in wide bandwidth applications.

A second approach²⁶ applies in cases where low gain antenna elements are used in an interferometer. In this case, additional antenna elements are inserted within the interferometric baseline. In this approach, the overall angular accuracy is obtained from the longer baseline, and interferometric processing of the shorter baselines provides the means of resolving the phase ambiguities.

The strategy of selecting the spacing of the additional interferometric elements within the overall baseline must be devised. If the element spacing is an integer fraction of the total baseline, some of the ambiguities of the smaller baseline will be aligned with the ambiguities of the overall baseline. Those ambiguities that are not aligned can be eliminated as possible signal directions, and the process is continued until the correct signal direction is determined. The fractional integer value can be selected by determining the phase measurement accuracy of the interferometric pairs, and again a probability of correct ambiguity can be determined; practically, an element spacing of one-quarter to one-fifth of the total baseline or the next subbaseline as appropriate yields a reliable indication of the possible ambiguities. Like the monopulse resolution of phase ambiguities, this system can be used over wide bandwidths since the overall accuracy increases with increasing frequency as well as the resolution of the ambiguities. At the highest frequencies, the minimum element spacing may be insufficient to resolve all possible ambiguities and the physical constraints on the element spacing may not permit additional elements. In this case, forming a synthetic element by arraying two elements with the shortest baseline results in a phase center location between the two actual elements, and this baseline can be used to resolve the remaining ambiguity. A comparison of wide bandwidth techniques for angular location²⁷ illustrates the angular accuracy of interferometric approach and other monopulse techniques for broad coverage antennas.

Three distinct system parameters exist for antenna tracking designs: sensitivity or antenna gain, field of view, and angular accuracy. A further system constraint for practical systems is overall size. If the overall size is fixed, a comparison of monopulse and interferometric systems can be made. Monopulse design have a higher antenna gain because in a size constrained application, a single aperture is larger than multiple apertures required by interferometric systems; at the same time, the field of view for monopulse designs is accordingly smaller than interferometric designs. The angular accuracy of the interferometric design is better than the monopulse designs. Thus, the role for interferometry is applications where the wide field of view and angular accuracy requirements are more important than signal sensitivity. An example application for an interferometric design is a short range system where S/N is not a constraint and high dynamics in signal direction are anticipated. In this case, the smaller interferometric antenna elements have a wider angular field of view than a single monopulse antenna. This wider field of view is advantageous in following the angular position of the signal. Additionally, the reduced size of the interferometric antennas compared with the single large monopulse design eases the mechanical requirements for angular beam positioning.

42.7 ANTENNA TRACKING TESTING

Testing antenna tracking designs²¹ generally requires not only RF evaluation but also mechanical and control testing. The RF testing includes the normal evaluation of antenna gain, pattern, polarization, and bandwidth capabilities. The testing generally evaluates the feed performance and then the integration of the feed into the antenna. Monopulse testing is more complex, since the performance of both the sum and difference channels must be determined along with the error response characteristics. Careful attention to the coincidence of the sum channel's boresight axis and tracking channels' null is required. Attention must also be paid to the group delay differences between the sum and difference channels. Finally, the error response of the antenna, or the difference over sum pattern ratio, must be measured to establish the tracking sensitivity of the design and the angular region over which the linear error response prevails.

Having established the RF performance, the boresight axis of the antenna must be referenced to the mechanical axes of the antenna positioner. Small antennas can be measured in general purpose antenna test facilities and such testing does not necessarily require the operational positioner. The boresight alignment in this case is most conveniently performed in the test facility and the mechanical position of the antenna can be referenced to the electrical boresight axis, through the use of optical cubes, for example. Larger antennas, which cannot be readily accommodated in a test facility, require alignment when integrated with the positioner into the site. In addition to leveling the positioner, the positioner must be aligned to true north so that the angle encoders are properly registered.

Independent of how the antenna boresight is mechanically referenced to the positioner, any biases in antenna pointing must be determined. Signals whose directions are known are measured using the antenna system; such signals can include radio sources, signals of opportunity such as satellites, and calibration sources in known directions. The directions of these signals can be measured by step track and monopulse processing as appropriate. The antenna is commanded to point at the signal and differences in this direction and the direction indicated by antenna tracking provide the means to determine azimuth and elevation biases. Generally, antenna patterns are symmetric about the boresight axis near the main beam peak. Selecting different angular offsets (for example, 2, 2.5, 3, 3.5 dB) from the beam peak and looking at the boresight axis determined by the midpoint between the respective angular offsets provides some averaging opportunities for defining the boresight axis further. Least square fits to an approximate or measured beam shape is another alternative. The end objective is to verify the open loop pointing commands yield the same signal alignment as that determined by the antenna tracking technique. Independent signal of opportunities such as satellites can also be used to assure further confidence in the antenna boresight registration.

Monopulse systems alignment is more complex. The sum and difference patterns must have coincident boresight axes and open loop measurements are a starting point. The error response can also be measured and verification of null coincidence yields confidence. Measurement of the error response, and its deviation from linear, provides a measure of the acquisition range of the design. The need to have proper phasing between the sum and difference channels in order to minimize crosstalk between the azimuth and elevation channels also requires verification. An external signal source provides a tracking source; and signals of opportunity at relatively high elevation angles to avoid multipath should be used. (Such signals include existing satellite signals or radio sources.) The antenna is commanded to an offset angular position in azimuth, for example, and the tracking system is then activated. The azimuth and elevation encoders are observed and the tracking return to boresight should only occur in the azimuth direction in this example. Such tests are then repeated in the elevation plane. Testing of this type is commonly referred to as *snap on*

tests and should be repeated at different angular offsets to determine the angular limits of the tracking capability.

Other tests are required to evaluate the control system for closed loop tracking designs. The control system is evaluated by measuring its step response and ramp response.²¹ Again, a signal source is required for such testing and a low frequency function generator is used to inject offset error signals into the control system. The step response is measured by injecting a low frequency square wave into the error signal. The rise and fall characteristics define the control performance and the damping and overshoot characteristics are observed. The ramp response is obtained by using a triangular wave from the function generator and evaluates the linearity of the error response. By increasing the amplitude level of the function generator, the angular extent of the tracking system can be evaluated. This angular extent is limited by either the error response or when the amplitude modulation of the tracking signal saturates the tracking receiver. The dynamic range of the tracking receiver is measured by determining a threshold input level for acquisition and the input level needed to saturate the receiver.

The remaining testing requires a determination of the dynamic tracking performance. Such testing requires a moving signal source and knowledge of its dynamic motion. For satellite systems, the use of a polar satellite and measurements of the tracking during a satellite path provides such an opportunity. The satellite position is well known through the satellite's ephemeris and the time variation in azimuth and elevation can be determined a priori. Comparison of this time variation with the measured variation provides a dynamic evaluation of the performance. Selection of a satellite pass with a high elevation angle results in tracking trajectories having high dynamic motions and provides a good measure of the achieved satellite tracking performance.

The dynamics of the antenna are ultimately limited by the structural resonances of the design, which is a mechanical design issue. To first order from a control viewpoint, an antenna is an integrator until limited by structural resonance. A tabulation of roughly one hundred high performance antennas²⁸ has been made as a function of the antenna diameter. Examination of this data reveals the upper bound of the resonant frequency f_r shown in Figure 42-12.

$$f_r = 250/D, \text{ Hz}$$

FIGURE 42-12 Structural resonance versus antenna diameter (after D. D. Pidhayny²⁸)

where D is the antenna diameter in feet. When evaluating the resonant frequencies, care should be taken to ensure other structural resonances associated with the antenna feed do not limit tracking accuracy.

Antenna tracking evaluation normally required the development of an error budget to project the uncertainty in antenna tracking accuracy. This budget is specific to the design and application of the antenna tracking design, the S/N obtained by the system design, and in the terminal guidance case, must also address the target effects. The error budget contains both mean and random error components and generally, the error budget is comprised of the algebraic errors and an rss sum of the random components. Such error budgets require significant attention to quantifying the individual error components. An example²⁹ illustrates the evaluation of a K-band ground terminal and includes the design description and evaluation including crosstalk evaluation and the effects of wind.

43.1 INTRODUCTION

A microwave beacon system, like a radar, transmits a pulsed RF wave to locate a target, using the time delay of the “echo” to determine distance and using antenna directionality to determine angular location. The distinguishing feature of a beacon system is that the target cooperates in this process, using on-board electronics to enhance the returned RF wave with amplification, frequency shifting, or coding. Beacons are thus highly accurate and reliable surveillance systems and also can provide some data-link capability. Beacon systems typically consist of transponders and interrogators. *Transponders* are the active devices carried by the target to provide the enhanced echo. Transponders are usually located on moving platforms, although fixed transponders may be used to mark hazards, navigation points, or calibration points. *Interrogators* employ equipment similar to that of conventional pulsed radars, i.e., a transmitter which elicits replies from the transponder and a receiver to detect and process the replies.

The most widely deployed beacon system is the military Identification Friend or Foe (IFF) system and its civilian derivative Air Traffic Control Radar Beacon System (ATCRBS). The military systems are also known as Mark X, Mark XII, and Mark IV IFF. Mark IV, the latest version, is known internationally as the NATO Identification System (NIS). The civilian systems are also known internationally as Secondary Surveillance Radar (SSR). All systems have similar waveforms and share common frequencies of 1030 MHz for interrogation and 1090 MHz for reply.¹⁻³ Polarization is always vertical. NIS also can be interrogated by certain radar signal formats at frequencies near C-band.

Transponders typically must respond to interrogations from any direction in space. Therefore, antennas with omnidirectional coverage in azimuth (see Figure 43-1) are desirable for this part of the beacon link. For aircraft, the antennas are usually blade antennas

FIGURE 43-1 Handheld Identification Friend or Foe (IFF) radar transponder with omnidirectional antenna (© 2007 Sierra Monolithics, Inc. All rights reserved.)

(aerodynamically shaped monopoles) protruding from the aircraft skin or flush-mounted annular slots in the skin. The design of these antennas is relatively straightforward, with primary emphasis on location to minimize shadowing.^{4,5} A modest 8 percent bandwidth covers the interrogation and reply frequencies. Interrogators, which also must respond to NIS radar interrogations, must have additional bandwidth. When aircraft shadowing prevents omnidirectional coverage from a single antenna, transponders are available with a time-sharing switch to rapidly sample two antennas (e.g., one on top of the aircraft and another on the bottom).

The interrogator may be either ground-based or airborne. In either case, the interrogator antenna is highly directional, with some means for scanning the directional beam over a volume of space. Thus, interrogator antennas are more complex in design and operation. These constitute the central focus of this chapter.

43.2 INTERROGATOR ANTENNA DESIGN PRINCIPLES

Requirements for interrogator antennas are similar to those for radar antennas, with the following differences:

- Beacons do not benefit from the “two-way” sidelobe suppression of radar.
- The beacon’s greater link reliability mandates greater attention to suppression of false targets due to multipath and sidelobe effects.
- Beacon power levels can be much lower because of target cooperation.
- Beacon antenna gain is often less critical than radar.

Minimization of false targets from multipath and sidelobe effects is a central design consideration. Collocation with a primary radar and the large physical dimensions imposed by the relatively low frequency are other factors.

Vertical Pattern Design

The preferred vertical pattern shape for surface-based interrogators is a sector pattern (uniform gain from the horizon to some prescribed upper limit) or a modified cosecant pattern. The cosecant pattern is preferred for long-range systems requiring high gain near the horizon. The upper limit of coverage is typically about 40° elevation.

Multipath reflection from surrounding terrain is a major contributor to false targets for surface-based interrogators. Multipath is minimized by shaping the vertical radiation pattern to reduce radiation below the horizon. Older antenna designs used small vertical apertures with broad vertical patterns, resulting in considerable radiation onto surrounding terrain. More recent designs have larger vertical apertures to shape the vertical pattern for substantially reduced radiation below the horizon. Figure 43-2 shows examples of vertical lobing for small and large apertures.

The antenna beam is usually tilted up slightly so that the pattern level at the horizon is –6 dB. A useful measure for multipath rejection is the slope of the vertical pattern at the horizon, measured in decibels per degree. Figure 43-3 shows the envelope of the multipath minima as a function of this cutoff rate. Since higher cutoff rates require larger apertures, the trade between antenna size and reduced multipath must be made carefully. A cutoff of 2 to 4 dB per degree has been found to be satisfactory for most installations.

FIGURE 43-2 Influence of vertical aperture on elevation lobing patterns

FIGURE 43-3 Envelope of lobing minima for various horizon cutoff rates

FIGURE 43-4 Normalized horizon cutoff rate (after Lopez⁷ © IEEE 1979)

Pattern-synthesis techniques have been developed to optimize horizon cutoff subject to constraints on antenna size, above-horizon coverage, and sidelobe levels. For the synthesis of sector beams, Evans⁶ has adapted a procedure originally developed for digital filters. For engineering estimates, Lopez⁷ provides curves (normalized to a vertical aperture of one wavelength) relating horizon cutoff, sidelobe level, and ripple within the sector beam (see Figure 43-4).

For urban interrogator locations, limited electronic scan of the vertical pattern is very useful to avoid direct illumination of tall buildings, thereby reducing reflected false targets. This feature, called *beam hopover*, allows the -6-dB pattern point to be tilted up slightly when interrogating in the direction of the obstruction. Array implementations of the interrogator can use a multiple-beam feed network to achieve this feature with a minimum number of switches or phase shifters. With a reflector antenna, a secondary feed below the focus can achieve the result.

Recent designs have used dipole arrays because they provide the control of vertical illumination needed to obtain shaped patterns, good horizon cutoff, and effective use of vertical aperture. Shaped reflectors also can be used, with multiple-horn and line feeds.

Because the vertical pattern is broad, it provides no significant ability for vertical-plane direction finding. This is usually not a limitation, because many transponder replies include a coded report of altitude. Thus the interrogator often receives a direct report of the target's vertical coordinate.

Horizontal Pattern Design

In the horizontal plane, accurate determination of target angle and minimization of false targets are of central importance. Surface-based interrogators typically use a low-sidelobe beam with a 3-dB width of 2 to 4°. The target's location can be measured to an accuracy of about one-tenth the 3-dB beamwidth by scanning the beam across the target

while interrogating continuously, with the target location estimated as the centroid of the “run” of replies that is received. For greater accuracy, a monopulse difference pattern is included in the horizontal plane. Standard off-boresight monopulse processing is used. With monopulse, angle accuracy of 1 to 2 percent of the half-power beamwidth is possible.⁸ For monopulse antennas, the two patterns are called the Σ (sum) and Δ (difference) beams, respectively.

For arrays, the Σ beam is formed with cophased illumination in the horizontal dimension. Amplitude tapering for -25 - to -30 -dB sidelobes is typical. The Δ beam is obtained by feeding opposing sides of the aperture in phase opposition. Use of the Σ amplitude taper for both the Σ and Δ patterns gives a simple feed network but results in quite high Δ sidelobes. This high-sidelobe Δ pattern is suitable only for noncritical uses. A more complex multibeam feed network, capable of producing an independently optimized Δ illumination (such as the Bayless taper), is usually required. Optimal Σ and Δ illuminations are very similar on the outer parts of the array, so the multibeam feed is only required for the center portion of the array. Figure 43-5 shows the two types of difference patterns and their respective aperture illuminations.

For reflectors, a conventional parabolic contour in the horizontal plane gives the desired pencil beam. Careful control of feed spillover is needed to ensure that backlobes are -30 dB or lower. Standard monopulse feed design will give suitably low Δ sidelobes.

Sidelobe Suppression

A procedure called *interrogation sidelobe suppression (SLS)* cues the transponders to avoid replying to sidelobes of the interrogator antenna. With SLS, the interrogation is transmitted first by the Σ pattern and then by an omnidirectional “control” pattern (Ω). The Ω gain is lower than that of the Σ beam but higher than that of the sidelobes. The transponder replies only if the amplitude for the Σ interrogation exceeds that for the Ω by some prescribed margin, indicating that the interrogation came from the main beam. A variation called *improved*

FIGURE 43-5 Typical far-field horizontal patterns with the corresponding aperture distributions shown in the insets

SLS (ISLS) provides for suppression of reflected main-beam interrogations. With ISLS, a pulse is transmitted simultaneously on the Σ and Ω beams, and the transponder measures timing differences to detect an interrogation arriving via a reflected path. Some beacon systems also employ SLS on the reply link (RSLs). With RSLs, a two-channel receiver compares replies received on the Σ and Ω antennas, blanking the reply when the relative amplitude indicates a pulse received by a Σ sidelobe.

When the directional and control beams (Σ and Ω) are derived from the same aperture, they share a common phase center. Consequently, the multipath lobing (see Figure 43-1) will be the same for both beams, so the proper Σ/Ω amplitude is preserved at all elevations. If, however, the phase centers are vertically displaced, the lobing does not match, and faulty SLS operation occurs. When a Σ peak aligns with an Ω null, sidelobe amplitude may be high enough to “punch through” the Ω coverage. When a Σ null aligns with an Ω peak, even the main beam may be unable to exceed the Ω gain, and all replies are suppressed. This differential lobing can be a serious problem, so most recent designs have used common phase centers.

Common types of Σ and Ω patterns are illustrated in Figure 43-6 and described below.

- **Omnidirectional pattern** This pattern is usually formed by a separate antenna, often a collinear array of dipoles. Its advantage is simplicity. It does not rotate and therefore does not require an additional rotary joint channel, and it does not constrain the design of the

FIGURE 43-6 Generic control-pattern types

directional antenna. The vertical pattern of this Ω antenna is often designed to match that of the Σ . To avoid mutual blockage, the two antennas are displaced vertically, causing differential lobing. Such systems exhibit marginal SLS operation^{9,10} and are avoided in critical applications.

- **Difference pattern** The high-sidelobe difference pattern formed by an abrupt phase reversal at the center of the Σ illumination is sometimes used for Ω coverage. The vertical patterns and phase-center locations are closely matched, so differential lobing is minimized. The pattern is easily formed, requiring only a “magic T” power divider at the center of the array, and it imposes no other design constraints. Its principal shortcoming is that it provides little Ω coverage behind the antenna, allowing possible interrogation by backlobes and reflections.

With this pattern, the Ω pulse can be transmitted at a higher power level relative to the Σ because the null precludes main-beam blanking. The higher power compensates for the relatively poorer Ω coverage. This also narrows the effective beamwidth over which replies are elicited, because a substantial part of the main beam skirts are also blanked. Airborne military interrogators, where aperture size is often limited, use this effect to improve angular accuracy. For example, with Ω power that exceeds Σ by 5 to 10 dB, an antenna with a 35° 3-dB beamwidth can elicit replies over only a 5° sector. The design must consider the substantially higher power at the Ω port.

- **Notch pattern** For array implementations, this type offers an excellent combination of common phase center, central null, and control of sidelobe punch-through. The pattern is produced by the broad radiation from a single central column of the array, with simultaneous out-of-phase by the Σ pattern to produce the notch. Because of the Σ 's greater gain, little power is needed to produce the notch, typically about 1 percent of the total. An auxiliary “backfill” antenna is usually added to cover backlobe radiation in this approach. (A backfill antenna is also useful with the difference-pattern omni.)

43.3 INTERROGATOR ANTENNAS: PRACTICE

The following paragraphs describe practical issues faced by designers of ground- and air-based beacon interrogation antennas.

Ground-Based Systems

For many years the standard configuration for ATCRBS/IFF interrogators consisted of a linear array (commonly called a *hog trough* because it resembles an animal feeder) and a stationary omnidirectional antenna. The hog trough is a sectoral horn fed by a horizontal array of dipoles and is about 26 ft long. The beamwidth is 2.3° in azimuth and 42° in elevation. Peak sidelobe level is typically -23 dB. The omnidirectional antenna is a biconical horn or collinear dipole array mounted on a fixed mast beside the interrogator. Figure 43-7 shows such an installation at a Federal Aviation Administration (FAA) site. A more recent design,¹¹ shown in Figure 43-8, features an integral notch-type SLS pattern and also a difference pattern that can be used for monopulse angle estimation and RSLs. The military uses various shorter versions of the hog trough for its mobile interrogators. An example is shown in Figure 43-9. These are approximately 14 ft long, have a difference-pattern Ω , and have a wider azimuth beamwidth, typically about 4°. All of these antennas have little elevation beam shaping and little horizon cutoff (about 0.3 dB per degree). All are subject to problems of multipath.

FIGURE 43-10 Open-array SSR antenna. The ladder-like top section makes up the SSR directional antenna.

More recently, designs have employed increased vertical aperture to control multipath. The *open-array antenna*¹² shown in Figure 43-10 is a planar array of dipoles with a vertical aperture of 5 ft. It has a horizon cutoff of 2.2 dB per degree and employs an integral notch-type Ω pattern (with backfill radiator) for SLS, so multipath problems are greatly reduced compared with the hog trough. The dipole array is made unidirectional by columns of parasitic reflector dipoles located behind and between the columns of driven dipoles. This eliminates the need for a ground plane, giving a very open construction that has low wind loads, even with ice accumulations. Typical radiation patterns for this antenna are shown in Figure 43-11 and Figure 43-12. The open array has replaced the hog trough as the standard ATCRBS antenna at FAA terminal radar sites.¹³

At sites which have a large radar reflector as part of the surveillance equipment, a sharp horizon cutoff for the beacon can be obtained by sharing the reflector with the radar, using an *integral beacon feed*. Since both feeds must be located approximately at the reflector's focal point, the principal design problem is ensuring that each feed operates properly in

FIGURE 43-11 Open-array azimuth patterns (Courtesy of Texas Instruments, Inc.)

FIGURE 43-12 Open-array elevation pattern (Courtesy of Texas Instruments, Inc.)

the presence of the other. S-band and L-band radars are commonly associated with beacon systems. The two bands have somewhat different design concerns, as follows:

- The S-band reflectors are relatively small, yielding approximately a 4° azimuth beamwidth and 2 dB per degree horizon cutoff. The 4° beam is too wide for most FAA applications but is useful for certain less-demanding military applications. The S-band feed horn is small relative to the longer beacon wavelength, so an array of beacon dipoles can usually be disposed around the horn to make a beacon feed whose phase center is at the focal point.
- The L-band reflectors are larger, giving a 2° azimuth beamwidth and 4 dB per degree cutoff. However, the larger physical size of the L-band feed horn usually precludes a separate dipole array around the radar horn. Therefore, either the beacon must be duplexed into the radar horn or the beacon feed must be displaced from the focal point.

For either band, the beacon feed must be isolated from the radar so that it is not damaged by high radar-power levels and so that radar power is not coupled into the beacon receiver. In many cases the radar feed is circularly polarized, with both amplitude and phase patterns carefully adjusted for good axial ratio and proper illumination of the reflector. The beacon feed, being vertically polarized, can alter the axial ratio, degrading polarization performance of the radar. For either band, the elevation pattern is largely determined by the reflector contour, and it often approximates a cosecant-squared shape. The beacon feed pattern can be modified to direct more energy at the “spoiled” part of the parabolic contour, thereby increasing elevation coverage at higher angles to more nearly approximate a sector pattern.

FIGURE 43-13 Tactical S-band radar antenna with integral IFF feed (*Courtesy of Thomson-CSF*)

Figure 43-13 shows beacon dipoles around the feed of an S-band radar. An array of dipoles, as shown in Figure 43-14, provides the feed-pattern control needed to optimize the beacon's azimuth and elevation-pattern shapes.

In the L-band ARSR-3 radar, the beacon feed is located beside the radar horn, off the focus (see Figure 43-15 and Figure 43-16). This introduces an azimuth offset between the

FIGURE 43-14 Integral beacon feed for elevation-pattern shaping (*Courtesy of AEG-Telefunken*)

FIGURE 43-15 ARSR-3 long-range surveillance radar antenna (*Courtesy of Westinghouse Electric Corp.*)

beacon and radar patterns. The returns are corrected with signal processing so that they appear coincident on the display. Radiation patterns for the ARSR-3 beacon feed are shown in Figure 43-17.

Experimental beacon antennas using electronic scanning have been constructed. Cylindrical arrays are used to provide 360° azimuth scan. The version shown in Figure 43-18, built by Hazeltine Corporation's Wheeler Laboratory, mounts on the fixed portion of the tower for an S-band radar.¹⁴ The vertical pattern is a sector beam with 3 dB per degree horizon cutoff.

FIGURE 43-16 Integral beacon feed for the ARSR-3 (*Courtesy of Westinghouse Electric Corp.*)

FIGURE 43-17 Typical radiation patterns for the ARSR-3 beacon antenna (*Courtesy of Westinghouse Electric Corp.*)

It includes beam hopper to avoid reflection obstructions. The antenna has Σ , Δ , and Ω horizontal patterns, with a 2.4° beamwidth. The azimuth beamwidth is held nearly constant for all elevation angles (see Figure 43-19) by a multiple-angle collimation scheme. Scanning, performed by a combination of switches (sector steps) and phase shifters (fine incremental steps), can emulate the uniform continuous motion of a mechanical-scan system (for compatibility with existing systems) or can be completely agile to support more advanced interrogation management schemes. To date, this antenna has not been widely deployed.

The array shown in Figure 43-20 has been developed for tactical applications.¹⁵ The 65° azimuth beam is scanned in increments of 5.6° using a modal Butler-matrix feed that

excites all eight dipole columns. The SLS and monopulse functions share a difference-type pattern synthesized to provide backlobe coverage. All beams have the same elevation pattern with a high horizon cutoff rate.

The cylindrical array shown in Figure 43-21 has been developed for shipborne IFF use. The directional beam, complemented by a stationary omnidirectional SLS beam, is positioned by a Lockheed-proprietary trimode scanner system.¹⁶

Airborne Systems

To date, most IFF interrogators on airborne platforms have been for military use. Airborne interrogators have not seen wide use in civilian aviation.

Airborne IFF interrogators almost always have limited availability of aperture size. They are typically used in conjunction with a radar at X- or Ku-band. Figure 43-22 shows a typical implementation in which L-band dipoles for IFF are mounted on the surface of a radar reflector. The dipoles use resonant techniques to reduce scattering at the radar frequency. Use of thin dipole arms and baluns also reduces the effect on the radar. Radar/beacon interaction is most easily controlled when the polarizations of the two systems are orthogonal. Because the beamwidth is always relatively large, beam sharpening using difference-pattern SLS is employed, with the power level for the difference pattern at nominally 9 dB above the sum pattern.

Other, similar radar antennas have used cavity-backed L-band slots instead of dipoles. The slot apertures are flush with the reflector surface, and the slots and cavities are carefully tuned to maximize reflectivity at the radar frequency. Folded $\lambda/2$ slots in which the slots are very thin (width $< 0.01\lambda$) have been found to be quite invisible to the radar.

IFF dipoles also have been added to “flat plate” radar antennas (planar arrays of waveguide slots). Thin, carefully tuned dipoles and orthogonal polarization are used to minimize interaction of the two systems.

The use of airborne interrogators on civilian aircraft has been investigated to provide traffic-alert and collision-avoidance information. An experimental antenna for this purpose is shown in Figure 43-23. This antenna can form either a directional beam or a notched beam in any one of eight azimuth directions. Using sidelobe suppression, the antenna is used to interrogate selected 45° sectors. The replies are received on multiple beams and are processed to provide 360° direction-finding capability with 8° rms accuracy. Top-loaded monopoles are used in this design to provide a low-drag antenna. Four monopoles spaced at approximately $\lambda/4$ are used. The dipoles are fed by a beam-forming network consisting of stripline couplers, diode switches, and phase shifters.

44.1 INTRODUCTION

Antennas for satellite systems are required for both the space and user segments. Such antennas pose interesting design and test challenges. Space segment antenna designs are arguably the most diverse spacecraft technology varying with frequency, coverage requirements, and flexibility of operation. Likewise, user segment antenna designs vary drastically with frequency and data rate requirements, and can vary from very small designs as satellite services are extended to individual users to much larger ground terminals for high data rate services. The technology for both the space segment and the user segment is quite diverse and draws upon those technologies described in detail elsewhere.

Communication services are a major application for satellite systems and the diversity of antenna technology¹ that has been used for communication satellites has a significant range of performance capabilities. Both commercial and military services are commonly found and the differences in their objectives are apparent in the choice of technology. Commercial communication systems are strongly motivated to obtain as much communication capacity from their allocated bandwidth thereby increasing the amount of data that can be communicated. This motivation has resulted in the development of frequency and polarization reuse techniques. Frequency reuse uses the same bandwidth in portions of the satellite's field of view that are isolated by the satellite's antenna patterns. Polarization reuse techniques increase throughput by transmitting and receiving orthogonally polarized signals. Commercial systems are developed based on projected capacity demands in well defined coverage areas. Military systems, by contrast, require flexibility in their coverage characteristics in order to respond to changing geopolitical needs. Military services use technology to mitigate interference from undesired sources to protect authorized users. Other satellite applications provide navigation services and remote sensing data. The requirements for these applications provide differing challenges from communication applications. Finally, every satellite system requires tracking, telemetry, and control (TT&C) capabilities to determine the satellite's orbital location, provide health and status information on the satellite, and inject and validate commands to maintain satellite operation over its lifetime.

While specific applications have differing antenna technology requirements, these applications have common issues. The mantra for the space segment is size, weight, and power (SWaP) because of limitations imposed by the satellite launch capabilities. A significant development effort in composite materials and reduced weight fabrications has resulted. Space segment antennas must have the capability to withstand launch and on-orbit environments and consequently, the designs must be sufficiently rugged to survive launch as well as have adequate thermal protection for accommodating the on-orbit thermal extremes while having a low mass. Satellite antennas must also reliably operate unattended over the long orbital lifetimes. Reliability concerns result in rigorous prelaunch testing and the antenna designs are generally required to substitute redundant RF electronics to maintain operational capability over the required lifetime. In many cases, restrictions on the launch vehicle envelope result in the need for antenna deployment mechanisms to position antenna components to their operational configuration, so the reliability required for such mechanisms is understandably high. Still other requirements for electromagnetic interference/electromagnetic compatibility (EMI/EMC) are necessary to avoid mutual interference to/from satellite subsystems. The user segment also faces common requirements in their development/implementation. User antennas for communications have established requirements for antenna sidelobe control to avoid interference to/from adjacent satellites. The spectral crowding with other microwave services in adjacent frequency allocations, particularly at the lower microwave frequencies, requires increased design attention to protecting user systems from unintentional out-of-band interference from terrestrial users using other microwave services. As the trend to extend satellite services to individual users continues, design challenges include low fabrication cost to control the overall system acquisition

costs and developing reliable minimal testing techniques to assure design compliance on a production basis.

The satellite orbits provide other differences in space and user segment antenna designs. Predominately, satellites are in a geostationary earth orbit (GEO), which maintains these satellites in a fixed position above the earth as the earth rotates. This orbit locates satellites 20,000 nmi above the earth where the earth subtends about a 16.9° field of view. The combination of the long range separating the user segment and the satellite and the relatively narrow field of view dictates the use of high gain antennas on the space segment to permit link closure. Nonetheless, maintaining a fixed position over the earth has a significant advantage in providing continuous service to users. One disadvantage of this orbit is the limited coverage in polar regions. Applications, such as navigation, require complete global coverage including polar regions. These applications generally use inclined orbital constellations in a lower medium earth orbit (MEO) 12-hour orbit, with a 10,000 nmi altitude where the earth subtends about 28.7° . Other applications, particularly for remote sensing, use still lower low earth orbit (LEO) inclined 450 nmi orbits where the earth subtends 83° . This is used both to meet resolution requirements in their determination of feature contrasts and to achieve global coverage. As the satellite altitude decreases, the earth subtends a wider field of view from these lower altitude orbits, while a broader antenna coverage is required for the space segment. Satellite orbits between MEO and LEO altitude extremes are less attractive because the ionizing radiation from the Van Allen belts imposes significant protection requirements for electronic components. These orbital alternatives also impact the user segment. For example, geostationary satellites that maintain their position have very minor user antenna tracking requirements, especially in comparison to low altitude satellites that require user terminals to follow the satellite's trajectory when the satellite is in view. The reduced range to LEO satellites can also reduce user performance requirements. However, since an individual satellite within the constellation has a limited time in view of the user, switching to another satellite within the constellation is necessary to maintain service availability.

Clearly, antennas for satellite systems have a wealth of challenges for design, development, and operation. The subject is truly multidiscipline, requiring not only an RF understanding but also mechanical and thermal awareness, interface issues with RF and control electronics, weight, volume and power, implementation costs, and extensive testing requirements following both established practice and test issues peculiar to space systems. The diverse technologies used in satellite systems provide opportunities for creative designs, and, as in the past, significant development challenges exist for future satellite system antennas.

At a system level, two parameters specify antenna system level performance for satellite communications:

1. The G/T (antenna gain, G , divided by system noise temperature, T) for receiving antennas
2. Effective radiated power (ERP), equal to antenna gain multiplied by transmitted power, for transmitting antennas

The required values of these system parameters are derived from link analyses for communications. Generally, E_b/N_o , the received signal energy per bit divided by the noise spectral density, is determined from

$$E_b/N_o = \text{ERP } G/T [L/(kR_b(4\pi R/\lambda)^2)]$$

where L is the system loss that includes propagation loss and receiver implementation loss, k is Boltzmann's constant, R_b is the bit rate of the data, R is the separation between transmitting and receiving antennas, and λ is the wavelength corresponding to the data rate. The value of E_b/N_o is determined from the data fidelity requirements in terms of bit error

rate (BER), the statistical average of the number of bits received in error out of a specified total number. The BER values are a function of E_b/N_o , which is commonly referred to as a “waterfall” curve that is dependent on the modulation format used and the receiver’s implementation loss. Both ERP and G/T directly depend on the antenna gain value.

The space segment is characterized by the uplink G/T for the receive antenna and the downlink ERP for the transmit antenna. The system parameters for the space segment are generally specified as minimum values over their required coverage area and also include the effects of antenna pointing errors resulting from the satellite’s attitude uncertainties. The user segment is characterized by the uplink ERP transmit capability and the downlink G/T receive capability and are burdened by user antenna pointing errors.

The system noise temperature T has two components, the antenna temperature and the receiver noise temperature of the electronics. Both the antenna gain and system noise temperature must be specified at a common reference plane (for example, the input terminals of a low noise amplifier) to quantify the G/T capability of the design. For the space segment, the specification of earth-directed antennas typically references an ambient 290 K noise level for the antenna temperature. In practice, antenna temperature values² are somewhat lower, resulting from the emission characteristics of the particular portion of the earth the antenna is servicing. The antenna temperature is typically higher than existing low noise receivers and it limits the uplink system sensitivity. An exception is crosslink antennas that provide connectivity between satellites; these antennas view a cold 3 K background noise temperature. The user antenna temperature, as will be discussed in Section 44.3, depends on atmospheric path loss that is a function of the elevation angle to the satellite and ohmic loss.

44.2 SPACE SEGMENT ANTENNAS

One approach in describing space segment antennas separates the designs by their coverage requirements. This separation results in earth coverage designs that span the earth’s field of view, spot coverage designs that serve a limited portion of the earth’s field of view, multiple beam designs that serve the entire or a limited portion of the earth’s field of view, and hemispheric coverage antennas needed for TT&C applications. When connectivity between satellites is required, point-to-point antennas are used in crosslink subsystems. Such crosslink subsystems allow global connectivity without the need for a relayed link with a ground terminal. Additionally, antennas for remote sensing applications require narrow beamwidths to obtain the required resolution for extracting the desired parameters and these narrow beamwidth antennas must be scanned to obtain their coverage requirements. This separation by coverage will be used in this discussion.

Earth Coverage Designs

The simplest satellite antenna design provides coverage over the complete earth disk visible from the satellite. Earth coverage antennas were the only feasible option for early satellites because of weight constraints and satellite attitude stability. Today, such designs are used in a limited number of applications, such as user access and routing, gateway (a link to a ground terminal that processes the uplink information into the downlink), services to avoid steering a more directive antenna beam, and so on. The technology for geostationary satellites generally uses simple horn antennas at microwave frequencies; corrugated or dual mode technologies are commonly used to obtain efficient rotationally symmetric patterns with good axial ratio performance. Such antennas are both small and lightweight. When both receive and transmit earth coverage services are required, and

a tradeoff exists between using a single horn for both receive and transmit or using individual horns for each function. When the individual horns are used, physical separation provides isolation to reduce the filtering requirements for diplexing and, with reduced filtering requirements, lower loss can be achieved.

When earth coverage antennas are used in orbits lower than geostationary, the earth subtends a greater angle and the range differences between the subsatellite point and the earth's limb also increase. In this case, antenna designs with a shaped pattern can be used to equalize performance for users within the visible portion of the earth. Arguably, the best known example of such designs is the antenna array³ used in navigational satellites. This array design produces higher gain towards the earth limb than at the subsatellite point, in order to offset the range differences between the subsatellite point and the limb of the earth.

Spot Coverage Designs

Spot coverage antennas serve a limited portion of the available field of view. A simple example is a parabola antenna mechanically positioned to serve a specified region of the earth. If communication needs change, the antenna can be repositioned to provide coverage in that area. Since a limited portion of the field of view is covered with a narrow antenna beamwidth, the antenna coverage area must also encompass the uncertainty resulting from the attitude stability of the spacecraft.

In some applications, coverage over the specified area and reduced coverage in other portions of the field of view is required. Such requirements typically arise to satisfy regulatory issues that limit coverage in other geographic areas or when the same satellite reuses the same frequency subband in different portions of the earth field of view and subsequent isolation between the two coverage areas is required to avoid cochannel interference. Often, the single beam parabola can satisfy the coverage requirements, but the sidelobes from this design may not adequately suppress the radiation beyond the specified coverage area. What is needed in such cases is an antenna design which has a sufficiently large aperture and a corresponding sidelobe response with the angular resolution to control its coverage beyond the specified area.

One means for achieving both the coverage and reduced sidelobe levels beyond the coverage area uses a parabola with a cluster of feeds in the focal region, producing a corresponding cluster of beams. The individual beams in this cluster are combined to produce the specified coverage area and the antenna pattern rolloff beyond the coverage area is dictated by the sidelobe response of the large aperture. The combining can be passive and implemented with fixed power dividers or active where each element has an active RF device and the collection is combined to form the coverage area. Active combining imposes amplitude and phase tracking requirements on the electronic devices, in order to maintain coverage characteristics. In addition, the coefficients that are used in the active combining can also be varied to change the antenna pattern coverage during the satellite's lifetime. This operational flexibility is obtained at the expense of increased weight and power consumption. The variation in the active combining is commanded through the satellite's TT&C subsystem. In some cases, the specified coverage area has an irregular shape and, by combining a large number of individual beams, the overall coverage can closely conform to such shapes. Typical examples of such requirements are coverage for time zones or coverage restricted, for regulatory reasons, to particular political boundaries. As the number of narrow beams increases to cover the specified area, the antenna aperture size has a corresponding increase to produce the narrow beamwidths. A better fit for the desired coverage irregularities can be achieved, but the spacecraft must accommodate this larger aperture size and more complex feed network.

Another approach to providing irregular coverage areas shapes the reflector surface.⁴⁻⁶ This approach still requires a larger aperture than would be used by a single spot beam; the required aperture size is comparable to multiple feed cluster designs so that the angular resolution and sidelobe rolloff requirements can be met. The design does simplify the feed requirements and typically a single feed horn is used. Synthesis approaches have been developed for this shaping technique. The pattern of this antenna design is fixed by the reflector surface shaping and unlike active feed combining cannot be changed by command.

Commonly in commercial system designs, the communication capacity becomes limited by the available bandwidth in the frequency allocation. The communication capacity to spot coverage areas can be increased by a factor of two when independent data signals are communicated by using orthogonal polarizations (a technique referred to as polarization reuse). Independent data streams are communicated on each polarization component; a technique used by direct broadcast services. In operation design, attention must be paid to maintaining isolation between the orthogonally polarized channels to avoid cochannel interference, as the design of both the space and user segment antennas requires high purity in the orthogonal polarizations. A typical requirement for space segment antennas is a -27 dB cross polarization level, and similar polarization purity requirements are levied on user antennas. These polarization purity requirements are specific for particular system applications. The isolation provided by orthogonal polarization depends on the polarization purity of both the incident field and the receiving antenna. Often, polarization is expressed in terms of axial ratio, defined as the ratio of the major and minor axes of the polarization ellipse. The isolation depends on the axial ratios of the incident field and receiving antenna, as well as the relative orientation of their polarization ellipses. In many cases, the axial ratio is known but the relative orientations of the polarization ellipses are generally unknown.

The statistics of the isolation⁷ have been derived assuming the axial ratio values of the incident field and the receiving antenna are known, but their polarization ellipse orientations are unknown. The unknown orientations of the polarization relative to one another can have values between 0° and 180°. The statistics are derived by assuming their values are equally likely and uniformly distributed over that range of relative orientations. The minimum, maximum, mean, and rms spread of the isolation may be evaluated from the axial ratio values of the incident field and receiving antenna. The statistics are derived from the polarization efficiency. When the incident field and receiving antenna have opposite polarization senses, the polarization efficiency is the isolation; when the incident field and the receiving antenna have the same polarization sense, the polarization efficiency is the polarization mismatch loss. The polarization efficiency is given by

$$\eta_p = (1/2) + A + B \cos \Delta$$

where

$$A = \frac{2r_w r_r}{(1 + r_w^2)(1 + r_r^2)}$$

$$B = \frac{(1 - r_w^2)(1 - r_r^2)}{2(1 + r_w^2)(1 + r_r^2)}$$

and r_w and r_r are the axial ratios of the incident wave and the receiving antenna, respectively. When the incident field and the receiving handedness is the same, A is positive, and when their handedness is opposite, A is negative. The angle, Δ , is the phase difference between right- and left-handed components of the polarization ellipses and equals twice the difference in the tilt angle alignments of the ellipses. The commonly used bounds on polarization

efficiency are $(1/2) + A \pm B$. Assuming the tilt angle differences are equally likely and uniformly distributed from 0 to 180° , the first order (mean) statistics become

$$E_p = (1/2\pi) \int_0^{2\pi} \eta_p d\Delta \\ = (1/2) + A$$

When the incident field and receiving antenna have the same sense, the mean efficiency is $\geq 1/2$, and when the handedness is opposite, the efficiency is $\leq 1/2$ yielding the polarization isolation. The second order (variance) statistics become

$$V_p = (1/2\pi) \int_0^{2\pi} (\eta_p - E_p)^2 d\Delta \\ = B^2/2$$

so that the standard deviation equals $B/\sqrt{2}$. Since these statistics have a non-zero mean value, the second order statistics are generally expressed as $\pm 1\sigma$ about the mean value, also known as the rms spread about the mean. Notice that the polarization efficiency statistics are not Gaussian. The peak to peak bounds are $\pm B$ for these statistics while the rms spread is $\pm 0.707 B$. Thus, the bounds equal 1.41 times the standard deviation.

Example statistics for isolation and polarization mismatch loss in Figure 44-1 illustrate the variations, assuming an incident field with a 1 dB axial ratio and receiving antennas with axial ratio values as great as 4 dB. The isolation has a finite value even with an ideally polarized receiving antenna resulting from the cross polarization of the incident field and also has a possibility to achieve ideal cancellation when received by an orthogonal polarization, 1 dB axial ratio receiving antenna. The polarization mismatch has minimal values for the range of receiving axial ratio values and again, zero loss is probable with an ideally matched 1 dB axial ratio receiving antenna. It is also apparent these statistics do not have a Gaussian distribution. This example illustrates that achieving high values of polarization isolation require significant design attention to the polarization purity of the link antennas and minimizing depolarizing effects in the link.

Military communication systems generally have spot coverage requirements for serving military theaters and this coverage is mechanically repositioned to respond to changing geopolitical requirements. Interference threats and issues of privacy are also concerns to military systems. These concerns are addressed through spread spectrum modulation formats, error correction techniques, data interleaving, and encryption, as well as the protection that can be achieved through sidelobe control and adaptive antenna processing⁸ to negate

FIGURE 44-1 Polarization statistics (after R. B. Dybdal⁷ © IEEE 1999)

uplink interference. Sidelobe protection reduces interference power beyond the design coverage area. Adaptive processing using a cluster of uplink beams with a reflector design⁹ provides the ability to negate interference within the coverage area. Reflector antenna technology,¹⁰ for adaptive uplink antennas, is generally preferred to array technology both for performance reasons and SWaP. Rather than using a fixed combination of beams to conform to a specified coverage shape, the adaptive design provides amplitude and phase control to dynamically produce antenna pattern nulls in the direction of interference sources. Because these systems generally use spread spectrum modulation as well, for interference protection, the interference power must significantly exceed the user power if the interference is to be effective.

Adaptive antennas must:

1. Distinguish desired signals from interference
2. Respond to interference that can degrade system performance
3. Combine antenna elements with adaptive weighting circuitry to reduce interference
4. Provide a control processor to derive the adaptive weight values to satisfy an optimization criteria
5. Monitor and respond to changes in the interference.

Since spread spectrum techniques are generally used, interference is distinguished from desired signals on the basis of the spreading technique. The adaptive design is generally activated when a threshold power level is exceeded, indicating interference signals that are sufficiently strong to exceed the capabilities of other interference protection techniques. Correlation techniques are used to determine the amplitude and phase weighting of the individual beams. Iterative correlation measurements are typically processed by an algorithm based on least mean square measures. This algorithm is derived to satisfy an optimization criterion such as maximum $S/(N + I)$ or signal to noise plus interference ratio.

An interference scenario is specified to guide the adaptive antenna development and defines the number, geographic distribution, and RF performance of the interference sources. Adaptive system design¹¹ proceeds by developing a simulation program based on a candidate RF design, the RF circuitry, and the correlation and control electronics associated with the design. Two types of performance measures are required, one specifying the transient time in responding to interference initiation and the second measuring steady state performance. When nulls are produced within the coverage area, portions of the coverage area have insufficient performance to permit link closure for the users. The percent coverage area is a quantitative measure of performance and is defined as the fraction of the original design coverage area remaining after interference cancellation that permits user operation. A threshold $S/(N + I)$ is determined where acceptable communications as measured by a BER value can occur. This threshold $S/(N + I)$ level provides a means to define a coverage boundary and hence determine the percent coverage area. These measures depend on specific interference source locations. The simulation program varies the interference locations, power levels, spectral contents, and so on, as defined by the scenario in a Monte Carlo manner, in order to obtain statistical answers to the transient time and percent coverage characteristics as needed to evaluate adaptive system performance. Selected cases that are representative of the scenario are used to develop a test program, since it is impractical to test on a Monte Carlo basis. These test cases are then used to validate the simulation and the statistical measures of performance are obtained from the validated simulation.

The minimum angular separation between users and interference sources is an important parameter for adaptive uplink antenna design. Statistical answers for this parameter

can be obtained from the adaptive system simulation. The separation⁹ depends on the minimum beamwidth that can be formed by the antenna, the performance above a threshold level for a user, and the incidence angle on the earth's surface. An estimated separation distance in Figure 44-2 illustrates these factors as a function of the minimum beamwidth of the aperture and is based on aligning the antenna pattern null between the main beam and first sidelobe with the interference source. These systems, particularly at the higher EHF frequencies, are margined to maintain link availability during rain, and hence, under clear conditions, the margin can be reduced in the interest of interference negation and still maintain operation at the threshold $S/(N + I)$. Two values of antenna gain loss, 3 and 10 dB, are illustrated in Figure 44-2; if 10 dB of margin loss can be tolerated, the system can maintain threshold performance closer to the interference than if only 3 dB of margin loss can be accommodated, for example. Finally, the minimum separation differs between the subsatellite point and a lower 20° elevation angle because the beams spread further over the earth's surface at the elevation angles. These values provide a first order estimate of the required aperture size for meeting the desired angular resolution between users and interference, and are supported by more detailed simulation results. A further parameter of interest is the achievable amount of interference suppression. Interference cancellation is inherently a subtraction process, and the cancellation depth depends on the ability to match the amplitude and phase responses in the adaptive channels over the required bandwidth. The tolerance requirements in Figure 44-3 become increasingly stringent as the required interference suppression increases.

The protection of high data rate services¹² in a military area benefits from using a high gain space segment antenna and from the operation of EHF frequencies with wide bandwidth frequency allocations. Antenna pointing must be maintained and the attitude stability of the satellite becomes a significant contributor to the antenna pointing loss. One solution¹³ lies in actively tracking a ground beacon to maintain pointing; for this a coded beacon signal and correlation processing on the satellite can be used. This technique can also be used to reduce interference. The narrow beamwidth limits interference from ground-based sources removed from the ground terminal location. Because system transfers high data rate signals, only limited interference protection is afforded by spread spectrum modulation. Protection from interference located close to the ground terminal is provided by the narrow beamwidth.

FIGURE 44-2 Interference/User angular separation (after K. M. Soo Hoo and R. B. Dybdal⁹ © IEEE 1989)

FIGURE 44-3 Amplitude and phase tolerance for adaptive antennas

Additional protection can be obtained by offsetting the satellite antenna from the ground terminal in a direction away from the interference source, as illustrated in Figure 44-4. The ratio of the signal to interference power increases from R to R' as indicated as the beam is repositioned, with some loss in the received S/N . Because a significant rain margin is typically required for link availability, some loss in peak gain can generally be sacrificed in order to gain protection from interference close to the ground terminal. As the beam

FIGURE 44-4 Adaptive beam repositioning illustration (after R. B. Dybdal and S. J. Curry¹³
© IEEE 1996)

FIGURE 44-5 Margin loss with beam repositioning (after R. B. Dybdal and S. J. Curry¹³ © IEEE 1996)

is offset from the ground terminal away from the interference source, the interference is reduced more than the desired signal because of the increased slope of the antenna pattern. As the signal margin permits, it is desirable to offset the narrow beam in order to align the null between the main beam and the first sidelobe with the interference source to improve the $S/(N + I)$. The required margin is shown in Figure 44-5 as a function of the angular separation between the user and interference source.

The implementation of adaptive beam repositioning follows the functional diagram in Figure 44-6. The desired signal is accompanied by a pseudo-random code for tracking purposes. The correlation of the data (Σ channel) and the tracking (Δ channel) signals produces outputs for tracking that are not affected by interference, because the interference signal is not correlated with the coded desired signal. Thus, independent of fluctuations in the desired received signal level that may result from weather events, the desired signal location is always determined. When interference is present, the cross correlation of the data

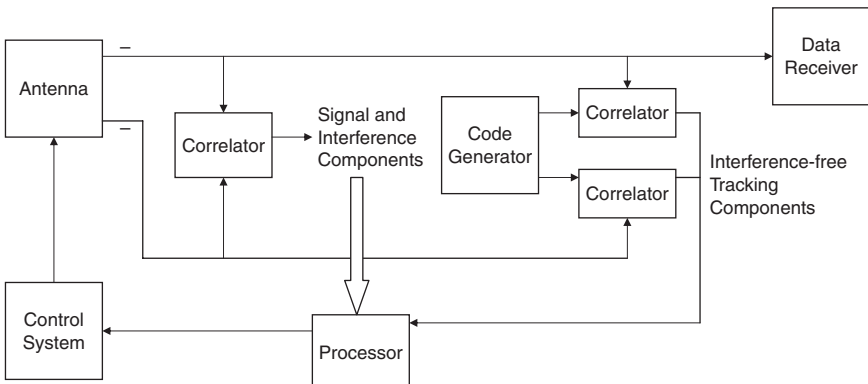

FIGURE 44-6 Functional diagram of adaptive beam repositioning (after R. B. Dybdal and S. J. Curry¹³ © IEEE 1996)

and tracking channels contains components that include both the desired signal and interference; additionally, power meters on the data and tracking channels can also indicate interference initiation. The cross correlation output level indicates the interference strength and open loop commands can be initiated to reduce the interference as indicated in the cross correlation output. During such commanding, the desired signal level in both the data and tracking channels can be monitored independent of the interference levels, and the signal reduction relative to the margin and the signal growth in the tracking channel can be observed.

Antennas for spot beam applications are typically reflector technology, since a limited field of view is required and reflector antennas have attractive SWaP. In many cases, the number of antennas that can be used is limited by the available space on the satellite. One approach¹⁴ for systems using multiple frequency bands integrated several such bands into the same aperture to provide more compact designs. This design example provides both shaped and multiple beam capabilities. In many cases, frequency selective surface technology can be used to isolate frequency bands in multiple frequency designs. More commonly, the coverage requirements must be maintained for both the uplink and downlink services that use different frequency bands, the required aperture sizes for the uplink and downlink antennas differ, and separate uplink and downlink antennas are often used to maintain the same coverage characteristics at both frequencies to reduce design complexity.

Multiple Beam Antennas

In many applications, the system design requires covering large portions of the field of view with high G/T and ERP beams for link closure reasons and/or achieving greater data capacity than the frequency allocation can support, if a single coverage beam is used. Multiple beam antenna technology provides the means to meet these objectives for such applications. The field of view is served by a collection of beams where the narrow antenna beamwidth is used to meet G/T and ERP requirements. Isolation between individual beams permits frequency subbands to be reused in separated coverage areas and this frequency reuse increases the system data capacity.

Multiple beam antennas typically use reflector antennas with a cluster of feed elements in the focal region to generated independent beams in different directions. The beams are arranged on an equilateral triangular grid. Commonly, a central beam is surrounded by a ring of six feeds surrounded again by a ring of 12 feeds, then by a ring of 18 feeds, and so on. This results in the sequence, 7, 19, 37, 61, 91, ... and so on for the number of beams to service a coverage area. Figure 44-7 illustrates an example beam pattern for 91 beams. The required number of beams greatly increases as the beamwidth of the individual beam decreases, and the peak gain for each beam also increases. Figure 44-8 illustrates a typical variation of these parameters for the complete field of view coverage of geosynchronous satellites, along with the required aperture size at selected frequencies. The required aperture size variation is also indicated in this figure for selected frequencies. As the beamwidth of the individual beams becomes narrower, not only is the system complexity increased by the number of beams, at lower frequencies, deployment of the reflector surface is also required at lower operating frequencies.

FIGURE 44-7 Multiple beam arrangement for 91 beams

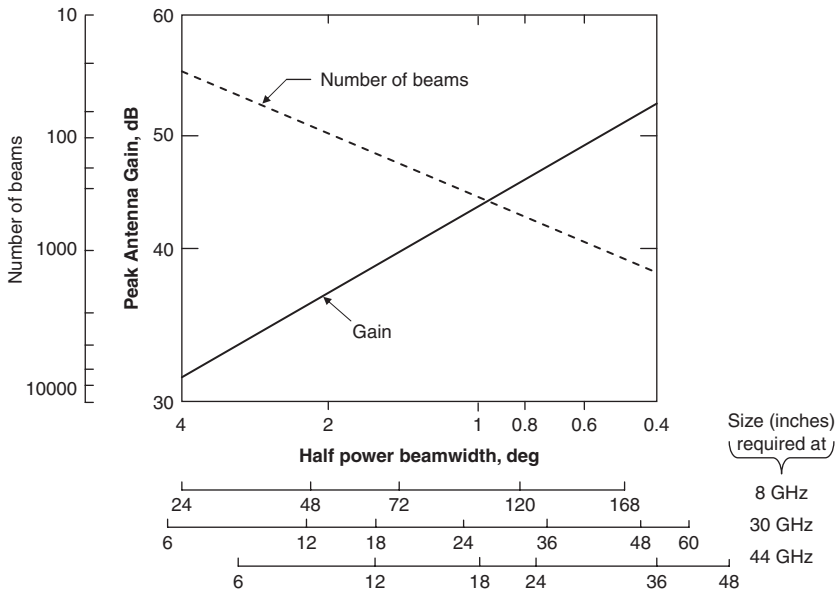

FIGURE 44-8 Multiple beam parameters

A design conflict¹⁵ results between the desire for beams with low sidelobes to isolate beam positions and the desire for the beams to crossover at a high pattern level to maximize the minimum gain within the coverage area. Reduced sidelobe levels require an aperture distribution with amplitude tapering that in turn requires directive antenna feeds. However, the antenna feed size is limited by the inability for the antenna feeds to physically overlap. Two different approaches have been investigated for addressing this conflict between beam overlap and sidelobe levels. One approach¹⁶ defocuses the feed cluster and under-illuminates the reflector. A second approach¹⁷ develops low sidelobes by combining a feed with a weighted sum of the six adjacent feeds, which results in a complex beamformer. The scan performance of reflector antennas¹⁸ is limited by phase aberrations for feed positions removed from the reflector's focal point. Reflectors with a long f/D ratio and dual reflector designs benefiting from the magnification ratio are means for reducing the phase aberrations and producing high quality beams over a field of view.

Multiple beams commonly use frequency reuse techniques to extend system capacity. Frequency reuse imposes isolation requirements between beam positions that share a common frequency subband. The isolation between beam positions depends on the sidelobe response of the closest beams sharing the same subband. The required isolation depends on the susceptibility of the modulation to cochannel interference and the dynamic range of the users. In practice, these two factors are used to devise a frequency reuse plan defining the subband assignments to individual beams within the multiple beam collection. Since the beams are typically arranged on an equilateral triangular grid, the minimum number of subbands to avoid the same subband in adjacent beam is three. More commonly, a frequency reuse plan based on seven frequency subbands is selected to provide adequate isolation.

Multiple beam antennas can also be used in a limited portion of the earth's field of view¹⁹ to provide high data rate, high capability communications to a limited geographical area. As the individual beamwidths of the design become narrower, their width can become

comparable to the attitude stability of the spacecraft. In such cases, actively tracking ground beacons²⁰ can be used to maintain beam pointing. Such designs are attractive for military communications to theater operations. Not only are the high data capacity advantages provided by such designs, protection from interference is afforded by the narrow beamwidths and the effectiveness such interference is limited to a few beam positions.

In multiple beam operation, capacity demands are often not uniformly distributed over the collection of beams and can dynamically vary. One approach²¹ to provide high capacity in a limited number of beam positions would use a frequency reuse plan providing a basic capacity to the individual beams within the collection along with separate frequency subbands that can be switched to beam positions with higher capacity demands as required. Because these frequency subbands do not overlap the subbands in the basic service, the necessary isolation is provided. As memory technology expands and becomes space qualified, storing non-time critical data for transmission at a later time when capacity is available may also provide a means to lower the peak capacity requirements. While such approaches add flexibility and capacity to the system design, they also add complexity and the need for network control.

The preponderance of multiple antenna technology for GEO satellites is reflector designs because the earth subtends a relatively small field of view. When multiple beam designs are used at lower microwave frequencies, the required aperture size requires the use of deployable reflector technology. When multiple beam designs are used for satellites in lower LEO orbits, beam generation over a wider field of view is required. For such applications, array technology is used to produce relatively broad beams over the larger field of view. Such array designs²²⁻²³ have a manageable number of elements, whereas applying array technology at the higher GEO altitudes results in an excessive number of elements. Array designs require active receive and transmit elements to offset losses in their corporate feed networks resulting in a prime power penalty. Transmit arrays require attention to the transmitter operating points because intermodulation of carrier components when multiple beams are routed through the transmit modules degrade performance. Failure of active elements has a minor effect on the peak gain levels of array antennas, but the sidelobe response²⁴ does not have the same graceful degradation. If a small number of elements fail, rephasing can maintain sidelobe performance, but as the number of failed elements increase, rephasing cannot maintain sidelobe performance. Further attention is also required to devise on-orbit calibration techniques to identify and verify array element excitation errors. Design attention is required to establish performance projected to the end-of-life levels accounting for the anticipated number of element failures. Further, the array elements must be commanded to produce the required beam patterns and beam steering, and such control also incurs additional weight and power impacts. As digital technology matures, digital beamforming techniques will evolve. Development experience for this technology²⁵ is described for a multiple beam design, albeit for a mobile user terminal.

Crosslink Antennas

Communication links between satellites provide a means to relay information between system users that are not in the field of view of a single satellite, and are referred to as *crosslinks*. Crosslinks permit global linkage of users without using a relay through ground stations. The antennas used in crosslinks are point-to-point configurations in contrast to other spacecraft antennas that serve a coverage area on the earth's surface.

Antennas for crosslink applications are typically reflector designs mechanically pointed at the corresponding antennas on other satellites within the constellation. Such designs use antenna tracking²⁶ to maintain beam alignment with their destination satellite. For GEO satellites, the antenna must have the capability to track other satellites within the equatorial plane and accommodate the elevation variations that depend on how well the satellite is stationkept; at GEO, orbital perturbations result in satellites following a figure eight motion

about the equatorial plane over a 24-hour period. Spacecraft thrusters control the size of this figure eight maintaining the satellite's position on the equatorial plane. This adjustment of the satellite's orbit is referred to as stationkeeping. Crosslink antennas, therefore, are required to provide principally azimuth positioning to link with different satellites within the constellation and a smaller elevation positioning requirement dependent on how well the satellites maintain stationkeeping.

Crosslink systems often operate at 60 GHz where wide bandwidth allocations exist to transfer high data rates. The 60 GHz frequency range corresponds to the resonances of oxygen absorption spectra^{27,28} and provides broad bandwidth, high level attenuation of terrestrial signals. Thus, operation at 60 GHz also isolates the crosslinks from ground based interference.²⁹ Satellite crosslinks often transfer high data rate data between satellites. The EHF operation also results in antennas with a compact physical size—an important factor in satellite systems. These antennas achieve high gain performance and their corresponding narrow beamwidths require antenna tracking capabilities to maintain beam alignment with adjacent satellites.

TT&C Antennas

All satellites require a TT&C subsystem to provide information on the satellite's orbital position, monitor the health and status of the spacecraft, and to inject and validate commands for the satellite's operation. The spacecraft's TT&C subsystem communicates to a dedicated mission control station that maintains the operation of the satellite. Antenna systems for TT&C applications require two types of antenna coverage. During launch operations, complete spherical coverage is required so if the spacecraft begins to tumble, a command can be injected to attempt to control the spacecraft independent of the satellite's orientation. Once on orbit, an earth coverage pattern is required so that alternative mission control stations can perform the TT&C operations. However, because the data rate requirements for TT&C applications are modest and ground terminal designs with ample performance can be configured, many satellite programs simply use the earth facing hemispheric coverage antenna to reduce design complexity.

Two antennas that provide hemispheric coverage are typically used to satisfy the spherical coverage requirement. One antenna covers the forward hemisphere and is also used in the on orbit position, and the second covers the rear hemisphere. During launch operations, the antenna with the higher signal power is used. Attempting to coherently combine the two antennas results in significant pattern ripple where their patterns overlap because of the physical separation between the two antennas. These broad hemispheric coverage requirements have the generic problem of isolating the TT&C antenna from the satellite blockage and scattering. Such systems typically operate at lower microwave frequencies with a relatively long wavelength. The long wavelength further limits the ability to control antenna backlobes that interact with the satellite's structure with a compact design. The receive and transmit frequencies can also be a relatively large percentage bandwidth. To satisfy these diverse requirements, generally a frequency independent antenna is used and the antennas are mounted on booms to provide a clear field of view and to minimize the interactions with the spacecraft structure. Design attention to reducing the backlobes of TT&C antennas³⁰ and the development of analysis and measurement techniques for projecting and verifying the performance of TT&C antennas in the presence of the spacecraft structure would be useful capabilities.

Remote Sensing Antennas

Remote sensing satellites can use RF sensors³¹ to collect data. Two types of sensors have been developed: active or radar sensors and passive or radiometric sensors. Such sensors

are used in low orbiting satellites for global coverage characteristics and high resolution of surface features.

Radar sensors³² for remote sensing applications use array antennas operated in a synthetic aperture mode. An example design is the SIR-C radar flown on the space shuttle. This design uses two active array antennas, one operating a L-band and the other operating at C-band. Additionally, the program also uses an X-band slotted waveguide array. Such a design approach allows the evaluation of image quality at different frequencies. The arrays are also capable of operation using orthogonally polarized beams so that the polarization contrast can be judged. Like other spaceborne antennas, SWaP has a significant impact on the design. Further development of this technology can be anticipated in the future; as the remote sensing data gathered by this effort provides a proof of concept and an example data base with which to refine estimates of remote sensing extraction algorithms.

Two categories of radiometric designs are used in passive RF remote sensing applications.³³ One category uses narrow antenna beamwidths that are mechanically scanned to obtain data across a terrain swath beneath the satellite. The beam is scanned across the swath and the spacecraft orbital trajectory fills in the swath in subsequent scans. A portion of this scan looks at reference temperatures to calibrate the radiometer, a “hot” reference is provided by an ambient temperature and a “cold” reference is provided by the deep space background with a 3 K temperature.

Radiometric sensors receive data from the emission of the surfaces and contrasts of the surface emission properties allow the generation of an image. Such sensors normally look obliquely at the earth’s surface and the combination of the polarization dependence of the surface emissivity and multiple frequency data allows estimates of remote sensing parameters. The resolution of the emission temperatures depends on the ΔT of the radiometer that is defined by

$$\Delta T = T_s / (B\tau)^{1/2}$$

where T_s is the total system temperature, B is the IF bandwidth, and τ is the integration time. Physically ΔT is the standard deviation of the output temperature. For specification purposes of the radiometric sensitivity, a 290 K antenna temperature is used as a reference value and the integration time is 1 second. In practice, the resolution of the emission temperature depends on the integration time at each pixel (picture element). Design attention to minimizing RF loss and to utilizing low noise amplifiers is necessary to achieve good resolution in emission temperature as measured by a low ΔT .

The second performance parameter for radiometric system concerns the spatial resolution of the design. The spatial resolution is measured by the antenna’s solid beam efficiency. The solid beam efficiency is the ratio of the integrated antenna pattern over a specified solid angle for a particular polarization to the total integrated pattern for all polarizations. The sense of this definition is to examine the collected emission over a specified solid angle in comparison to the emission collected over the entire pattern. The solid beam efficiency measured the ability of the antenna to respond to its intended pixel coverage and not the surrounding radiometric background. High solid beam efficiency values require both high polarization purity and attention to reducing the antenna sidelobes by tapering the aperture’s amplitude distribution and maintaining a uniform phase distribution.

A second type of radiometric is referred to as a *sounder*, which uses simple broad coverage antennas. Sounders use frequencies corresponding to the molecular absorption frequencies. The center frequency corresponds to the peak absorption value and several IF bandwidths are used. As the IF bandwidth increases, the absorption at the band edges decreases. Using different IF bandwidths results in a height profile of the radiometric response results, meaning that wider IF bandwidths respond to absorption characteristics at lower altitude levels.

44.3 USER SEGMENT ANTENNAS

Like the space segment, the user segment of satellite systems has a wide array of antenna technology. The early user segments required relatively large ground terminal antennas because of the limited satellite performance, the broad coverage space segment antennas necessitated by uncertain satellite attitudes, and the high receiver noise temperatures of early designs. The large ground terminals generally served as a hub for distribution by terrestrial segments. Improvements in satellite capabilities and user technology availability results in satellite services presently being extended to the personal level with examples being cost effective handheld GPS receivers and direct broadcast services. Such trends can be anticipated to continue in the future. These trends prompt the development of cost effective designs to control total system costs and appeal to individual users. These trends also pose interesting challenges in testing on a production level.

At a system level, like the space segment antennas, the user segment antennas have G/T and ERP requirements to meet the specified link performance. Unlike the space segment antennas, which are required to meet G/T and ERP performance over a specified coverage area, the user segments must align their main beams with the satellite, so that the peak antenna gain values burdened with the antenna pointing loss determines the link performance.

While the user segment exploits a diversity of antenna technology, common issues exist. These issues include antenna temperature characterization, interference protection, duplexing, and production issues.

Antenna Temperature

Unlike space segment antennas, the antenna temperature for the user segment depends on the propagation path and its loss. Propagation loss, in common with ohmic loss in RF circuitry and antenna feeds, both attenuates the received signal and generates additional noise. In both cases, the increased noise is a consequence of blackbody radiation. At microwave frequencies, propagation loss depends on the water vapor and oxygen absorption characteristics in the atmosphere.³⁴ At higher EHF frequencies, the propagation loss is weather dependent.³⁵⁻³⁶ The principal impact results from raindrops within the propagation path, because their size becomes comparable to the EHF wavelength. The loss results from the absorption cross section of rain drops. Other hydrometeors, such as fog, are smaller, and then there are ice crystals and snow, which are both even smaller and have reduced absorption. Statistical projections of path loss at EHF frequencies are commonly made using climate models of the geographical locations based on cumulative rainfall rate statistics. The specific attenuation (dB/km) of the path has an aR^b dependence,³⁷ where R is the rain rate (mm/hr), and the a and b constants depend on the operating frequency. Using the cumulative rain rate statistics and a freezing height, above which rain drops become ice crystals with little loss, projections can be made of link availability. In addition to loss in the propagation path, antennas enclosed by radomes also suffer performance degradation when radome surfaces are wet³⁸⁻³⁹ and must be factored into projections of link availability. These link availability statistics are stationary only in a long-term multi-year sense—for example, some years are drier than others. While such analyses provide a basis of establishing rain margin requirements, the availability of a given system at a particular time is subject to meteorological conditions prevailing at that time.

Like other loss components, such as ohmic loss, the propagation loss not only reduces the signal level but also increases the system noise level. The increase in the system noise temperature for user antenna contrasts with uplink satellite receiving antennas where the 290 K earth background antenna is not increased by noise contributions from loss. Practical antenna systems likewise contain ohmic loss and other necessary components such as filters

unavoidably contain loss. Today's availability of low noise receiver technology often results in receiver noise temperatures that are less than the total antenna noise temperature. Because the user's G/T dictates the received signal sensitivity, attention must be paid to the total system noise temperature T that equals the sum of the antenna temperature and the receiver temperature. In the past, the achievable receiver noise temperature greatly exceeded the antenna noise temperature and consequently, simply reducing the receiver noise temperature almost directly reduced the system noise temperature. This is not the case with available low noise receiver technology.

Antenna temperature for user systems depends not only on the operating frequency but also the propagation path. The loss increases as the elevation angle to the satellite decreases, because the path traveling through atmosphere where loss occurs is longer. The antenna temperature depends on the emission temperature of the environment surrounding the antenna. Finally, practical antennas are not ideally lossless and matched to the receiver input impedance, and corrections must be made for those effects.

The total system noise temperature must be referenced to a specified elevation angle because the antenna temperature depends on the path length through the atmospheric loss. At low elevation angles, the antennas are limited by obscura from natural terrain and man-made structures specific to the site. As a consequence, a moderate elevation angle, for example, 20° , is often selected for specification purposes. Such a choice allows compliance measurements without the measurement uncertainties at the lower elevation angles. In practice, however, the elevation angles used operationally must be addressed and at the lower elevation angles, the antenna temperature can depend on the azimuth angle because of obscura; in such cases, blockage may be a further problem. These concerns must be addressed when a site selection is made for user antennas.

The antenna and receiver noise temperatures comprise the total system noise temperature. The user terminal's G/T requires determining the antenna gain and the system noise temperature at the same terminal reference plane. In many cases, the input to the receiver's LNA is a convenient terminal plane because the receiver temperature can be measured at the LNA input, using standard Y factor hot/cold load measurements. Additionally in many cases, the LNA input is convenient to terminate in a matched load to provide a stable noise temperature value for measuring the antenna temperature.

The total system temperature for a terminal is comprised of the antenna temperature at the reference plane and the receiver noise temperature at the reference plane. The system temperature at this reference plane⁴⁰ T_s is given by

$$T_s = (1 - \Gamma^2) [T_{\text{ant}}L + 290(1 - L)] + T_{\text{rec}}$$

where Γ is the magnitude of the reflection coefficient (for well matched systems, $(1 - \Gamma^2)$ is very close to 1), T_{ant} is the antenna temperature, L is the loss, and T_{rec} is the receiver noise temperature. Physically, the noise power received by a lossless antenna is reduced by that loss but the noise generated by the loss must be included. If significant impedance mismatch loss $(1 - \Gamma^2)$ exists, the noise incident on the LNA must be reduced by the mismatch loss.

The antenna temperature can be established through measurement. If such measurements are not available, the antenna temperature of a lossless antenna can be calculated from the pattern characteristics and the emission background levels. Such a procedure has been done⁴¹ and verified by measurement of a Cassegrain reflector antenna, as shown in Figure 44-9. The antenna temperature differs from the sky temperature values,³⁴ particularly at the lower elevation (high zenith) angles, because of ground emission coupling through the antenna sidelobes. The sky temperature values correspond to the noise received by an ideally lossless antenna with an infinitely small beamwidth. The measured and calcu-

FIGURE 44-9 Calculated and measured antenna temperature (after K. M. Lambert and R. C. Rudduck⁴¹ © *Radio Science* 1992)

lated antenna temperatures were performed using very low loss antenna. Practical antenna systems must be corrected for loss in filters and other RF components needed for system operation. Often, data for only the antenna is available and when determining the G/T the gain must be reduced by the RF loss and the antenna temperature likewise compensated by the RF loss as indicated.

Interference Issues

The utilization of satellite and terrestrial systems has greatly expanded in recent years, a trend that can be expected to continue. As a consequence, interference between systems increases both as a possibility and as a concern. Two distinct types of interference problems exist. One type results from interference between satellite programs and the second type is interference to/from user terminals and other terrestrial systems.

The dense population of satellites in geostationary orbits prompted concerns of interference between users and satellites, for example, user illumination of unintended satellites create interference at the unintended satellite and likewise, user reception, from not only the desired satellite but also unintended satellites, creates interference. Accordingly, constraints were placed on the sidelobe envelope for user antennas, and are commonly followed by antenna vendors. A typical envelope requirement⁴² is

$$\begin{aligned}
 G &= 32 - 25 \log \theta, \text{ dBi}, 1^\circ < \theta < 48^\circ \\
 &= -10 \text{ dBi}, 48^\circ < \theta < 180^\circ \\
 &\text{for } D/\lambda > 100
 \end{aligned}$$

and

$$\begin{aligned} G &= 52 - 10 \log (D/\lambda) - 25 \log \theta, \text{ dBi}, (100D/\lambda)^\circ < \theta < 48^\circ \\ &= 10 - 10 \log (D/\lambda), \text{ dBi}, 48^\circ < \theta < 180^\circ \\ &\text{for } D/\lambda < 100 \end{aligned}$$

where D/λ is the antenna aperture size in wavelengths and θ is measured from the antenna's boresight axis.

The spectral crowding at the lower microwave frequencies results in potential interference between user satellite antennas and other terrestrial antennas. While frequency regulations are imposed to isolate users, the proximity of terrestrial systems to users is much closer than satellites. While emissions from terrestrial users are isolated in frequency, the higher power levels from nearby terrestrial systems can degrade user systems by saturating the receiver at out-of-band frequencies. Such interference is unintentional. Military systems also have concerns of intentional interference or jamming, and have developed effective means for negating such interference.

User systems can be protected from interference by a variety of techniques. In many cases, site alternatives can be effective in avoiding interference; and spectrum analyzer instrumentation⁴³ is commonly used to determine potential interference sources at a given site. Another operational alternative that can be effective is determining the feasibility of restrictions on the operational use of the interference source (sector blanking for nearby radars, for example), not transmitting in a limited angular sector, is sometimes effective in controlling interference from radar systems.

In addition to such operational alternatives, four basic techniques may be applied to user systems to negate interference. The gain and filtering distribution of the receiver should be examined to filter interference so that the receiver remains in its linear operating range is a basic technique that should be addressed in the terminal design. Spread spectrum modulation and data interleaving are commonly used to dilute and distribute the effects of interference.

In addition to the receiver architecture and the modulation alternatives, two antenna techniques are also available to negate interference. One technique is the passive control of antenna sidelobes.⁴⁴⁻⁴⁶ In many cases, the interference arrives through the antenna sidelobes. Because the radiation mechanisms for the wide angle sidelobes do not contribute to the aperture distribution, these sidelobe control techniques can be employed without significantly impacting the antenna's main beam gain performance. A second technique is the adaptive cancellation of interference. For user antennas, adaptive sidelobe cancellation⁴⁷⁻⁴⁸ is an appropriate design choice. In this design, auxiliary antenna elements with gain levels that exceed the sidelobe gain are used to sample the interference power. Correlation of the auxiliary antenna elements with the main antenna response is used as a means to dynamically determine the adaptive weight settings. Since the main antenna output is made up of both desired signal and interference components, whereas the auxiliary antenna elements have predominantly interference. The control circuitry for the adaptive weight values is based on minimizing the correlation of the main antenna and the auxiliary antenna elements. The gain of the auxiliary antenna elements and the circuitry is purposely constrained to avoid canceling the main beam of the main antenna containing the desired signal power. One problem with such designs is that the frequency response of the main antenna does not match the response of the auxiliary antenna elements nor are their phase centers coincident. Effective interference over a bandwidth requires equalization of the responses of the main and auxiliary antennas. The differences in these antenna responses have been examined⁴⁹ and generally, an adaptive transversal equalizer is used to equalize these antenna responses. The number of taps and the required tap spacings for the adaptive transversal filter design have been derived for a specified interference cancellation performance.

44.4 SATELLITE ANTENNA TESTING

Spacecraft antennas require rigorous RF and environmental testing because of the reliability needed to perform over their long operational lifetimes. While antenna measurement techniques are well established,⁵⁰ spacecraft antennas have some specialized test requirements that are not commonly used in other applications. User segment antennas also pose antenna test challenges, particularly testing in a production basis as services are extended to a personal level. Larger ground terminals also present test challenges, particularly from excessive far field requirements. Radio source techniques are commonly used in such situations.

Spacecraft Antenna Test Phases

There are three distinct phases in testing spacecraft antennas, as illustrated in Figure 44-10. The first phase is developmental testing, where the compliance of candidate design(s) with system requirements are established; requirements include both RF performance and testing for compatibility with the launch and on-orbit environments. The second phase is qualification testing, which verifies that the flight hardware conforms to the RF performance established during development testing and that the flight hardware can withstand launch and on-orbit environments. The third phase is on-orbit testing that has the objectives of establishing compliance with system specifications, providing baseline data for subsequent trending, and complementing satellite telemetry to diagnose on-orbit performance shortcomings that may arise during the satellite's lifetime.

Each test phase differs in both scope and requirements. Additionally, the test parameters in each of these phases evolve from component level parameters in the development phase to system level parameters used in the on-orbit phase. Detailed testing can be conducted using general purpose instrumentation and facilities in the development phase, while specialized ground terminals that are generally part of the program's mission control terminal are required for on-orbit testing and the satellite in its orbital location rather than in a test facility.

Development Testing

Development testing can generally be accomplished with general purpose test facilities and instrumentation, and it uses engineering model hardware. Much of the RF testing is

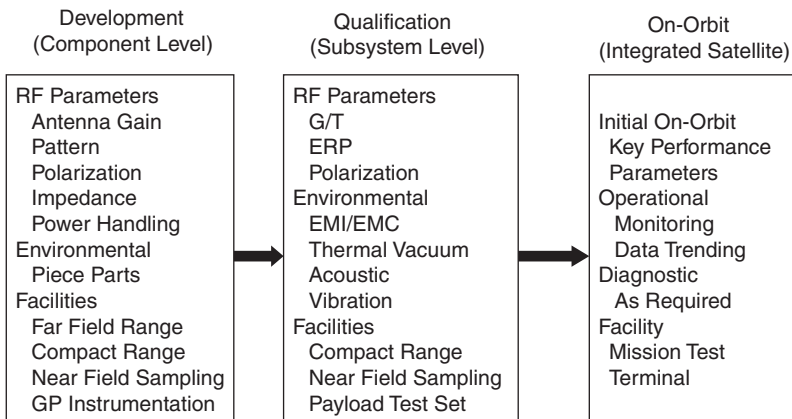

FIGURE 44-10 Satellite test phases

conducted at the component level and detailed measurements on the engineering model are performed. Typically, the projected performance of the antenna is evaluated using analytic codes; agreement between these analytic projections and engineering model measurements provides confidence in the results. In some cases, more than one candidate design exists at the initiation of the program, and design tradeoffs are conducted during the development phase to select a final design. In other cases, requirements for other issues such as electromagnetic interference/electromagnetic compatibility (EMI/EMC) result in test requirements at out-of-band frequencies or in specialized models needed to emulate the spacecraft structure and/or payload antennas. Examination of the candidate designs for identifying potential workmanship issues is a prudent practice for assisting in flight hardware testing. Finally, present testing is often conducted using software test procedures and experience with these procedures provides benefits for subsequent qualification testing.

At the initiation of the program, a requirements verification matrix is generally constructed flowing down the specific antenna requirements from the system specification and identifying how these requirements are to be verified at each phase of the testing. Attention to the test requirements identified in this matrix is necessary early in the program's initiation in order to identify instrumentation and facility needs, as well as necessary test points within the antenna hardware. In some cases, development is required to conduct the qualification testing. Additionally, the requirements verification matrix helps to identify the scope of the test procedures and planning. Such steps are necessary in determining program needs and schedule requirements.

Qualification Testing

Flight hardware must be space qualified to demonstrate its capability for properly performing over its orbital lifetime. Qualification testing is performed on flight hardware that must be properly protected. RF testing is therefore performed in protected test facilities to avoid damage to flight hardware. Compact ranges and near field sampling facilities are in common use for this testing. Qualification testing also requires demonstrating that the flight hardware is capable of withstanding launch and on-orbit environments. These environments typically require acoustic, thermal and vacuum, and vibration testing. Such testing is often performed at a more stringent level, on engineering development hardware that emulates the flight hardware in order to determine design margins. The flight hardware is then tested at a somewhat lower qualification level following environmental values anticipated during launch and on-orbit operations. One of the important features of the qualification level testing is the identification of workmanship errors (such as cable integrity) and specific payload assembly errors that would limit on-orbit reliability. Such testing benefits from identification of potential workmanship errors in the development test phase.

Qualification testing is generally conducted at the component, subsystem, and integrated spacecraft levels. The RF testing is distributed over these levels with attention at the component and subsystem levels using common antenna measurement parameters and at the integrated spacecraft level, transitioning to system level parameters such as ERP, G/T , and BER values for the overall transponder. Redundant electronics paths are also evaluated in this testing, but this involves not just the performance of these redundant paths but the command paths needed to select the redundant components as well. Testing of this type particularly within the test environments precludes the normal RF test facilities. Testing in these environments often involves "hat couplers" that are comprised of RF sealed enclosures containing RF probes to allow test signal injection and reception. Such hat couplers permit testing within environmental facilities such as thermal vacuum chambers that preclude conventional test facilities. The hat coupler designs are specific to the antenna technology used, and require development and calibration prior to their use in

qualification testing. Likewise, testing to evaluate both the antennas and payload electronics is typically desired after shipment to launch sites and spacecraft assembly areas. The development of suitably portable RF test facilities would benefit testing in these areas, and as the spacecraft antennas become more complex and integrated with RF electronics, test requirements for the assembled payload will evolve from a “light bulb” evaluation of the health to more insightful evaluations of the antenna systems functionality.

The evaluation of EMI/EMC compliance is a spacecraft-wide issue. At the initiation of the spacecraft design, the frequency plans should be examined to avoid conflicts. All frequency components and their harmonics need to be examined and the coupling between these components and other potentially susceptible components throughout the entire spacecraft need to be examined. Estimates of these potential coupling paths need to be examined and those paths with limited susceptibility margins need to be identified and verified by test. It is not unusual for the number of potential coupling paths to exceed 10,000, and after examination the number of paths with limited margin will be substantially less. The spacecraft antennas are generally well isolated from the majority of the payload electronics and their coupling can be estimated and/or augmented by measurement particularly at out-of-band frequencies that are not normally characterized. Some of the coupling paths can be compromised by workmanship errors and call for examination of the flight hardware. Some EMI/EMC testing is performed at the component and subsystem levels. Generally, the assembled flight hardware is tested in an EMI/EMC facility to assure compliance. The natural background levels within these facilities needs to be established first, and these levels compared with the required sensitivities. Emissions from the test equipment and any anticipated leakage of the cabling that supports the testing bears scrutiny prior to the spacecraft examination. The EMI/EMC testing should concentrate on those paths previously identified as well as a more general survey of the emissions. Measurements of potential emissions are often sniffed using waveguide probes at microwave frequencies to detect leakage components that could degrade system operation.

Satellite qualification testing includes some specialized evaluations that are not normally a concern in other antenna applications. One concern for spacecraft transmitting antennas is multipaction⁵¹ that results in vacuum conditions when sufficient electrical field strength exists to strip electrons from metallic surfaces. A resonant condition produces an electron avalanche damaging the surfaces. Multipaction susceptibility depends on the product of gap size between surfaces and the RF frequency the spacing between surfaces, vacuum conditions, and the secondary electron emission properties of the materials as well as the RF power levels. Multipaction generally occurs at the smallest separation between surfaces in components. Testing components with potential multipaction concerns is generally performed under vacuum conditions, and since a 6 dB margin in power handling capability is commonly used, the transmitter power for such testing is accordingly higher than that used operationally.

Space segment antennas serve a variety of users and thus typically have modulations with multiple carrier components. In addition to transmitter linearity requirements, concerns also exist regarding the linearity of the antennas and RF components, particularly in the case where the same antenna aperture is used to both receive and transmit; the receive and transmit bandwidths are isolated by the filtering in a diplexer. Mechanical joints within the RF and antenna components can exhibit nonlinear behavior creating intermodulation products that interfere with signal reception. This phenomenon is referred to as (passive intermodulation) PIM.⁵²⁻⁵³ Electroforming techniques can minimize the required number of joints in RF components and reduce potential PIM levels. The generation of PIM products is often determined by injecting two CW tones into the components. The frequencies are chosen to produce PIM products within the received passband. An examination of various orders of potential PIM products is typically performed to understand what problems can arise and guide the evaluation of potential PIM generation.

Another concern for satellite antennas is the potential of electrostatic discharge (ESD), which can damage or interfere with RF electronics. Satellite antennas are generally protected from the on-orbit thermal extremes by thermal covers. Such covers necessarily must have low insertion loss and are typically dielectric materials. On-orbit, such covers can accumulate sufficient charge to produce a discharge⁵⁴⁻⁵⁵ and while the spectra of the discharge has strong low frequency components, sufficient energy can couple into RF electronics at levels that can cause damage or interference. In other cases, the same thermal control materials are used to protect other spacecraft components such as solar arrays, and while the discharge is not associated with the antenna itself, nonetheless, spectral coupling from the discharge into the antenna must be considered to evaluate potential interference. The potential for ESD is particularly high during geomagnetic storms. Thermal covers, therefore, require sufficient conductivity in either their composition or through special ESD paints and ground paths to control the charge buildup. Generally, ESD characteristics are measured on material samples that are charged with electron beams to determine the spectral characteristics of the discharge. Such tests are often performed on samples of the materials and in some cases, on the assembled antenna to verify the integrity of the grounding paths.

A common problem involves testing antennas that have broad coverage requirements such as the hemispheric coverage required by TT&C antennas. Because these designs often use lower microwave frequencies and must be compact, isolating such antennas from the surrounding spacecraft becomes a challenge. The antenna performance on the spacecraft differs from its free space performance and the interaction between the antenna and spacecraft results in pattern ripples in the coverage area that can lead to noncompliance. Antenna backlobe reduction helps to reduce the interaction. Testing on the spacecraft has its challenges not only from the physical size of the spacecraft but also the increased far field distance requirements compared to antenna itself. Development attention to address analysis and measurement techniques for such situations is recommended.

The environmental testing on spacecraft components includes acoustic, vibration, and thermal vacuum evaluations. Such testing is performed on the antennas by themselves and repeated when the antennas are integrated with the payload. In cases where the design margins relative to the environmental tests are required, testing performed on engineering model hardware is often performed at more stringent protoqualification levels. The test levels depend on the launch vehicle characteristics and structural details of the payload and the thermal characteristics projected in orbit. These tests are useful in ascertaining workmanship defects such as cable shortfalls. Testing within the environmental facility, particularly for the assembled payload, often require an end-to-end evaluation, such as BER measurements. Since conventional antenna test facilities cannot be configured within the environmental facility, a means of injecting test signals and measuring their output is required. In some cases, test couplers are integrated into the antenna hardware for such purposes and in other cases, hat coupler are used to inject or receive test signals from the antenna. Both injection methods require attention to calibration and measurement repeatability to obtain meaningful results particularly for evaluating the noise characterization for uplink receiving antennas.

On-Orbit Testing

On-orbit testing verifies compliance with the key system level parameters for the spacecraft initially, and provides performance monitoring capabilities of the satellite over its lifetime. These measurements are at the system level, such as ERP, G/T , BER, and others. Such testing is performed with a specialized ground terminal. The requirements for these terminals include rigorous calibration and diagnostic capabilities to ensure accurate results, and other capabilities that are specific to the programs requirements. For example, systems that use

polarization reuse place stringent polarization purity requirements on the ground terminal to accurately measure the satellite's polarization isolation. Likewise, some satellite systems have requirements for antenna sidelobe control (such as isolation characteristics) between multiple beams, and the sensitivity required to verify such sidelobe requirements dictates the ground terminal aperture size to perform accurate measurements. Other monitoring requirements include the satellite user loading characteristics versus the satellite transmitter operating point to control the level of intermodulation products.

On-orbit testing requires a dedicated ground terminal to monitor the on-orbit satellite operation. Such terminals are generally a part of the program's mission control facilities. These test terminals require particular attention to calibration to obtain accurate measurements. Additionally, these terminals require effective diagnostic capabilities to assure indicated shortfalls result from the spacecraft rather than the test terminal. Generally, the performance requirements for the test terminal exceed those of the user terminals. For example, measurement of the isolation between antenna beams requires a significantly larger test terminal aperture than the data reception requirements for a user terminal.

User Antenna Testing

User antennas for satellite systems also have requirements that differ from other applications. One problem that will become more commonplace is the ability to test at production levels. This problem results as satellite services are extended more broadly at the personal level and the number of user terminals increases. Testing each individual antenna is often both cost and schedule prohibitive. One approach for testing at a production level examines those areas where workmanship shortfalls can lead to noncompliance. One example of such shortfalls is user terminals where polarization reuse is used and the polarization purity must be maintained to isolate signals on orthogonal polarizations. An example of workmanship shortfall leading to noncompliance of these isolation requirements is the failure to maintain the required mechanical tolerance in the internal antenna feed dimensions that can increase cross-polarization levels. In this case, simple mechanical tolerance testing and random RF testing can provide assurance of compliance with polarization purity requirements without testing each individual feed.

Compliance testing for user antennas is generally conducted using general purpose instrumentation and test facilities. The normal antenna characterizations of gain, polarization, bandwidth, and impedance parameters are conducted using standard measurement practices. Other requirements, such as sidelobe envelope compliance, must address the capabilities needed for the sensitivity for accurately measuring lower power levels from the sidelobes and attention to the facility multipath levels that can degrade measurement accuracies. In such cases, attention to leakage levels in the RF test instrumentation and microwave components are needed to assure the apparent sidelobe levels are from the antenna rather than leakage components. The correlation of these sidelobe responses with analytic projections of the design performance provides increased measurement credibility.

Radio Source Measurements

A measurement technique using radio sources has proved useful for characterizing the G/T of user antennas. Originally, the technique was applied to large ground terminal antennas,⁵⁶⁻⁵⁷ which have a physical size that cannot be accommodated in general purpose test facilities and which have far field distances that are excessive. Because of available low noise receivers in system use, the technique can be applied to much smaller diameter antennas⁵⁸ and, as RF electronics are integrated into the antenna design, it can provide a means of testing designs that have no convenient antenna terminals.

The measurement technique⁵⁹ consists of measuring the noise power from a radio source and measuring the cold sky background noise at the same elevation angle; the ratio of these noise power measurements is a Y factor. The noise flux densities of radio sources are very well known. For large antennas, radio sources such as Cassiopeia A are used. If the antenna does not have the sensitivity to measure the noise from these sources, the moon is commonly used. The strongest radio source is the sun, and measurements can be made on much smaller antennas using this source. The sun has some limitations. Solar flare activity results in variations in the noise flux densities, but measurements of the solar flux are made daily by a global network, so that variations in the solar flux are determined. The solar disk subtends about a $1/2^\circ$ angular width so that it does not appear to be a point source for antennas whose beamwidths approach the $1/2^\circ$ width. Techniques to correct for the angular width have been devised. However, because of solar flares, the solar flux density is not uniformly distributed over the solar disk, and experience has shown that particularly during active solar periods, measurements of antennas with beamwidths smaller than $1/2^\circ$ experience experimental results that are not always repeatable. By contrast, the correction for the angular width of the moon is not limited because the lunar flux results from solar reflection and does not have the variability of flare activity. The G/T from these measurements is derived from

$$G/T = 8\pi k (Y - 1)/S\lambda^2$$

where k is Boltzmann's constant, Y is the noise power ratio of antenna pointed at the source and the antenna pointed at a cold sky background, S is the radio source flux density, and λ is the wavelength.

In practice, the G/T is referenced to a specified elevation angle because of the antenna noise temperature dependence on elevation angle. Since the radio source is generally at a different elevation angle, the G/T must be compensated for the differences in the cold sky noise measurement where the source is located, as well as the cold sky noise measurement at the specified elevation angle. The radio source flux density does not include the propagation loss of the atmospheric path and compensation for this path loss must be made. At microwave frequencies, the path loss can be estimated, but at the higher EHF frequencies, the path loss depends on weather conditions. A separate measurement of the antenna temperature versus elevation angle is made as a means of determining weather effects at the time of the G/T measurement. The antenna temperature can be measured from the ratio of the noise powers when the receiver is terminated by an ambient load and when the receiver is terminated by the antenna pointed at the desired elevation angle. This ratio equals the sum of the ambient and receiver noise temperatures divided by the sum of the antenna and receiver noise temperatures. The antenna temperature is determined from this ratio and the receiver noise temperature. The G/T measurements need to assure the antenna is properly pointed at the noise source and that the measurements are not degraded by interference.

In many cases, the antenna gain rather than the G/T is required. The total system temperature is the sum of the antenna noise temperature and the receiver noise temperature. The antenna temperature can be measured and the receiver noise temperature is typically measured using the standard Y factor technique with hot and cold loads. The antenna gain is determined from the product of the measured G/T and the system noise temperature comprised of the sum of the antenna temperature at the elevation angle where the radio source was located for the G/T measurement and the receiver noise temperature. The sensitivity of the antenna temperature to elevation angle is of interest not only to obtain the correct value for determining the antenna gain but also in understanding how the user antenna system will perform at different elevation angles. The antenna gain can then be determined by multiplying the antenna's G/T by the system noise temperature. In addition, a common reference plane must be used for both the antenna's G/T and system noise temperature values. In some cases, the antenna gain within the transmit band is desired. If an LNA

operating in the transmit band is substituted for the transmitter, a G/T measurement using a radio source can be performed. Determining the system noise temperature T for this case allows the determination of the transmit antenna gain.

Diplexer

User antennas commonly require the same antenna for both receive and transmit operation. A diplexer is required to separate the transmitting and receiving frequencies. While a variety of techniques may be used for diplexing, the requirements for diplexing are common to all designs. A diplexer provides the filtering necessary to isolate the receiver and transmitter and a means to connect the receiver and transmitter to the antenna. Diplexer loss is to be minimized to avoid reduced received and transmitted signal levels. The requirements of filtering are derived in the following manner. The transmit filtering must pass the transmitted spectrum with low loss and with sufficient amplitude and phase flatness to avoid transmit signal distortion. The transmit filter must sufficiently suppress the out-of-band emissions from the transmitter that fall within the receive bandwidth sufficiently to avoid degrading receiver performance. This filtering requirement requires knowledge of the out-of-band spectral characteristics of the transmitter and generally, the required filter rejection in the receive bandwidth reduces the out-of-band transmitted spectrum to a level 10 dB below the receiver noise spectra density. This requirement also forms a basis to test the rejection by observing the receiver noise level with the transmitter off and the increase in the receiver noise level with the transmitter on. Testing for high transmit power levels also involves examining the power handling capabilities. Two requirements exist for high transmit power levels and are reflected in the testing. The first requirement is to ensure breakdown does not occur, a peak power limitation. The second requirement concerns average power limitations and involves demonstrating the increased temperature resulting from ohmic loss stays beneath a safe operating temperature limit. In such cases, the transmit diplexing filtering might be distributed with some of the filtering being located on the transmitter and other filtering located near the antenna's diplexer combiner to distribute the thermal load.

The receive filter must pass the receive spectrum with low loss, as well as sufficient amplitude and phase flatness to avoid receive signal distortion. The filtering must also suppress the transmitted spectrum sufficiently to avoid compressing the receiver at out-of-band frequencies. This filtering requirement involves determining the spectral coupling of the transmitter into the receiver port, understanding the gain and filtering distribution of the receiver, and determining the power levels needed to saturate the receiver at out-of-band frequencies. Again, the filtering rejection is sized with a margin, commonly 6 dB, to avoid receiver compression throughout the receiver architecture. Testing involves measuring the receiver's amplifiers output levels at the out-of-band frequencies where saturation could potentially occur.

In practice, a significant amount of filter rejection can be required. Attention should be given to leakage around filter sections to assure the overall filtering rejection is not compromised. Leakage components can be detected by using waveguide probes to assure component joints and tuning screws do not have excessive leakage levels. Electroforming techniques and distributing the filters at different locations can be helpful. The overall filter rejection may be sufficiently high to limit verification within the dynamic range of standard instrumentation such as network analyzers. The network analyzers provide the means to measure in-band insertion loss and amplitude and phase flatness as necessary but determining the rejection can require further sensitivity. Using additional amplification may provide the added sensitivity and in the case of distributed filtering, the individual components can be measured. In any event, measurements of the assembled system are necessary to assure the diplexer performance complies with requirements.

Radiation Hazard

Large ground terminal antennas often require significant power levels to meet link requirements for high data rate transfer. When high transmitting power levels, concerns exist that the power densities near the antenna can potentially harm personnel. Generally, the safe levels for RF exposure⁵⁰ are 2 mW/cm² and the debate on the safe level is ongoing. When such concerns exist, measurements of the antenna fields are performed. These measurements are typically within the antenna's near field and are performed using a probe antenna, as well as spectrum analyzer instrumentation. Because the power densities of concern have extremely high levels, measurements are generally performed using a signal generator in place of the actual transmitter to avoid concerns of potential harm to personnel performing the measurements and generally adequate sensitivity exists when the signal generator is used.

Such measurements are guided by first using available analysis codes to examine the near field characteristics to identify regions where the near field power densities could potentially exceed the safe levels of exposure. One region is the near field of the aperture distribution and since in operation, the antenna is pointed at the satellite, this region is not readily accessible to personnel on the ground. Other regions, for example, pillover and scattering by struts supporting the feed and/or subreflector, are potential near field locations where the safe levels can be exceeded. Using the near field analyses provides insight of where measurements should be performed and an indication of what their levels should be. Other regions need to be examined if their effects are not included in the analyses. For example, leakage through the reflector panel gaps in large reflector antennas and openings in the reflector surfaces for antennas feeds need to be separately probed.

45.1 INTRODUCTION

Almost all Earth station and ground station antennas are used for either telecommunications or science, and frequently the same antenna (as, for example, the 70-m antenna of the National Aeronautics and Space Administration [NASA] Deep Space Network [DSN]¹) is used for both purposes. The terms Earth station antenna and ground station antenna seem to be used interchangeably. However, most often, antennas used for supporting Earth-orbiting satellites are called Earth station antennas and those used primarily for science or deep-space satellites are termed ground station antennas.

This chapter primarily deals with telecommunications, and Chapter 49 covers the science applications. However, much of the material included in this chapter (e.g., analysis, design, and measurement techniques) applies equally well to both applications and will not be repeated in Chapter 49. This chapter also uses some material from previous editions of the book.

Reflector antennas have existed since the days of Heinrich Hertz (1857–1894) and are still one of the best solutions to requirements for cost-effective, high-gain, high-performance antenna systems. Consequently, virtually all ground station antennas are reflector antennas of one type or another.

Requirements for ground station antennas can be grouped into several major categories:

- Electrical or radio-frequency (RF) requirements
- Control-system requirements
- Structural requirements
- Pointing- and tracking-accuracy requirements
- Environmental requirements
- Miscellaneous, such as those concerning radiation hazards, primary-power distribution for de-icing, etc.

Only the electrical or RF requirements will be dealt with in this chapter.

The primary electrical antenna specifications are gain, noise temperature, voltage-standing-wave ratio (VSWR), power rating, receive–transmit group delay, radiation pattern, polarization, axial ratio, isolation, and G/T (antenna gain divided by system noise temperature). All parameters except the radiation pattern are determined by system requirements. For commercial Earth station antennas, the radiation pattern must meet the minimum requirements set by the International Radio Consultative Committee (CCIR) of the International Telecommunications Union (ITU) and/or national regulatory agencies such as the U.S. Federal Communications Commission (FCC). For antennas used for deep-space communications, the primary design requirement is for G/T , and, in general, there are no requirements for a specific radiation pattern.

Earth station antennas operating in the field of international satellite communications must have sidelobe performance as specified by INTELSAT standards or by CCIR Recommendation 580-1 (see Figure 45-1).

The CCIR standard specifies the pattern envelope in terms of allowing 10 percent of the sidelobes to exceed the reference envelope and also permits the envelope to be adjusted for antennas whose aperture is less than 100 wavelengths (100λ). The reference envelope is given by

$$\begin{aligned}
 G &= [49 - 10 \log (D/L) - 25 \log \theta] \text{ dBi} & D \leq 100\lambda \\
 &= (29 - 25 \log \theta) \text{ dBi} & D > 100\lambda
 \end{aligned}$$

FIGURE 45-1 Sidelobe envelope as defined by CCIR Recommendation 580-1 and the FCC

This envelope takes into consideration the limitations of small-antenna design and is representative of measured patterns of well-designed dual-reflector antennas.

For antennas used for deep-space communications, there is no specific sidelobe requirement. However, since the prime driver for deep-space missions is to receive extremely weak signals over vast interplanetary distances, a key element of telecommunications link performance is the received power signal-to-noise ratio (SNR), which is given by

$$S/N \approx \frac{P_T G_T G_R}{4\pi R^2 N} = \frac{4\pi P_T A_T A_R}{\lambda^2 R^2 k B T_s} \quad (45-1)$$

where

- P_T = spacecraft transmit power
- G_T = gain
- A_T = effective area of the transmit (spacecraft) antenna
- G_R = gain
- A_R = effective areas of the receive ground antennas
- N = total noise
- R = distance to the spacecraft
- T_s = receive system noise temperature
- λ = wavelength
- B = bandwidth
- k = Boltzman's constant

To do its part effectively, the ground antenna system must maximize the ratio of received signal to the receiving system noise power, which is measured by an antenna figure of merit (FM), defined as the ratio of antenna effective area (or equivalent gain) to system noise temperature.

The receive temperature consists primarily of the antenna feed system and amplifier contributions. For assessing the antenna FM, it is desirable to draw an imaginary reference plane between the receiver system and the antenna system, thus placing all noise contributions in one or the other of these categories. If the receiver contribution (including the feed system losses) is given by T_R and the antenna noise contribution by T_A , then the FM will be given by

$$FM = \frac{G_R}{T_R + T_A} \quad (45-2)$$

Antenna noise temperature properties are very significant contributors to FM, especially for cases of low receiver noise temperature systems. Thus, to maximize the FM for a given antenna size and frequency of operation, it is necessary to both maximize the antenna gain and minimize the total system noise temperature. Since the individual contributions to noise temperature are additive and essentially independent of each other, it is necessary to individually minimize each contribution. If any one of the noise contributions is large, minimizing the others only marginally improves the FM. However, by using cryogenic amplifiers, the receiver noise temperature contribution can be small (as low as 2 to 3 K for the best performing masers), and it then becomes imperative to minimize both the antenna and feed system contributions. For ambient conditions, it should be noted that feed system losses contribute to noise temperature at the rate of 7 K per 0.1-dB loss.

Ground station antennas can be grouped into two broad categories: single-beam antennas and multiple-beam antennas. A single-beam antenna is defined as an antenna that generates a single beam that is pointed toward a satellite by means of a positioning system. A multiple-beam Earth station antenna is defined as an antenna that generates multiple beams by employing a common reflector aperture with multiple feeds illuminating that aperture. The axes of the beams are determined by the location of the feeds. The individual beam identified with a feed is pointed toward a satellite by positioning the feed, generally without moving the reflector. An important subclass of single-beam antennas is the beam-waveguide (BWG) antenna, which is composed of one or more feedhorns with a series of flat and curved mirrors arranged so that power can be propagated from the horn through the mirrors to the main reflector with minimum loss.

45.2 SINGLE-BEAM EARTH STATION ANTENNAS

Single-beam antenna types used as Earth stations are paraboloidal reflectors with focal-point feeds (prime-focus antenna), dual-reflector antennas such as the Cassegrain, Gregorian, and dual-shaped configurations, BWG antennas, offset-fed paraboloidal antennas, and offset-fed multiple-reflector antennas. Each of these antenna types has its own unique characteristics, and the advantages and disadvantages have to be considered when choosing one for a particular application.

Axisymmetric Dual-Reflector Antennas

The predominant choice of designers of large Earth station antennas has been the axially symmetrical dual-reflector antenna (Cassegrain or Gregorian, classical or shaped).

1. The classical Cassegrain geometry^{2,3} employs a paraboloidal surface for the main reflector and a hyperboloidal surface for the subreflector (see Figure 45-2). The paraboloidal

FIGURE 45-2 Geometry of the Cassegrain antenna system

reflector is a point-focus device with a diameter, D_p , and a focal length, f_p . The hyperboloidal subreflector has two foci. For proper operation, one of the two foci is the real focal point of the system and is located coincident with the phase center of the feed; the other focus, the virtual focal point, is located coincident with the focal point of the main reflector. The parameters of the Cassegrain system, as shown in Figure 45-2, are related as follows:

$$\phi_p = 2 \tan^{-1}(0.25D_p/F_p) \quad (45-3)$$

$$f_s/d_s = 0.5(\cot \phi_p + \cot \phi_s) \quad (45-4)$$

$$\ell_s/f_s = 0.5(1 - \{\sin[0.5(\phi_p - \phi_s)] / \sin[0.5(\phi_p + \phi_s)]\}) \quad (45-5)$$

In a typical design, the parameters F_p , D_p , and ϕ_s are chosen, and the remaining three parameters are then calculated. Granet⁴ has given design formulas and procedures for both Cassegrain and Gregorian starting with different design parameters and design considerations such as minimum blockage.

The contours of the main reflector and subreflector are given by

$$\text{Main reflector: } y_m^2 = 4F_p x_m \quad (45-6)$$

$$\text{Subreflector: } (y_s/b)^2 + 1 = (x_s/a + 1)^2 \quad (45-7)$$

where

$$a = (f/2e) \quad b = a\sqrt{e^2 - 1}$$

$$e = \sin[0.5(\phi_p + \phi_s)] / \sin[0.5(\phi_p - \phi_s)]$$

The quantities a , b , and e are half of the transverse axis, half of the conjugate axis, and the eccentricity parameters of the hyperboloidal subreflector, respectively.

FIGURE 45-3 Circularly symmetric dual-shaped reflectors

2. An extremely important generalization of the Cassegrain geometry is that it consists of a special-shaped quasi-paraboloidal main reflector and a shaped quasi-hyperboloidal subreflector.⁵⁻⁸ Green⁹ observed that in dual-reflector systems with high magnification—essentially a large ratio of main-reflector diameter to subreflector diameter—the distribution of energy (as a function of angle) is largely controlled by the subreflector curvature. The path length or phase front is dominated by the main reflector (see Figure 45-3). Kimber⁵ and Galindo^{6,7} found a method for simultaneously solving for the main-reflector and subreflector shapes to obtain an exact solution for both the phase and the amplitude distributions in the aperture of the main reflector of an axisymmetric dual-reflector antenna. Their technique, based on geometrical optics, involves solving two simultaneous, nonlinear, first-order, ordinary differential equations. Figure 45-4 gives the geometry showing the path of a single ray.

FIGURE 45-4 Dual-shaped reflector geometry

The feed phase center is located as shown, and the feed is assumed to have a power radiation pattern (θ_1). The parameters α and β represent, respectively, the distance of the feed phase center from the aperture plane and the distance between the feed phase center and the back surface of the subreflector. The constraints to the dual-reflector system are as follows:

- a. The phase distribution across the main-reflector aperture plane will be uniform, or

$$r_1 + \rho^2 + \rho^3 + C_p(\theta_1) = \text{constant} \quad (45-8)$$

over the range $0 \leq \theta_1 \leq \theta_{1\max}$. $C_p(\theta_1)$ represents the phase distribution across the primary-feed radiation pattern in units of length.

- b. The feed energy, or ray bundles intercepted and reflected by the subreflector, is conserved and redistributed according to a specified aperture distribution, or

$$I(\theta_1) \sin(\theta_1) d\theta_1 = C \cdot I(X_2) X_2 dX_2 \quad (45-9)$$

where $I(X_2)$ represents the power radiation distribution across the main-reflector aperture, and C represents a constant that is determined by applying the conservation-of-power principle.

$$\int_0^{\theta_{1\max}} I(\theta_1) \sin \theta_1 d\theta_1 = C \int_{X_{2\min}}^{X_{2\max}} I(X_2) X_2 dX_2 \quad (45-10)$$

The lower limit of integration over the main reflector can be arbitrarily chosen so that only an annular region of the main reflector is illuminated.

- c. Snell's law must be satisfied at the two reflecting surfaces; applying it yields

$$\frac{dY_1}{dX_1} = \tan\left(\frac{\theta_1 - \theta_2}{2}\right) \quad (45-11)$$

$$\frac{dY_2}{dX_2} = -\tan\left(\frac{\theta_2}{2}\right) \quad (45-12)$$

Solving Eqs. 45-9 through 45-12 simultaneously results in a nonlinear, first-order differential equation of the form

$$\frac{dY_1}{dX_2} = f(\theta_1, \theta_2, \alpha, \beta, \text{etc.}) \quad (45-13)$$

which leads to the cross sections of each reflector when subject to the boundary condition $Y_1(X_2 = X_{2\max}) = 0$, where X_2 is the independent variable. Equation 45-13 can be solved numerically by using an algorithm such as a Runge-Kutta, order 4.

The above procedure is based on geometrical optics (GO), but it is evident that the assumptions of GO are far from adequate when reflectors are small in terms of wavelengths. An improvement in the design approach is to include the effects of diffraction. Clarricoats and Poulton¹⁰ reported a gain increase of 0.5 dB for a diffraction-optimized design over the GO design with a 400λ -diameter main reflector and 40λ -diameter subreflector.

Prime-Focus-Fed Parabolic Antennas

Prime-focus-fed parabolic reflector antennas are also often employed as Earth station antennas. For moderate to large aperture sizes, this type of antenna has excellent sidelobe performance in all angular regions except the spillover region around the edge of the reflector. The CCIR sidelobe specification can be met with this type of antenna. See Chapter 15 on reflector antennas for more information on parabolic antennas.

Offset-Fed Reflector Antennas

The advantage of offset-fed reflector antennas is the elimination of feed and feed-support blockage. This can be extremely important for radio-telescope antennas. Because they are asymmetric, offset antennas are more complicated to build per unit aperture than circularly symmetric antennas, but the additional cost of the offset aperture generally isn't warranted for telecommunications. Consequently, their use is generally reserved for smaller antennas, where eliminating blockage is important and the cost differential for producing the asymmetric aperture is small.

Offset-fed reflector antennas can employ a single reflector or multiple reflectors, with two-reflector types the more prevalent of the multiple-reflector designs. The offset front-fed reflector, consisting of a section of a paraboloidal surface (see Figure 45-5), minimizes diffraction scattering by eliminating the aperture blockage of the feed and feed-support structure. Sidelobe levels of $(29 - 25 \log \theta)$ dBi can be expected from this type of antenna (where θ is the far-field angle in degrees) with aperture efficiencies of 65 to 80 percent. The increase in aperture efficiency compared with that of axisymmetric prime-focus-fed antennas is due to the elimination of direct blockage. For a detailed discussion of this antenna, see C. A. Mentzer.¹³

FIGURE 45-5 Basic offset-fed paraboloidal antenna

FIGURE 45-6 Offset dual-reflector geometries: (a) double-offset geometry (feed phase center and paraboloidal vertex at 0), and (b) open Cassegrain geometry (feed phase center located at 0; paraboloidal vertex at 0)

Offset-fed dual-reflector antennas exhibit sidelobe performance similar to that of front-fed offset reflectors. Two offset-fed dual-reflector geometries are used for Earth station antennas: the double-offset geometry shown in Figure 45-6a, and the open Cassegrain geometry introduced by Cook et al¹¹ of Bell Laboratories and shown in Figure 45-6b. In the double-offset geometry, the feed is located below the main reflector, and no blocking of the optical path occurs. In contrast, the open Cassegrain geometry is such that the primary feed protrudes through the main reflector; thus, it is not completely blockage-free. Nevertheless, both of these geometries have the capability of excellent sidelobe and efficiency performance.

The disadvantage of offset-fed dual-reflector antennas is that they are asymmetric, which results in increased manufacturing cost. Also, offset-geometry antennas, when used for linear polarization, have a depolarizing effect on the primary-feed radiation and produce two cross-polarized lobes within the main beam in the plane of symmetry. For circular polarization, this depolarization effect introduces a beam squint whose direction is dependent upon the sense of polarization. The beam squint is approximately given by¹² $\psi_s = \arcsin [\lambda \sin(\theta_0)/4\pi F]$, where θ_0 is the offset angle, λ is the free-space wavelength, and F is the focal length. The effects of beam squint versus polarization for circular polarization and the relatively high off-axis cross-polarization performance for linear polarization must be considered by the antenna designer, since these characteristics may present a problem for the overall Earth station operation. Offset dual-reflector geometry has the capability of employing a feed tilt to correct for the polarization problems associated with the offset geometry resulting in the equivalent polarization performance of an axially symmetric antenna.^{13,15}

Galindo-Israel, Mittra, and Cha¹⁶ have studied the offset-shaped dual-reflector geometry for high-aperture-efficiency applications. Their analytical techniques are reported to result in efficiencies in the 80 to 90 percent range.¹⁷ See Galindo-Israel¹⁸ for a discussion of the synthesis of offset-shaped reflector antennas.

Beam-Waveguide Systems

A BWG feed system is composed of one or more feedhorns with a series of flat and curved mirrors arranged so that power can be propagated from the horn through the mirrors to the reflector system with minimum losses. Horns and equipment can then be located in a large, non-tipping enclosure at an accessible location.

Feeding a large, low-noise ground antenna via a beam BWG system has several advantages over placing the feed directly at the focal point of a dual-reflector antenna. For example, significant simplifications are possible in the design of high-power, water-cooled transmitters and low-noise cryogenic amplifiers. These systems do not have to rotate as in a normally fed dual reflector. Also, since a BWG system can transmit power over considerable distances at very low losses, BWG optics is often used in the design of very high-frequency feed systems.

Various design techniques¹⁹ have been used, but most frequently they are designed using either GO or Gaussian beams.

Geometrical Optics

The design for a BWG system using GO is based upon criteria introduced by Mizusawa and Kituregawa^{20,21} that guarantee a perfect image from a reflector pair. Mizusawa's criterion can be briefly stated as follows: For a circularly symmetric input beam, the conditions on a conic reflector pair necessary to produce an identical output beam are

1. The four loci (two of which may be coincident) associated with the two curved reflectors must be arranged on a straight line; and
2. The eccentricity of the second reflector must be equal to the eccentricity or the reciprocal of the eccentricity of the first reflector.

Figures 45-7a to 45-7c show some curved reflector pair orientations that satisfy Mizusawa's criteria.

Mizusawa's criteria were used in the design of NASA's first DSN BWG antenna, which is shown in Figures 45-8 and 45-9 and described in detail in Chapter 7 of *Large Antennas of the Deep Space Network*.¹ The design of the center-fed BWG consists of a beam magnifier ellipse in a pedestal room located below ground level that transforms a 22-dB gain feedhorn into a high-gain 29-dB pattern for input to a Mizusawa four-mirror (two flat and two paraboloid-case) BWG system. The system was initially designed for operation at 8.45 GHz (X-band) and 32 GHz (Ka-band) and has less than a 0.2-dB loss at X-band

FIGURE 45-7 Examples of two curved-reflector BWG configurations

FIGURE 45-8 Typical center-fed beam-waveguide antenna

FIGURE 45-9 First DSN beam-waveguide antenna named DSS-13

(determined by comparing the gain of a 29-dB gain horn feeding the dual-shaped reflector system with that obtained using the BWG system) Gaussian beam.

While GO is useful for designing systems with electrically large mirrors ($>50\lambda$ diameter with -20 dB or greater edge taper), some BWGs may be operated at low frequencies where the mirrors may be as small as 20λ in diameter. Due to diffraction effects, the characteristics of a field propagated between small BWG mirrors ($<30\lambda$ in diameter) will be substantially different from those resulting from the GO solution. For these small-mirror cases, the Gaussian beam technique was used.

The Gaussian beam is an approximate solution to a wave equation describing a beam that is unguided but effectively confined near an axis. The zero-order mode is normally used in the design. A major advantage of the Gaussian technique is the simplicity of the Gaussian formula, which is easy to implement and requires negligible computation time.

Because of the negligible computation time, a Gaussian solution can be incorporated into an optimization routine, providing a convenient method to search design parameters for a specified frequency range, mirror sizes and locations, and horn parameters.

G. Goubau gave the first mathematical expression of Gaussian modes, derived from the solution of Maxwell's equations. These Gaussian modes are described by a continuous spectrum of cylindrical waves.²²

Although Gaussian-beam analysis is fast and simple, it is less accurate than the physical optics (PO) solution for smaller mirrors ($<30\lambda$ diameter). However, by designing with Gaussian-beam analysis, then checking and adjusting using PO analysis, an accurate and efficient tool can be fashioned. Veruttipong²³ developed such a tool for designing a second 34-m BWG antenna for the DSN. The goal was to provide good performance over the range of 2 to 32 GHz.

The design is similar to that of the DSS-13 antenna (see Figure 45-9) in that it uses three curved mirrors (one in the basement room and two rotating in azimuth) and a 34-m dual-shaped reflector antenna (see Figure 45-10). Multiple-frequency operation is provided

FIGURE 45-10 BWG designed using Gaussian techniques

FIGURE 45-11 Parameters for BWG Gaussian design

by the dichroic mirrors. The goal is to have the radius of curvature and -18 -dB beam diameter of the Gaussian beam at the subreflector be the same at all frequencies. The size and locations of the mirrors are relatively fixed because of the basic structure geometry, so the pertinent variables are the horn diameters, horn positions, and mirror curvatures. Approximating the mirrors by applying a thin-lens formula (see Figure 45-11) and by using Gaussian-mode analysis to iterate the various design parameters, a design is achieved that meets the initial design constraint of identical patterns at the subreflector. The 34-m BWG antenna was built and measured at S-band, X-band, and Ka-band (see Chapter 8 of *Large Antennas of the Deep Space Network*¹ for details).

45.3 MULTIPLE-BEAM EARTH STATION ANTENNAS

There has been increasing interest in using a single antenna to receive signals simultaneously from several satellites. This interest has prompted the development of several multibeam-antenna configurations that employ fixed reflectors and multiple feeds. The antenna engineering community has been investigating multibeam antennas for many years. In fact, in the middle of the 17th century, Christian Huygens and Sir Isaac Newton first studied the spherical mirror, and the first use of a spherical reflector as a microwave antenna occurred during World War II. More recently, the spherical-reflector, the torus-reflector, and the dual-reflector geometries, all using multiple feeds, have been offered as antennas with simultaneous multibeam capability. Chu²⁴ in 1969 addressed the multiple-beam spherical-reflector antenna for satellite communication, Hyde²⁵ introduced the multiple-beam torus antenna in 1970, and Ohm²⁶ presented a novel multiple-beam Cassegrain-geometry antenna in 1974. All three of these approaches, as well as variations of scan techniques for the spherical reflector, are discussed below.

Spherical Reflectors

The properties, practical applications, and aberrations of spherical reflectors are not new to microwave-antenna designers. The popularity of these reflectors is primarily due to the large angle through which the radiated beam can be scanned by translation and orientation of the primary feed. This wide-angle property results from the symmetry of the surface. Multiple-beam operation is realized by placing multiple feeds along the focal surface. In the conventional use of the reflector surface, the minimum angular separation between adjacent beams is determined by the feed-aperture size. The maximum number of beams is determined by the percentage of the total sphere covered by the reflector. In the alternative configuration described below, these are basically determined by the f/D ratio and by the allowable degradation in the radiation pattern.

FIGURE 45-12 Conventional spherical multibeam antenna using extended reflector and multiple feeds

In the conventional use of spherical reflectors, the individual feed illuminates a portion of the reflector surface so that a beam is formed coincident to the axis of the feed. The conventional multibeam geometry is shown in Figure 45-12. All the beams have similar radiation patterns and gains, although the performance of spherical reflectors is degraded in comparison with the performance of a paraboloid. The advantage of this design is that the reflector area illuminated by the individual feeds overlaps, reducing the surface area for a given number of beams in comparison with individual single-beam antennas.

The alternative multibeam-spherical-reflector geometry is shown in Figure 45-13. For this geometry, each of the feed elements points toward the center of the reflector, with the beam steering accomplished by the feed position. This method of beam generation leads to considerable increase in aberration, including coma; therefore, the radiation patterns of the off-axis beams are degraded with respect to the on-axis beam. This approach does not take advantage of the spherical-reflector properties that exist in the conventional approach. In fact, somewhat similar results could be achieved using a parabolic reflector with a large f/D .

FIGURE 45-13 Alternative spherical multibeam antenna using minimum reflector aperture with scanned beam feeds

FIGURE 45-14 Torus-antenna geometry (© COMSAT Technical Review 1974. Reprinted by permission.)

Torus Antennas

Torus antennas are dual-curvature reflectors, capable of multibeam operation when fed with multiple feeds similar to those of the conventional spherical-reflector geometry. The feed-scan plane can be inclined to be in the orbital-arc plane, allowing the use of a fixed reflector to view geosynchronous satellites. The reflector has a circular contour in the scan plane and a parabolic contour in the orthogonal plane (see Figure 45-14). It can be fed in either an axisymmetric or an offset-fed configuration.

Offset geometry for use as an Earth station antenna has been successfully demonstrated by COMSAT Laboratories.²⁷ The radiation patterns meet a $(29-25 \log \theta)$ -dBi envelope.

The offset-fed geometry results in an unblocked aperture, which gives rise to low wide-angle sidelobes as well as providing convenient access to the multiple feeds.

Torus antennas have less phase aberration than spherical antennas because of the focusing in the parabolic plane. Due to the circular symmetry, feeds placed anywhere on the feed arc form identical beams. Therefore, no performance degradation is incurred when multiple beams are placed on the focal arc. Point-focus feeds may be used to feed the torus up to aperture diameters of approximately 200λ . For larger apertures, it is recommended that aberration-correcting feeds be used.

The scanning or multibeam operation of a torus requires an oversized aperture to accommodate the scanning. For example, a reflector surface area of approximately 214 m^2 will allow a field of view (i.e., orbital arc) of 30 deg with a gain of approximately 50.5 dB at 4 GHz (equivalent to the gain of a 9.65-m reflector antenna). This surface area is equivalent to approximately three 9.65-m antennas.

Offset-Fed Multibeam Cassegrain Antennas

Offset-fed multibeam Cassegrain antennas are composed of a parabolic main reflector, a hyperbolic oversized subreflector, and multiple feeds located along the scan axis, as shown in Figure 45-15. The offset geometry essentially eliminates beam blockage, allowing a significant reduction in sidelobes and antenna noise temperature. The Cassegrain feed system

FIGURE 45-15 Geometry of the offset-fed multibeam Cassegrain antenna (© American Telephone and Telegraph Company 1974. Reprinted by permission.)

is compact and has a large focal-length-to-diameter ratio (f/D), which reduces aberrations to an acceptable level even when the beam is moderately far off axis. Low-sidelobe performance is achieved by using a corrugated feedhorn that produces a Gaussian beam.

A typical antenna design consisting of a 10-m projected aperture would yield half-power beamwidths (HPBW) and gain commensurate with an axisymmetric 10-m antenna, 0.5 HPBW, and 51-dB gain at 4 GHz. The subreflector would need to be approximately a 3-m by 4.5-m elliptical aperture. The feed apertures would be approximately 0.5 m in diameter. The minimum beam separation would be less than 2 deg, which is more than sufficient to allow use with synchronous satellites with orbit spacing of 2 deg or greater. For the ± 15 -deg scan, the gain degradation would be approximately 1 dB, and the first sidelobe would be approximately 20 to 25 dB below the main-beam peak.

45.4 ANGLE-TRACKING TECHNIQUES

Automatic tracking of satellite position is required for many Earth station antennas. Monopulse, conical-scan, and sequential-lobing techniques described in the chapter on tracking antennas are applicable for this purpose. Two other types of tracking techniques are also commonly employed: single-channel monopulse (pseudo monopulse) and step-track. Single-channel monopulse is a continuous angle-tracking scheme, and steptrack is a time-sequencing, signal-peaking technique.

Single-Channel Monopulse Technique

This technique uses multiple elements or modes to generate a reference signal, an elevation error signal, and an azimuth error signal. The two error signals are then combined in a time-shared manner by a switching network that selects one of two phase conditions (0 and 180 deg) for the error signal. The error signal is then combined with the reference signal, with the resultant signal then containing angle information. This allows the use of a single receiver for the tracking channel. This technique is equivalent to sequential lobing in which the lobing is done electrically and can be adjusted to any desired fixed or variable scan rate.

FIGURE 45-16 Signal-strength gradients

Steptrack Technique

Steptracking is a technique employed primarily for maintaining the pointing of an Earth station's antenna beam toward a geosynchronous satellite. Since most geosynchronous orbiting satellites only slowly traverse a small angular region, a simple peaking technique can be used to keep the Earth station beam correctly pointed. The signal-peaking, or steptrack, routine is a software technique that maneuvers the antenna toward the signal peak by following a path along the steepest signal-strength gradient or by using some other algorithm that accomplishes the same result.^{28,29} Any method of direct search for a maximization of signal is applicable; one such method calculates the local gradient by determining the signal strength at three points (A, B, C ; see Figure 45-16). From the signal strength at points A, B , and C , an angle α_2 , representing the unit's gradient vector angle relative to the azimuth axis, is computed. Once C_1 has been determined, A_2 is set equal to C_1 and another angle θ_2 is defined by $\theta_2 = \theta_1 + \alpha_2$ ($\theta_1 = 0$). The angle is used to relate pedestal movements to a fixed-pedestal coordinate system. The procedure is repeated a number of times until the antenna boresight crosses throughout the peak. At this time, the step size is reduced by one-half, and for each time that the peak is crossed it is again reduced by one-half until peaking resolution is accomplished.

45.5 POLARIZATION

Many satellite communications systems are dual-polarized (frequency reuse) and are therefore susceptible to interference from the intended cross-polarized signals when the medium of propagation is such that the ellipticity of the signals is changed. This condition can occur during atmospheric conditions such as rain and Faraday rotation in the ionosphere. Therefore, in order to maintain sufficient polarization discrimination, special precautions must be taken in regard to the polarization purity of dual-polarization antennas; indeed, adaptive polarization-correcting circuits may be necessary.^{30,31}

Several types of polarization-discrimination-enhancement schemes may be used. They include:

- Simple rotation of the polarization major-ellipse axis to correct for rotation due to the ionosphere (applicable for linear polarization). Transmit and receive rotations are in opposite directions.

- Suboptimal correction of depolarizations; ellipticity correction with respect to one of the signals but not orthogonalizing the two signals (differential phase).
- Complete adaptive correction including orthogonalization (differential phase and amplitude).

Polarization-enhancement schemes may be implemented at RF frequencies, or they may follow a down-conversion stage and be implemented at intermediate frequencies (IFs). In either case, the circuitry must operate over the full bandwidth of the communications channel. Kreutel et al³¹ treat the implementation of RF frequencies in detail. See Gianatasio^{32,33} for both RF and IF circuitry and experiments to verify performance of the circuitry.

45.6 MEASUREMENT TECHNIQUES

A number of sophisticated measurement techniques are required to properly characterize the performance of a ground station antenna. There is a need to accurately measure the main reflector surface, which is achieved either by microwave holography, theodolite measurements, or photogrammetry. To determine an antenna's FM, it is necessary to measure gain (or efficiency) and noise temperature.

Microwave Holography

Microwave holography^{34–36} has proven to be a valuable technique for characterizing the mechanical and RF performance of large reflector antennas. This technique uses the Fourier transform relation between the far-field radiation pattern of an antenna and the aperture field distribution. Resulting aperture phase and amplitude data can be used to characterize various performance parameters, including panel alignment, panel shaping, subreflector position, antenna aperture illumination, and gravity deformation effects.

The raw data (the observable) for this technique is the complex far-field pattern of the antenna under test. For large reflector antennas, geostationary satellites are commonly used as far-field signal sources. A typical measurement system consists of the antenna under test, a reference antenna (generally much smaller), and a narrow-bandwidth receiver system architecture used for receiving the narrow-band beacon signal from the satellite. The reference antenna is needed as a phase reference for the measurement as well as to keep the receiver in phase lock with the carrier.^{37,38} The mathematical details are given in Rochblatt.³⁵ Essentially, the inverse Fourier transform of the far-field radiation pattern yields a phase map of the aperture distribution which, through GO, can be related to the surface error.

Accuracy across the holographic map varies with aperture amplitude illumination. Accuracy is better at the center of the dish and gradually worsens toward the edge, where the illumination falls off rapidly. For a uniformly illuminated antenna design, accuracy remains relatively constant, becoming quickly worse just at the edge, also where the illumination falls off rapidly. Typically, accuracies of 0.05 mm to 0.10 mm were achieved with a corresponding SNR of 73 dB to 60 dB.

The resulting aperture phase function needs to be corrected for modulo- 2π phase errors. These occur due to the small measurement wavelength and the large phase error that is partially caused by pointing and subreflector position errors. Next, it is necessary to remove those phase errors caused by pointing and subreflector position errors; this is achieved using the global best-fit paraboloid. Here, the entire data set is weighted-least-squares fitted to the paraboloid, permitting six degrees of freedom in the model, three vertex translations,

two rotations, and a focal length change. The antenna surface axial rms error is then computed with respect to the position of the fitting paraboloid.

The resultant aperture function at the end of this process is defined here as the effective map since it includes all phase effects that are contributing to antenna performance. These frequency-dependent effects consist of the subreflector scattered (frequency-dependent) feed phase function and struts' diffraction effects. Removal of the feed phase function and subreflector-support structure diffraction effects results in a frequency-independent map, which is defined here as the mechanical map. In general, panel-setting information is derived from the mechanical map since the latter is frequency-independent, and the antenna needs to be operated over a range of frequencies. Panel-setting information is determined by sorting all the data points within each panel and performing a rigid-body least-squares fit. The panel-setting algorithm allows for one translation and two rotations.

Theodolite Measurements

Theodolite measurements are typically used in the initial alignment of the antenna, after installation of the reflector panels. The method of determining the reflector surface is based on angular measurements performed with a theodolite.^{39,40} The theodolite is located at the main reflector vertex and is used to measure the angles to targets installed at the individual reflector panel corners. After installation on the antenna, the panels are drilled to accept targets by using a metal strap gage to position the holes.

Errors in theodolite measurements are caused by uncertainty in the angular measurement of the target position and radial distance to the target. At a radius of 13 m, which is the surface area median radius for a 34-m antenna, a 0.001-deg error in the angle to the target corresponds to a 0.2-mm error normal to the surface. Similarly, a 1.0-mm error in the radial distance corresponds to a 0.26-mm error normal to the surface.

A typical error budget⁴⁰ for the surface of a 34-m antenna is 0.3 mm root mean square (RMS). By far, the greatest source of error is in the radial distance measurement provided by using a drill tape. If, instead, a laser range finder is used to measure radial distance, the error could be reduced from 0.3 mm rms to 0.2 mm rms. In any case, microwave holography has been used to characterize and reset the main reflector surface after initial operation using theodolite-set panels.

A Leica TDM-5000 total station theodolite can also be used to measure large reflectors.⁴¹ It calculates vertical and horizontal angles and distances, downloads them to a PC that converts the coordinates from the spherical to a Cartesian system, and can be used to command the instrument to motor to a desired look angle.

Photogrammetry

Photogrammetry, as its name implies, is a three-dimensional coordinate-measuring technique that uses photographs as the fundamental medium for metrology (measurement). The fundamental principle used by photogrammetry is triangulation. By taking photographs from at least two different locations, so-called "lines of sight" can be developed from each camera to points on the object. These lines of sight (sometimes called rays, owing to their optical nature) are mathematically intersected to produce the three-dimensional coordinates of the points of interest. Photogrammetry can be used to measure the surface of a reflector antenna.⁴² Reflective targets are placed uniformly over the surface of the dish and photographs are taken from several different angles. With the aid of calibration targets, the target data are processed to produce a map of the reflective surface.

Aperture Gain and Efficiency Measurements

Determination of aperture efficiency follows a methodology developed by the Jet Propulsion Laboratory (JPL).^{43,44} For a radio source of known flux density, the increase in system noise temperature as determined by the boresight measurements is a measurement of antenna efficiency. Peak radio source noise temperatures are measured using a boresight algorithm.⁴⁵ These measured quantities are then normalized by dividing by T_{100}/C_r , where T_{100} is 100 percent antenna efficiency temperature, and C_r is the source size correction factor.^{43,46} Values of the temperature $T_a = T_{100}/C_r$ for radio sources used to calibrate DSN antennas are given in Richter.⁴⁷ The effects of atmospheric attenuation must also be considered, so the final measured values are then corrected to yield vacuum conditions. The boresight technique, determining antenna efficiency, and the correction for atmospheric attenuation are described in more detail in the following sections.

Boresight Technique The typical method used for calibrating the pointing of DSN antennas is the seven-point boresight technique, which moves the antenna sequentially in both the cross-elevation (XEL) and elevation (EL) directions, both on and off the source. In each direction, the antenna is positioned off-source 10 half-power (one-sided) beamwidths; 1 half-power beamwidth at the 3-dB point; approximately 0.576 half-power beamwidth at the 1-dB point; on source; and then similar offsets on the other side. For example, at X-band with the 34-m antenna, the full 3-dB beamwidth is 65 mdeg. The offsets used are 325, 32.5, 18.7, and 0 mdeg in each direction. At Ka-band, with a full 3-dB beamwidth of 17 mdeg, the offsets were 85, 8.5, 4.9, and 0 mdeg.

For each scan, an off-source baseline is generated from the two off-source points. A Gaussian curve (relative to the baseline) is fitted to the five remaining on-source points, and the peak value of the curve is calculated. Also, the position of the peak is calculated as a measure of the pointing error for that scan. One pair of scans (one XEL and one EL) is considered to be one measurement or data point. The seven pointing offsets for each new scan are corrected for pointing errors found from the previous similar scan in order to maintain pointing throughout a track.

Antenna Efficiency As defined here, the efficiency is referenced to the input of the low-noise amplifier and includes the losses of the feed system. Alternative methods specify efficiency at the aperture of the feedhorn or at the antenna aperture itself. The term "aperture efficiency" refers to antenna gain relative to that of a uniformly illuminated circular aperture having the same diameter as the antenna, e.g., a 70 percent efficient antenna has 1.549-dB less peak gain than does a uniformly illuminated circular aperture.

Radio-source noise temperature increase measured by the antenna is given by⁴⁸:

$$\Delta T = \frac{\eta SA}{2kC_r C_p} \quad (45-14)$$

where

η = antenna aperture efficiency

S = radio source flux, $\text{W/m}^2/\text{Hz}$

A = antenna area, m^2

k = Boltzmann constant, $1.3806503 \times 10^{-23} \text{ J/K}$

C_r = source size correction, typically 1.0 for point sources, up to ~1.5 for extended sources, including planets

C_p = pointing correction, assumed = 1.0

The lux, S , is typically given in units of Janskys, where 1 Jansky (Jy) = $1 \times 10^{-26} \text{ W/m}^2/\text{Hz}$

Measured ΔT is compared with the quantity $[(SA)/(2kC_r)]$ to give antenna efficiency

Thus:

$$\begin{aligned}\eta &= \frac{\Delta T}{SA / 2kC_r} \\ &= \frac{\Delta T}{T100 / C_r}\end{aligned}\quad (45-15)$$

$T100$ is what would be measured by a perfect antenna looking at a point source emitting the same flux as the observed radio source. C_r is a function of the source structure at a particular frequency and the antenna pattern of a particular antenna at that frequency. For a particular antenna, frequency, and radio source, $T100/C_r$ can thus be specified.

Correction for Atmospheric Attenuation ΔT is an on-off source measurement, and Earth's atmosphere attenuates the true source contribution that would be measured under vacuum conditions. The total atmospheric attenuation is estimated from surface weather conditions during all measurements. The surface temperature, pressure, and relative humidity at the site are recorded every half hour. Typical zenith values of attenuation at Goldstone under average clear-sky conditions are

$$\text{X-band: } A_{\text{zen}} = 0.035 \text{ dB}$$

$$\text{Ka-Band: } A_{\text{zen}} = 0.115 \text{ dB}$$

The attenuation in decibels at elevation angle θ is modeled as

$$A(\theta) = \frac{A_{\text{zen}}}{\sin(\theta)}$$

The loss factor at that elevation angle is

$$L(\theta) = 10^{A(\theta)/10}$$

The “vacuum ΔT ” then becomes

$$\Delta T = L(\theta) \Delta T_{\text{measured}}$$

Noise Temperature Measurements

There are a variety of noise temperature measurement techniques and instruments used in the DSN, such as a total power radiometer, noise-adding radiometer, thermal noise standards (cryogenically cooled, ambient, and hot), all well described in Stelzried.⁴⁹ These instruments typically calibrate low-noise systems by injecting a known amount of noise from either a gas tube or solid-state noise diode into the input. The system output power ratio is then used to calculate the operating noise temperature. However, it can be difficult to determine the equivalent noise temperature of the noise source, as defined at the receive input, because of component and transmission line loss between the noise source and the receiver. Determining the amount of noise injected involves either evaluating the noise source and loss separately or measuring the excess noise temperature directly at the receiver input.

A measurement technique that eliminates the difficulty of calibrating noise temperature and is most often used for low-noise ($\ll 300$ K) receiving systems in the DSN is the ambient termination technique,⁴⁹ in which the operating noise-temperature calibrations are performed by alternately connecting the low-noise amplifier input with a waveguide switch between the antenna and an ambient termination. The same effect can be achieved by alternately placing and removing an absorber load over the front of the feedhorn.

The operating noise temperature of a receiving system can be expressed as

$$T_{\text{op}} = T_a + T_e \quad (45-16)$$

where

T_a = antenna temperature, K

T_e = receiver effective noise temperature, K

Figure 45-17 shows a simplified block diagram of the instrumentation for operating noise-temperature calibrations. The precision attenuator is adjusted for equal output power when the receiver input is alternately connected to the ambient load and the antenna. The power ratio Y for an individual measurement is

$$Y_{\text{ap}}(i) = \frac{T_p + T_e}{T_{\text{op}}(i)} \quad (45-17)$$

where

T_p = ambient termination physical temperature, K

T_e = receiver effective noise temperature, K

$T_{\text{op}}(i)$ = individual operating noise-temperature measurement (on antenna), K

Rearranging yields an expression for $T_{\text{op}}(i)$ in terms of the power ratio Y :

$$T_{\text{op}}(i) = \frac{T_p + T_e}{Y_{\text{ap}}(i)} \quad (45-18)$$

A series of measurements is made, and a best estimate in a least-squares sense of Y_{ap} is obtained.

FIGURE 45-17 Simplified block diagram of the operating-noise-temperature calibration instrumentation

The operating noise temperature is then given by

$$T_{\text{op}} = \frac{T_p + T_e}{Y_{\text{ap}}} \quad (45-19)$$

The ambient termination temperature is measured, and the receiver temperature is estimated or calibrated. It is not necessary to know T_e accurately if $T_e \ll T_p$.

In the past, the waveguide beyond cutoff attenuator was the most accurate method to measure Y factors, so the equations for calculating noise temperature were written in terms of Y factors. Most recently, the power meter has been more accurate, and more convenient, mating easily with computers. The method described in Stelzried and Klein^{50,51} does not use Y factors but deals directly with power meter readings, in watts. In addition, this formulation leads to the determination of radiometer linearity.

46.1 INTRODUCTION

This chapter will focus on antennas forward-mounted in a missile functioning in the role of seeker of target emissions by radar homing or antiradiation homing. Such a seeker antenna is a critical part of the entire airborne guidance system, which includes the missile radome, seeker antenna, radio frequency (RF) receiver, antenna gimbal, autopilot, and airframe. The seeker has several functions: to receive and track target emissions so as to measure line of sight and/or line-of-sight angular rate, to measure closing velocity, and to provide steering commands to the missile autopilot and subsequently to the control surfaces. The signals received by the missile-mounted seeker antenna or antennas are thus utilized in a closed-loop servocontrol system to guide the missile to the target.

The seeker RF elements, radome and antenna, initially discriminate in angle through the seeker antenna's pencil beam or equivalent. This beam can be steered mechanically (the whole antenna moves), electromechanically (an antenna element such as a subreflector moves), or electronically (there is a phased-array movement). In some situations, the antenna is stationary and only forward-looking; thus beam motion occurs only if the entire missile airframe rotates. Fixed seeker-antenna beams are used when a pursuit navigation (or a variant) guidance algorithm is used. The use of movable seeker antenna beams occurs when a proportional navigation (or a variant) guidance algorithm is used.

46.2 SEEKER-ANTENNA ELECTRICAL CONSIDERATIONS

Seekers generally fall into one of three categories: conical scan (conscan), monopulse, or sequential lobing. Implementation details for each of these are well known.¹ Conscan radars locate the center of the target through the nutation of a single feed (or antenna) that is displaced from the axis. Monopulse antennas most often generate four simultaneous beams that are summed and differenced to produce azimuth and elevation-plane error voltages that are proportional to target displacement from the axis. Sequential-lobing radars sequentially sample the energy in four beams each corresponding to an antenna feed; the error voltage is derived by comparing the amplitude of the signal in opposite feeds.

Conical scan is used primarily for very-short-range, simple guidance systems. Conscan is in limited use because of its vulnerability to a form of ECM known as spin-frequency jamming, in which the jammer reradiates the seeker transmission, amplitude modulated at the conical scan frequency, thus creating spurious angle-error signals.² Sequential-lobing radars are seldom used in today's high-performance missile guidance systems, giving preference to monopulse, which provides simultaneous lobing of both principal-plane error channels.

Modern polarimetric seeker radars require dual-polarized seeker-antenna performance.³ Other parameters of particular concern include instantaneous bandwidth, transmit power capability, and low antenna sidelobe performance.⁴

Seeker antennas can be realized in a variety of technologies ranging from microstrip to waveguide (see Figure 46-1). Table 46-1 presents a summary of commonly employed seeker antenna

FIGURE 46-1 Representative planar-seeker waveguide flat-plate antenna (*Courtesy of Rantec Microwave & Electronics*)

TABLE 46-1 Seeker-Antenna Radiator Summary

Basic Radiator	Bandwidth Potential	Polarization	Dual-polarization Capability	Power
Stripline	Narrow	Linear or circular	Yes	Intermediate
Microstrip	Narrow	Linear or circular	Yes	Intermediate
Spiral	Large	Circular	No	Yes
Paraboloid	Large	Linear or circular	Yes	High
Waveguide slots	Narrow	Linear	Yes	High
Lens	Large	Linear or circular	Yes	High

element types; virtually all of these can be implemented in a body-fixed configuration. However, mounting the antenna on a mechanical gimbal is more popular for most missile-guidance applications using proportional (or modern) guidance. A gimballed slotted planar seeker antenna is shown in Figure 46-2. Detailed performance and design criteria for the basic antenna radiator types are found in the appropriate chapters of this Handbook.

Many system factors also must be considered in the antenna-design process. Antenna beamwidth determines whether spatial resolution of multiple targets occurs.⁵ The sooner that resolution takes place on a flight path, the more time the missile will have to correct errors induced by tracking the multiple-target centroid. Low sidelobes are important because they decrease electronic-jamming effects. This is particularly important if the missile gets significantly close to the jammer during the engagement. Noise injected in this manner can increase the final miss distance.

In a monopulse tracking system, low sidelobes are necessary in both the sum and difference modes in order to reduce the antenna's susceptibility to jamming threats. This creates the problem of achieving simultaneously low sidelobes in the sum and difference radiation patterns.⁴ Also, the selection and design of a monopulse feed network cannot proceed without consideration of errors and their effects on pattern performance. Precomparator phase shifts are more critical than postcomparator errors. After the comparator, any phase shifts or amplitude imbalances do not affect the position of the null but will decrease the sensitivity of the detector.⁶

The body-fixed antenna configuration confronts designers with unique problems. The beam may be very broad for a wide field of view (FOV), or it may be rapidly steered to form a tracking beam. The wide-FOV approach requires that the airframe and the autopilot be more restricted in their responsiveness. The steered-beam approach requires rapid beam forming and signal processing to isolate the missile-body rotational motion properly from the actual target motions. Some body-fixed antennas need to be mounted conformally to preserve the central forward viewing area for a second seeker in a dual-mode configuration.

It is often necessary to be able to integrate and test key receiver front-end elements and the RF elements of the transmitter as part of the seeker-antenna assembly. For example, it is generally possible to integrate in one package the feed antenna, monopulse comparator, mixer or mixers, local oscillator, and transmitter oscillator.⁷

46.3 IMPACT OF AIRFRAME ON ANTENNA DESIGN

The airframe and the autopilot steer the missile according to the guidance-computer commands to minimize the final miss distance at impact. The dynamic behavior of the missile in response to commands consists of attitude changes that cause the gimbal-mounted antenna to receive through an ever-changing portion of the radome.⁸ This, coupled with the natural geometry changes that occur as an engagement takes place, makes the antenna appear to have time-varying directivity and gain properties. The response characteristics of the airframe and the autopilot generate a pseudo-noise influence of the radome-antenna combination.

A definition of the angles relating to the seeker-radome and missile-target geometry is illustrated in Figure 46-3a. Here, the seeker antenna is shown, mounted on a mechanical gimbal whose pointing function is generally controlled by a servo loop. The difference between the actual missile-to-target line of sight (LOS) and the apparent LOS shown in this figure is the radome boresight error (BSE). Missile flight angles are referenced to airframe gyros, while antenna pointing angles are referenced to rate gyros mounted on the antenna gimbal.

For a body-fixed on-board sensor antenna, there is no track loop and the body isolation function is not present; the airframe gyros (roll, pitch, yaw) provide angular references for guidance toward the target. The implementations of these functions vary from system to system. Factors such as operational altitude and range, targets to be engaged, missile speed, and terrain over which missions are to be performed also influence the design.^{9,10}

FIGURE 46-3 Seeker antenna and overall guidance functional diagram: (a) seeker/missile/target angular relationships and (b) tracking system block diagram

The missile-borne gimbaled guidance antenna enters the picture as depicted in the block diagram shown in Figure 46-3*b*. This figure shows the major functional features present in missiles and projectiles with on-board guidance. Through the track loop, the antenna gimbal platform is inertially stabilized in space relative to the LOS, and the monopulse error voltage drives a feedback loop to keep the antenna pointed toward the target.

The airframe and the autopilot steer the missile according to the guidance-computer commands to minimize the final miss distance at impact. The dynamic behavior of the missile in response to commands consists of attitude changes that cause the antenna to receive through an ever-changing portion of the radome. This, coupled with the natural geometry changes that occur as an engagement takes place, makes the antenna appear to have time-varying directivity and gain properties. The response characteristics of the airframe and the autopilot generate a pseudo-noise influence of the radome-antenna combination.

46.4 SEEKER-ANTENNA MECHANICAL CONSIDERATIONS

Generally, the seeker antenna is of the maximum size possible within the limits of the missile-body diameter in order to maximize antenna gain and minimize the antenna beamwidth. Alternatively, conformal- and flush-mounted antennas (most often forward mounted) can utilize the entire conical forward area to achieve maximum gain.¹¹

Gimbaled antenna systems often must mechanically steer not only the antenna structure but also the attendant beam-forming network and critical transmitter and receiver elements. As the mechanical-steering rates become excessive, the conformal-mounted antenna with electronically steered beams must be used.¹⁰⁻¹⁶ When all the seeker-antenna and associated hardware are gimbaled together, the use of lightweight materials may achieve the desired results. Lightweight techniques include the following:^{7,17}

- The use of lightweight honeycomb materials (including low-density dielectric foams) for both filler and structural-load-bearing surfaces. Foam reflectors and waveguide elements including feed horns can be machined and then metallized by vacuum deposition, plating, or similar techniques.
- The use of stripline techniques. Using multilayer techniques, one can have a layer with microstrip radiating elements, a layer with beam-forming networks, and a layer with beam-switching and signal-control elements such as a diode attenuator and phase shifters. The use of plated-through holes and/or pins to make RF connections can eliminate cables and connectors. Excess substrate can be removed and printed-circuit-board edges plated in lieu of the use of mode-suppression screws.
- The use of solid dielectric lenses, above Ku-band, with no significant weight penalty. Lenses can also be zoned to remove excess material.¹⁸

46.5 APERTURE TECHNIQUES FOR SEEKER ANTENNAS

Precise control of both amplitude and phase to permit aperture illumination tailoring is necessary for achieving a well-behaved antenna pattern.¹⁹⁻²⁵ Aperture tapering of rotationally symmetric illuminations starts with the feed itself and continues by varying the energy across the aperture by several methods: corporate-power splitting, aperture-element proportional size or spacing, surface control of the reflector or lens surface, and element thinning.

Circular antennas form the largest single class of seeker aperture antennas. The antenna patterns for circular aperture distributions that apply to seeker antennas are shown in other sections of the Handbook and in Kozakoff.²⁶ The case of cosine on a pedestal with $p = 0.3$ (−10.46 dB) edge illumination or $p = 0.2$ (−13.98 dB) edge illumination is practical when using horn feeds. The uniform illumination condition can be approximated using array techniques, but a tapered illumination is often preferred to achieve lower sidelobes.

Reflector or Lens Antennas

A consideration in the design of monopulse reflector antennas is the four-horn-feed design and the effects of aperture blockage. One criterion posed for an optimum monopulse feed configuration is maximizing the product of the sum times the derivative of the difference error signal.²⁷ The monopulse horn size for optimum monopulse sensitivity is shown in Figure 46-4. The impact of optimizing monopulse feed design on antenna performance is illustrated in Figure 46-5, in which a 5.5-in- (139.7-mm-) diameter aperture is assumed in the calculations. These data illustrate that at millimeter wavelengths (above 30 GHz), the effects of aperture blockage on antenna performance are small for this size of antenna even when a reflector is used.

Other criteria, such as the requirement for equal E- and H-plane antenna beamwidths, may enter into the details of monopulse feed design. An example of a monopulse-feed antenna operating near 95 GHz that meets equal-beamwidth requirements appears in Kozakoff and Britt.²⁸ For operation near 95 GHz, the individual waveguide apertures of the four horn feed were 0.080 by 0.100-in- (2.032- by 2.54-mm). They were fabricated using an electroforming process.

A wide-angle-scan capability can be achieved by using a twist-reflector concept with a rotatable planar mirror.^{29,30} In this configuration, the forward nose of the missile can be approximately paraboloidal-shaped, or the paraboloid can be located inside a higher-fineness-ratio radome. The paraboloid is composed of horizontal metal strips. The movable planar twist reflector uses 45°-oriented strips $1/4\lambda$ above the planar metallic reflector. (Grids may also be used to combine widely separated frequencies to permit dual-band operation.³¹)

Beam steering is obtained by moving the planar mirror. The steering is enhanced because for every 1° that the mirror moves, the beam moves 2°. By using a parallelogram gimbal to move the planar mirror, beam accelerations of 20,000°/s² have been demonstrated.³⁰

FIGURE 46-4 Monopulse antenna horn size or spacing for optimum monopulse sensitivity

FIGURE 46-5 Performance of optimized four-horn monopulse-fed 5.5-in- (139.7-mm-) diameter apertures: (a) sidelobe level and (b) gain degradation

In this situation, a 42° beam scan was achieved with 21° of mirror motion, and less than 2 dB of sidelobe degradation of the sum pattern occurred.

By using a corrugated horn with a rotationally symmetric feed pattern providing a -17 -dB edge taper (capable of achieving a -30 -dB sidelobe level), one can further taper by varying the inner- and outer-surface contour of a collimating lens to achieve a circular Taylor amplitude distribution ($\bar{n} = 7$) with a -40 -dB sidelobe level.¹⁸ Practically, one can make the lens out of a material having an $\epsilon_r = 6.45$ (titania-loaded polystyrene) and follow up with a surface-matching layer made out of a material having an $\epsilon_r = 2.54$ (Rexolite-polystyrene).

Ring-Array, Planar-Array, and Conformal Antennas

Array techniques can be used to provide a nearly planar (flat-plate) aperture. Commonly used are arrays that provide symmetric patterns and offer a maximum use of the available

FIGURE 46-6 Monopulse planar-array geometries: (a) five-ring monopulse array, (b) waveguide slot array, and (c) thinned-slot (image) ring array

circular aperture with reduced grating-lobe potential. In such an array, higher aperture efficiency with low sidelobes can be achieved because of reduced aperture blockage and spill-over. In monopulse applications, it is noted that the ring array contains no central element and exhibits quadrantal symmetry, as indicated in Figure 46-6.

The choices in a ring-array design include the number of rings and the number of elements in each ring and the feed network.^{32,33} Constraints include the following:

- Minimum distance of the outer elements to the antenna edge
- Minimum spacing of the elements as impacted by excess mutual coupling (between elements and quadrants and feed geometry)
- Desired radiation pattern (as impacted by the density tapering)

Optimization of small ring arrays (having diameters $< 10\lambda$) is often carried out heuristically or nonlinearly. Examples of array geometries that have been analytically determined to have -17 - to -20 -dB sidelobes are given in Table 46-2 for the array geometry shown in Figure 46-6a.

Array elements can be of many types.³⁴⁻⁴¹ A two-dimensional array of waveguide slots excited by a network of parallel waveguides forming the antenna structural supports has been used.⁴⁰ Waveguide slot arrays have demonstrated low cross-polarized response as well. The bandwidth of a waveguide slot array is inversely proportional to the size of the array. A variety of outer contours can be utilized to conform to the space available.

Thinning techniques for these types of arrays reduce complexity.⁴² By using an image-element approach, a reduction of the number of elements by over 90 percent is possible (see Figure 46-6c). This method also readily allows for integration of the monopulse comparator.

TABLE 46-2 Data on Five-Ring Monopulse Uniformly Excited Array (Array OD = 8.16λ)³²

Ring number	Case A*	Case B*
	Directivity = 27.6 dB Maximum Sidelobe Level = -20 dB	Directivity = 28.1 dB Maximum sidelobe level = -17 dB
	Radius, λ	Radius, λ
r_1	0.45	0.50
r_2	1.25	1.33
r_3	2.08	2.16
r_4	3.06	2.98
r_5	3.72	3.72

*The maximum outer diameter = 8.16λ for both cases.

FIGURE 46-7 Monopulse circuit for a four-arm spiral antenna

Multimode and Single-Mode Spirals

The multimode spiral antenna is a very broadband, broad-beamed, circularly polarized antenna that is amenable to ARH (antiradiation homing) applications.^{43,44} Such an antenna can also be synthesized by using a circular array.⁴⁵ A simplified circuit to resolve monopulse sum-and-difference patterns is shown in Figure 46-7; typical angular coverage is from $\pm 30^\circ$ to $\pm 40^\circ$. The rather wide instantaneous FOV makes these antennas attractive for body-fixed applications.

The printed-circuit construction of four-arm spirals limits their use to low-power applications. Thus, this type of antenna is almost always used for passive (nontransmitting) applications. Loading techniques can be employed to reduce size, permitting operation at low frequencies. Current fabrication technology permits high-frequency operation to above 40 GHz. Single-mode spirals are also very useful as elements in small arrays. For operation between 2:1 and 3:1 bandwidths, small pyramidal dielectric elements or horns can be placed on the spiral front surface. The conical extensions act as endfire elements that narrow the element beamwidth and aid in suppressing array grating lobes.⁴⁶

46.6 PACKAGING SEEKER ANTENNAS

The seeker antenna functions require some unique considerations.

Conformal Array

Because the typical tactical-sized missile is about six inches in diameter, the seeker antenna must be packaged to accommodate both its own function and be compatible with other missile functions as well. Newer missiles are capable of combining two or more sensing techniques. Thus, clever arrangements of components are needed to accommodate the hardware involved in the seeker functions.

One antenna location, shown in Figure 46-8, is a cylindrical array covering the complete circumference that is located in the forward portion of the missile, offering the forward viewing area for another sensor. The array elements are essentially flush mounted with a minimal depth into the missile interior.

Assuming an actual 5.7-in (144.8-mm) diameter is available, the total array circumferential shaded length about 18-in-(457.2-mm-). This length could accommodate 18 elements of nominal 1-in (25.4-mm) circumferential width. The axial length can be longer than 1 in (25.4 mm). Microstrip antenna elements lend themselves to the seeker package. The array element mounting and dielectric radome cover are compatible with compact seeker electronics.

FIGURE 46-8 Conformal-mounted circumferential seeker antenna array. The portion of the missile forward of the array can be used for another seeker. (Adapted from U.S. patent 6,407,711)

Forward Viewing Array

The seeker antenna may need to provide a dual-polarized monopulse capability and be packaged to work intimately with another sensor. Figure 46-9 shows a similar 6.0-in- (152.4-mm-) diameter antenna package offering this capability. The antenna is comprised of four dual-polarized slotted waveguide subarrays arranged to form an aperture and combined to form the sum, difference, azimuth, and elevation signals, each with the correct sense of circular polarization.

The dual-polarized antenna design uses balanced orthogonal polarizations. This approach provides low cross-polarization interference performance. The use of the slot array provides low loss, compact size, and high-volume producibility.

The antenna is used for the millimeter wave portion of single- or multimode seekers. It is comprised of three major subsystems: a three-layer, meander-line linear-to-circular polarizer; a dual-linear waveguide slot array; and a dual-channel, waveguide monopulse beamforming network. A through-hole in the center of the antenna can accommodate other sensing modes such as laser and infrared.

FIGURE 46-9 Dual-polarized monopulse seeker antenna (Courtesy of EMS Technologies, Inc.)

46.7 SMALL ARRAYS FOR SEEKER ANTENNAS

Arrays of two, three, four, and five elements can be used for seeker antennas in small interferometers. These types of arrays are usually fixed-mounted (nongimballed) and used when pursuit navigation algorithms are suitable. With the addition of a gyroscope to sense missile angular motion, line-of-sight data can be derived.⁴⁷

Good sum-and-difference or phase monopulse angle-tracking performance can be achieved when the array elements, the array beamwidth, and the array element spacing are properly chosen. Broadband performance is often achievable by using antenna elements such as spirals or log-periodic antennas. Small arrays can be used by themselves, or they can illuminate apertures such as reflectors or lenses.

A four-element square or diamond array can be sized to fit within a given missile diameter using

$$D_{\text{missile}} = d_{\text{spiral}}(\sqrt{2} + 1)$$

The spiral diameter is sized for its lowest frequency of operation. Mode 1 spirals usually have a maximum diameter bounded by an upper value of $\lambda/2$ and a nominal value of λ/π . For operation to as low as 2 GHz, the desired missile diameter is between 7.12 in ($\lambda/2$ criterion) or 4.54 in (λ/π criterion). This condition occurs when the spirals of Figure 46-10 are enlarged so that they just touch and collectively fill the full missile diameter. The upper frequency of this type of array is limited by array pattern grating lobes.

Control of the array element pattern is important in reducing energy spillover beyond the difference-pattern lobes. As noted earlier, these lobes and the sum pattern grating lobes can be limited by adding dielectric rods in front of the spiral to cause the spiral antenna element pattern to narrow as the frequency increases. A 3:1 band can usually be achieved.

A four-element array can serve as an RF seeker by utilizing a phase processor. The effects of system errors for such an array on antenna patterns, S curves, and angular sensitivity as ascertained analytically can be used to form a catalog of results that can be employed to diagnose fabrication errors or tolerances based on measured data.⁴⁸

FIGURE 46-10 Four-element square or diamond array fitted within a given missile diameter

46.8 RADOME EFFECTS

The introduction of a protective radome over a seeker antenna results in an apparent boresight-error (BSE) because of the wavefront phase modification over the seeker antenna aperture. A published PC-based software radome code can be used to compute the electrical effects of a radome over a seeker antenna.⁴⁹ These effects need to be carefully considered in the selection of a radome design because they impact seeker-system performance.^{9,50-52}

In the case of pursuit guidance, the miss distance is proportional to the BSE. Conversely, in the case of proportional guidance, it is the boresight-error slope (BSES) that more directly impacts miss distance. The relationship between BSE or BSES and miss distance is not straightforward but generally is quantified only by a hardware-in-the-loop (HWIL)^{53,54} or computer simulation that takes into account a variety of scenarios and flight conditions. A BSE requirement of better than 10 mrad (or a BSES requirement of better than 0.05 deg/deg) and maximum transmission loss of 1.0 dB are typical for many radome types.

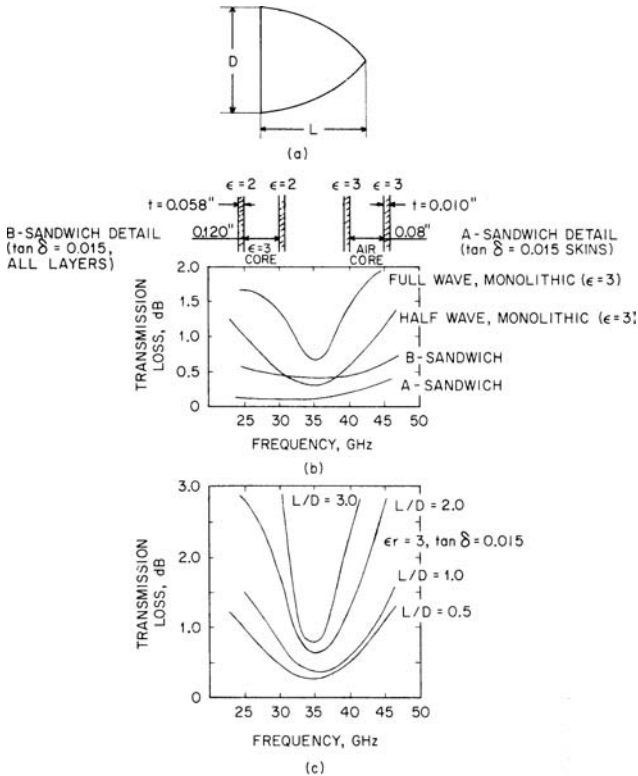

FIGURE 46-11 Missile-radome transmission data: (a) radome geometry, (b) hemispherical-radome ($L/D = 0.5$) performance for a low-velocity ($< \text{Mach } 1$) missile, and (c) monolithic half-wave radome performance for various fineness (L/D) ratios

The method most often employed for the evaluation of radome effects on seeker antenna performance utilizes open-loop testing in a suitable anechoic-chamber facility.⁵⁵ This requires a precalibration of the monopulse error-channel sensitivity in volts per degree without the radome and subsequently measuring the error-channel outputs with the radome over the seeker antenna.

Broadband ARH antennas generally require the use of multilayer radome walls to obtain a required radome bandwidth commensurate with antenna performance. Figure 46-11 illustrates hemispherical-radome performance for half-wave, full-wave, A, and B sandwich walls. Half-wave radomes generally have a useful bandwidth on the order of 5 to 20 percent, depending on dielectric constant and radome-fineness ratio. Higher-order wall radomes have considerably narrower useful bandwidths and thus are limited to narrowband-antenna applications. Figure 46-11 also demonstrates transmission loss versus frequency for a half-wave wall radome when radome-fineness ratio is taken as a parameter.

46.9 EVALUATION OF SEEKER ANTENNAS

Seeker-antenna testing proceeds from conventional methods utilizing anechoic-chamber techniques with the antenna alone.⁵⁶⁻⁶¹ Next, open-loop testing including critical elements of the seeker electronics (*S* curves) is most often performed. Ultimately, a variety of simulations are used to ascertain the seeker-antenna performance in both benign and complex environments.

The many nonlinear elements in the guided missile make complete closed-form analytical simulations unsuitable for final analyses. The precise simulation of these elements is also difficult. The final analyses are best done with an HWIL simulation.⁵²⁻⁵⁴ As many hardware items as possible should be inserted, leaving only the propulsion, aerodynamics, and instrument feedback to be simulated analytically.

There are several concepts for implementing a simulation with seeker hardware. Placing the seeker in an anechoic chamber with the target of appropriate characteristics moved about according to the engagement geometry is one method. Flying a target with the seeker on an orientation table is another. The HWIL simulation serves as a tool not only for statistical performance analysis but for provision of validity information for an improved all-analytical model of the system. The HWIL method provides the only valid present means of evaluating the interaction of the radome-antenna combination in a missile-guidance-seeker environment.

46.10 ADDITIONAL DEVELOPMENTS AND SOURCES OF INFORMATION

A number of allied technology factors⁶²⁻⁶³ that affect the design and fabrication of seeker antennas are summarized in the following:

- Low-mass antenna techniques for high-*g* environments:
 - Use of negative space, i.e., plated hollow areas for feeds and transmission lines, e.g., horns, waveguides
 - Cannon-launched projectile-mounted antennas must withstand *g*-forces at launch of 10,000 to 16,000 *g*
 - Use of physically small (but electrically large) apertures, including classic slots, dipoles, patches, spirals, and Vivaldi slots/notches
 - Use of thin, flat, printed-circuit reflector antennas⁶⁴
- Advanced seeker-antenna manufacturing techniques:
 - Higher millimeter frequencies, i.e., above 100 GHz
 - Nonplanar geometries, i.e., conical spirals
 - Slotted waveguide antennas at Ka-band and higher⁶⁵ and waveguide monopulse comparators at W-band
 - Millimeter-wave microstrip antennas (including annular rings) and microstrip comparators⁴
 - Better packaging techniques to divide aperture space among several antenna requirements^{2,66}

- Small four-element arrays using both amplitude and phase monopulse techniques (amplitude monopulse used to resolve phase ambiguities) and the use of GPS for tactical missile navigation.⁶⁷
- Use of the U.S. Patent Office (<http://patents.uspto.gov/>) to assess extensive information on seeker antenna concepts and fabrication techniques. A short list of related U.S. patents follows:
 - 6,407,711 Antenna Array Apparatus with Conformal Mounting Structure
 - 6,127,985 Dual-polarized Slotted Array Antenna
 - 5,818,393 Wide Field-of-View Fixed Body Conformal Antenna Direction Finding Array
 - 5,686,929 RF Homing Head Antenna System for Missiles
 - 5,483,894 Integral Missile Antenna Fuselage Assembly
 - 5,344,099 Missile Beamrider Guidance Using Polarization Agile Beams
 - 5,307,077 Multi-spectral Seeker Antenna
 - 5,218,361 Interferometer Ambiguity Resolution Using Missile Roll
 - 4,577,196 Missile Mounted Waveguide Antenna
 - 4,431,996 Missile Multi-frequency Antenna
 - 4,204,212 Conformal Spiral Antenna
 - 4,194,204 High Resolution Microwave Seeker

47.1 INTRODUCTION

Although radio direction finding (DF) is as old as radio itself, new algorithms and new techniques are used in modern digital systems. This chapter looks at the classical underpinnings of DF and its modern applications.

Purpose of Direction Finding

In essence, DF is any technique that determines the direction of a radio transmitter.¹ More formally, radio DF is defined by the National Telecommunications and Information Administration (NTIA) as: “the determination of the position, velocity and/or other characteristics of an object, or the obtaining of information relating to these parameters, by means of the propagation properties of radio waves.”² Radio DF systems as well as radar and navigation systems are registered in the U.S. Patent system under Class 342.

Application of Direction Finding Systems

The practical applications of DF are numerous:

- **Radio navigation and satellite global positioning services** The terrestrial Long Range Navigation (LORAN) uses phase-comparison of beacon signals for hyperbolic line of bearing (LOB) and geolocation. The U.S. satellite Global Positioning System (GPS) and the Russian counterpart Global Navigation Satellite System (GLONASS) provide time of arrival signals for measuring precise geolocation and velocity.
- **Search and rescue services** The U.S. Coast Guard and worldwide organizations such as COSPAS-SARSAT monitor emergency radio channels for rescue. Both terrestrial and satellite DF networks are used to continuously locate emergency signals.
- **Signal direction finding and location systems** These systems operate throughout the radio spectrum from the high-frequency (HF) band to 18 GHz for purposes that range from animal tracking to locating stolen cars to gathering military intelligence.
- **Homing systems** These are typically small DF systems designed to guide a weapon or artillery shell toward a location. Active RF systems use radar, while passive systems can DF target emitter signals (i.e., “home on jam”).
- **Warning systems** Also called Electronic Support Measure (ESM) systems. These are typically rapid response DF and identification systems to protect against hostile radars and homing systems.
- **Radio astronomy** These are characterized by large antenna dishes or arrays that can be synchronized into large interferometric systems spanning continents. The resulting radio maps show density and velocity of natural signals from spin-flip states of hydrogen and various molecular energy state transitions.
- **Smart antennas** Recent advances in adaptive arrays or “smart antennas” provide spatial isolation of emitters, interference cancellation, and resistance to multipath signal fading³ (see Chapter 25).

Brief History of Direction Finding

Heinrich Hertz began radio DF with experiments in the directionality of antennas in 1888. The first mobile DF system occurred in 1906 when the Stone Radio & Telegraph Co.

installed a direction-indicating device on the U.S. naval collier *Lebanon*. The device was not particularly effective as it “necessitated the swinging of the ship to obtain the maximum signal [strength] and the bearing.”⁴ In 1915 Dr. Frederick A. Kolster, a former Stone Radio & Telegraph employee working at the U.S. Bureau of Standards, discovered that wire wound on a rectangular frame could be rotated to determine the direction of a signal. One year later, 20 Kolster loop DF systems called the “SE 74” were installed on U.S. ships.⁵

Radio navigation service experiments continued at the U.S. Bureau of Standards, resulting in the first workable aircraft DF system in the early 1920s.⁶ The first aircraft DF antennas were manually rotated, but by the 1940s, systems such as the Japanese Type 1-3 system and the Fairchild Aero Compass from which it was copied, provided a twin-loop antenna rotated by a motor.⁷

In the mid-1920s Robert Watson-Watt, inventor of radar, conducted DF research at Ditton Park. Co-researcher Edward Appleton rediscovered the Heavyside propagation layer 300 km above the earth’s atmosphere, which Watson-Watt dubbed the “ionosphere”.⁸ By 1937 the U.S. Navy was using the ionosphere for long-range High Frequency Direction Finding (HFDF, pronounced “Huff-Duff” by old-timers) and in 1941 established both the Atlantic and Mid-Pacific Strategic Direction-Finder Nets, giving Allies the worldwide capability to track German submarines.⁹ In 1943 the Germans improved HFDF with the Wullenweber circularly disposed antenna array (CDAA). After the war, it was copied by the Russians (naming their version “Krug”) and by the U.S. (whose operators called it the “Elephant Cage” for its size).

The LORAN system was also an outcome of World War II. Developed at the Massachusetts Institute of Technology, the system used a set of continuous wave beacons that could be phase differenced for hyperbolic contours of constant phase. LORAN-C replaced the original LORAN in the 1950s using pulsed signals, resulting in 0.5-km accuracy.

The mathematics for using Doppler direction finding were first developed by the Russian Kotelnikov,¹⁰ but it was the U.S. who launched the first operational satellite system in 1960. The system was called “Transit” and it used a cluster of six low earth orbit (LEO) satellites to provide precise 150/400-MHz reference transmissions.¹¹ In 1967 the Soviet Union launched Tsyklon, a similar Doppler navigation system.¹² Today the U.S. NAVSTAR GPS and its Russian counterpart, GLONASS, provide precise time, position, and velocity determination worldwide.

Using the same Doppler method as for navigation, Lehan and Brown received U.S. Patent 3063048 for a satellite search and rescue location system.¹³ In 1977 the COSPAS-SARSAT satellite search and rescue system was realized as a joint U.S.-Soviet effort that now includes over 35 countries from Algeria to Vietnam.¹⁴

Since 1980 satellite and terrestrial DF systems have gone through a digital revolution, replacing analog DF processing with digital algorithms such as Bartlett correlation and Schmidt’s now famous Multiple Signal Classification (MUSIC) algorithm.¹⁵

Section 47.2 examines DF systems and sources of error. Section 47.3 looks at specific antenna array systems, while Section 47.4 surveys digital DF algorithms. Section 47.5 explains two techniques for combining LOBs into geolocations, and because of the parallel in approach, Section 47.5 presents a basic Time Difference of Arrival (TDOA) geolocation algorithm.

47.2 DIRECTION FINDING SYSTEM DESIGN

DF systems with antenna arrays determine a signal’s LOB by using antenna voltage measurements. While signal direction may be sufficient for many applications, a network of DF systems can combine LOBs to form signal “fixes” or geolocations. Systems that measure time and frequency without antenna arrays may work in a Time Difference of Arrival (TDOA) network to determine signal geolocation directly without LOBs.

System Components

At its core, a DF system requires an antenna array, a receiver to amplify and filter antenna radio frequency (RF) voltages, some means to process the antenna array voltages into a signal angle of arrival (AOA), and an operator display (see Figure 47-1, solid boxes). Modern DF systems now include automated signal detection, classification, digital processing, and remote display (see Figure 47-1, dotted boxes). In all, modern DF systems are comprised of the following elements (numbers correspond to those in Figure 47-1):

1. An antenna or antenna array to collect signal energy from an emitted signal. Arrays can span continents, be compact in a handheld wireless device, or be virtual extensions of an existing array, exploiting techniques such as ESPRIT.¹⁶
2. An RF distribution system to provide interference filtering, antenna element combining, antenna element selection or switching, and distribution of RF output to the rest of the DF system. An important attribute of the RF distribution system is to allow calibration signals to be switched or multiplexed with the RF input.
3. A calibration system that provides known noise characteristics or test signal amplitude and phase to allow measurement of filter, cable, and receiver effects on system estimates of time, amplitude, and phase.
4. A receiving system to measure the response of the antenna system. RF radio waves are transformed into electron currents. Historic systems used analog measurements and processes to determine DF. Modern systems use analog to digital (A/D) converters to represent signal measurements in digital form.
5. A time and frequency reference system. Modern systems that digitize voltages and use both amplitude and phase information need all receivers and A/D converters synchronized.
6. A DF processor to extract radio determination information such as signal LOB and elevation angle. DF processors may estimate geolocation from multiple signals (e.g., navigation satellites), from coordinated DF systems (e.g. a worldwide HFDF network), or from a single DF system using running LOBs.
7. The DF processor may need extensive antenna array manifold calibration data on the response of the array at different signal angles and different frequencies. Some DF processors, such as the Watson-Watt DF system, use a predetermined mathematical formulation of the signal response. Correlation and eigen decomposition systems process the signal covariance matrix.
8. A signal detection and qualification processor. It is important for the DF processor to provide valid measurement output on signal energy. Further, some systems may qualify the energy as a “signal of interest” before performing DF.
9. In modern DF systems, there is usually a function of signal parameter collection, including time, frequency, angle of arrival, signal strength, etc.
10. If the DF system is on a mobile platform, platform position, velocity, time (PVT), attitude, and heading reference system (AHRS) information is required. This allows transformation of platform measured AOA to earth fixed LOB.
11. Network infrastructure allows control and display to be distributed worldwide to a multitude of users.
12. What was once a simple cockpit indicator has evolved into remote displays of LOBs, emitter location estimates, and confidence error ellipses on a geographical information system (GIS) used by one or many operators.

FIGURE 47-1 Traditional (solid boxes) and modern (dotted boxes) DF system design

The use of real-time signal-processing techniques now makes it possible to use phase and amplitude responses, employ antennas of any polarization, and to dynamically calibrate the receiver system for accurate measurements. Now the Internet makes it possible for remote command and control and worldwide data distribution.

System Accuracy and Sources of Error

Direction finding and geolocation system performance are measured primarily in terms of accuracy, timeliness, and throughput. DF accuracy is usually specified in degrees root mean squared (rms), while TDOA systems use rms time. Geolocation accuracy for both is described in terms of a confidence containment ellipse and occasionally in terms of Geometric Dilution of Precision (GDOP). Emitter to receiving site geometry is important and can greatly influence geolocation accuracy. The best geolocation accuracy is obtained when the emitter is in the center of an equilateral triangle of sensor sites.

For DF AOA systems, as a rule of thumb, the array DF accuracy is inversely proportional to the array aperture size. The upper frequency limit of the array is set by the Nyquist spacing of array elements. Ambiguous AOA occurs if the spacing exceeds $c/2f$ where c is the speed of light and f is the highest frequency of operation. DF accuracy degrades proportional to $1/f$ (see Figure 47-2), and there is no distinct bound for lowest frequency of operation. Most common wideband antenna arrays span a frequency range of 1:5 up to 1:8. For example, the VHF/UHF range can be broken into arrays that span 100–500 MHz and 500–3000 MHz.

An array can be made “sparse” when antenna elements are left out of a periodic structure. For example, a simple uniform linear array can be altered to minimal redundancy¹⁷ by leaving certain elements out. Additional elements can be added to an array to provide a larger eigen processing space that gives interference cancellation capability, immunity to fading, and increased hearability, especially in the presence of co-channel signals.

Other key parameters influencing DF accuracy include signal-to-noise ratio (SNR) resulting from a combination of emitter power, propagation distance and path mode (e.g. HF ground wave, ordinary and extraordinary skywave paths, and ionospheric tilting), atmospheric propagation (ducting, especially at VHF and UHF frequencies), atmospheric noise (e.g. lightning in HF), manmade noise (e.g. power line noise, automobile, broadcast

FIGURE 47-2 DF accuracy vs. frequency for VHF array 100–500 MHz

transmitters, etc.), and system internals (antenna gain, cable loss, receiver noise figure, and signal integration time). All of these effects can degrade and possibly corrupt DF results.

Antenna arrays and the systems behind them are usually calibrated and characterized under high SNR conditions, and whenever possible under threshold or minimum SNR conditions. The high SNR conditions establish instrumentation error, while threshold SNR testing more closely predicts operational performance. DF rms error and the Cramer-Rao bound is discussed at the end of Section 47.4.

For TDOA systems, Stein¹⁸ shows that the rms error in measurement from cross correlating two signal samples is based on the Cramer-Rao bound

$$\sigma_{\text{TDOA}} = \frac{\sqrt{3}}{\pi B_s \sqrt{B_{\text{rcv}} T \gamma_{\text{SNR}}}} \quad (47-1)$$

where B_s is the signal bandwidth, B_{rcv} is the receiving system bandwidth, T is correlation time, and γ_{SNR} is the input correlation SNR. γ_{SNR} is derived from the sensor site pair contributing to the correlation

$$\frac{1}{\gamma_{\text{SNR}}} = \frac{1}{2} \left[\frac{1}{\text{SNR}_1} + \frac{1}{\text{SNR}_2} + \frac{1}{\text{SNR}_1 \cdot \text{SNR}_2} \right] \quad (47-2)$$

When the site pair signals are well above the noise floor, the effective γ_{SNR} is just the average of the two intercepts and the cross term $1/\text{SNR}_1 \text{SNR}_2$ can be ignored. Under low SNR conditions, all terms must be considered, and under very low SNR conditions, the cross term of Eq. 47-2 dominates. If one of the site pairs has a strong signal intercept, the correlation process can “pull out” the signal from the second site even when the signal is buried in noise (see Table 47-1).¹⁹

TABLE 47-1 SNR Input, Correlation Gain, and TDOA Measurement Error

Sensor 1 SNR (dB)	Sensor 2 SNR (dB)	Effective Input SNR to Correlator (dB)	Time-Bandwidth Ideal Correlation Gain (dB)	Correlator Peak SNR (dB)	TDOA error (ns)
20	20	20.0	37.0	57.0	16
20	12	14.3	37.0	51.3	30
20	4	6.9	37.0	43.9	71
20	0	2.9	37.0	39.9	111
20	-4	-1.0	37.0	35.9	176

System Calibration and Characterization

A core set of DF processing algorithms relies on the existence of a well-defined array manifold. The array manifold describes the antenna voltage response for an arbitrary N -element array from a set of M signal azimuth angles θ . This can be written in a matrix as

$$\mathbf{a}(\theta) = \begin{bmatrix} a_1(\theta_0) & a_1(\theta_1) & \cdots & a_1(\theta_M) \\ a_2(\theta_0) & a_2(\theta_1) & \cdots & a_2(\theta_M) \\ \vdots & \vdots & \ddots & \vdots \\ a_N(\theta_0) & a_N(\theta_1) & \cdots & a_N(\theta_M) \end{bmatrix} \quad (47-3)$$

Actual array manifolds are composed of more terms than the idealized response to azimuth described in Eq. 47-3. Array manifolds are taken at discrete steps of azimuth over many frequencies (typically at steps ~ 5 percent of the frequency) and may also include the dimensions of signal elevation and polarization angle. When raw manifold data is measured on a range, the result must be smoothed and interpolated to produce a manifold with uniform azimuth steps. Metadata may be included with the manifold to indicate what frequency, elevation, polarization, or other parameters are used for the manifold creation.

The accuracy of the array manifold typically dominates the system error budget and establishes DF performance. The design of the array can mitigate manifold errors through careful selection of antenna element position and number of elements. Both of these choices are almost always constrained by the platform or site physical boundaries and obstacles, and by the number of processing resources available.

For fixed-site HF antenna arrays, the electrical properties of the ground plane contribute significantly to low angle signal response, particularly the signal magnitude. For this reason, phase-only solutions should be considered. Site errors can be caused by array element interaction with adjacent antennas and nearby structures (mutual coupling, multipath, and blockage), and terrain irregularity (ground plane discontinuities). More information on site errors can be found in Gething.²⁰

For transportable or mobile systems, the arrays may need preliminary Numerical Electromagnetics Code (NEC) modeling for antenna position selection. Many times there is a difference between NEC modeling and actual field measurements (see Figure 47-3).

As expected, accurate measurements are typically difficult to obtain near resonant frequencies when the array antennas electrically couple with other antennas or structures. There is an unwritten law of DF that frequency ranges which are difficult to calibrate tend

FIGURE 47-3 (a) VHF array phase and (b) gain comparison between NEC and measurement

to match the ranges where the greatest manifold accuracy is needed. Range calibration planning is required to ensure that all frequencies, azimuth and elevation angles, and signal polarizations are adequately covered.

The process of array manifold generation is performed using “collect” and “verify” functions. For the “collect,” test emissions are generated at the frequencies and polarizations of interest and the antenna array is rotated and/or tilted for the range of azimuths and elevations of interest. This may be done at a test range where the antenna array is tilted and rotated, or done on a ship or aircraft moving in a circle, arc, or other pattern at a distance from the test emitter. DF array voltages are recorded in approximately equal steps (e.g. every 1° in azimuth and at FCC allowable frequencies), smoothed, and interpolated to the final array manifold.

For the “verify,” the test emitter repeats a subset of the “collect” frequencies and polarizations. Additional frequencies are also included. The DF system receives and processes these emissions using the prepared “collect” array manifolds and computes the LOB rms error to the test emitter. Figure 47-4a illustrates LOB error magnitude versus both azimuth (y-axis degrees) and frequency (x-axis MHz). Figure 47-4b plots aggregate rms error (y-axis degrees) across the azimuth range versus frequency (x-axis MHz). The LOB accuracies expected from the system and array manifold are determined and verified in this fashion.

Built-in system features that facilitate testing of individual antenna elements, cabling loss, time delay and phase error, and overall system processing are vital to long-term AOA direction finding and TDOA geolocation effectiveness. Without such features, degradations in antenna dielectric or temperature changes in electrical properties go uncalibrated. Since DF systems often coexist with other electronic equipment, antenna element responses may change when nearby equipment and structures change. Degradations are manifested as a lack of DF productivity or increase in wild LOB estimates. Antenna designs need to include the ability to inject, couple, and radiate calibration signals without impacting voltage standing wave ratio (VSWR) and reliability.

47.3 DIRECTION FINDING SYSTEM EXAMPLES

This section examines the radio DF systems of the classic Wullenweber CDAA, the popular amateur pseudo-Doppler DF system, the historic Watson-Watt DF system, variations of the *N*-channel DF system, and Butler DF using antenna phase combining.

FIGURE 47-4 (a) Azimuth error vs. azimuth and frequency and (b) mean azimuth error vs. frequency

CDAA Goniometer Direction Finding System

During the 1950s the University of Illinois improved the HFDF Wullenweber CDAA for the U.S. Navy. A ring of 120 monopole antennas was cabled to a central operations building for HF analog beam combining. In the building, matched cables from the antennas were brought together at a circular stator. A spinning rotor, called a *goniometer*, capacitively coupled to 36 contiguous elements of the stator at any moment in time provided both summed and differenced outputs. Thus, the goniometer acted both as a commutator sequentially switching between antenna elements and as a beamformer.

The goniometer delay lines (see Figure 47-5) were electrical lengths equal to the free-space path of the signal to the antenna elements referenced to the center of the goniometer.

The HFDF operator could select either the sum or the difference output on a CRT display with a synchronized rotating time base so that the response pattern of the antenna appeared as a polar beam pattern centered on the direction of the emitter. When searching for an emitter, the sum mode was used, but when the emitter had been identified, the difference mode was used so that the sharp null response pattern displayed azimuth angle with maximum accuracy.

Pseudo-Doppler Direction Finding System

The pseudo-Doppler DF system is a phase-measurement system that uses commutation and stems from the research of Earp and Godfrey in 1947.²¹ This DF system is sometimes described in terms of a rotating antenna and the Doppler effect. However, the antennas do not move and there is no change of frequency due to true Doppler ($\Delta f = v f / c$). Rather, this is a clever system that measures signal phase changes using commutated (switched) sequential elements located on the circumference of a circle.

FIGURE 47-5 CDAA array goniometer beamforming

As each antenna element is sampled, the signal phase appears spatially shifted. The pseudo-Doppler DF system (see Figure 47-6) relies on a very short sampling time from each element. This is done by using a simple pin-diode set of switches that funnels each antenna element sequentially into a common RF path. The spatially induced phase shifts become manifest in the FM demodulator as slightly different audio tones. The audio is

FIGURE 47-6 Pseudo-Doppler DF system using phase commutation

integrated into different summing units, commutating them synchronously at the same clocking speed that sampled the antenna elements. The integrated voltages are fitted with a sine curve whose phase is directly proportional to signal azimuth θ .

Watson-Watt Direction Finding System

The Watson-Watt DF system is a simple, but continuous, amplitude comparison scheme using two orthogonal Adcock beamforming arrays.²² Each Adcock array is made of two dipole elements that are phase-reversed to create a figure “8” beam pattern (see Figure 47-7). The optimal array spacing is about $\lambda/8$ with relatively short (0.1λ) dipole element lengths.

The Watson-Watt Adcock DF process (see Figure 47-8) uses two orthogonal Adcock arrays nicknamed the “sine” and “cosine” receiver channels, where the angle of arrival θ is estimated by taking the arctangent of the voltages from these two RF channels.²³

$$\theta = 90 - \arctan\left(\frac{V_{\sin}}{V_{\cos}}\right) \quad (47-4)$$

The Watson-Watt DF process has two fundamental problems: first, the correct quadrant of the azimuth cannot be determined uniquely, and second, the arctangent approximation deviates as the array diameter to signal wavelength (D/λ) ratio changes. That is, Eq. 47-4 is only an approximation to the true relationship between the two antenna array voltages, which is fully given as

$$\frac{V_{\sin}}{V_{\cos}} = \frac{V(E_2 - E_4)}{V(E_1 - E_3)} = \frac{\sin\left(\frac{\pi D}{\lambda} \sin(\theta)\right)}{\sin\left(\frac{\pi D}{\lambda} \cos(\theta)\right)} \quad (47-5)$$

The LOB error in using the Watson-Watt arctangent approximation is illustrated in Figure 47-9.

FIGURE 47-7 Adcock antenna and azimuthal beam pattern

FIGURE 47-8 Watson-Watt DF system

Brueninger Direction Finding System

To correct the deficiencies of Watson-Watt DF, the Brueninger DF system makes a number of improvements:

1. A sense (reference) antenna is used to distinguish signal phase that resolves LOB quadrant ambiguities. The omni antenna may be a separate antenna or can be formed from the sum of all four Adcock elements.

FIGURE 47-9 Watson-Watt DF error

- More than two antenna elements may be combined to create the sine and cosine beam patterns (e.g. a symmetric set of 8 or 16 dipoles is common).
- Explicit phase-amplitude correlation methods are used instead of taking the arctangent of voltages (e.g. Bartlett correlation DF is common).

The Brueninger DF uses three RF input channels: omni, sine, and cosine channels. Modern systems use A/D voltage conversion for digital RF processing, as shown in Figure 47-10.

In this example the DF processor implements the Bartlett correlation algorithm exploiting both the phase and amplitude of the voltages. The RF omni, sine, and cosine beam pattern complex voltages ($1 + jQ$, or “IQ” for short) are collected into an array manifold over 0° to 360° in azimuth.

To determine the direction of a signal, the voltages v_o , v_s , and v_c from the omni, sine, and cosine RF channels are measured in K snapshots, forming a voltage matrix representing all data. The voltage matrix is then used to form a time-integrated covariance matrix, \mathbf{R} :

$$\mathbf{v} = \begin{bmatrix} v_o(1) & v_o(2) & \cdots & v_o(K) \\ v_s(1) & v_s(2) & \cdots & v_s(K) \\ v_c(1) & v_c(2) & \cdots & v_c(K) \end{bmatrix} = \begin{bmatrix} \hat{v}_o \\ \hat{v}_s \\ \hat{v}_c \end{bmatrix} \quad (47-6)$$

where $v_n(k)$ indicates the k th snapshot of complex voltages from element n = omni, sine, and cosine and \hat{v}_n is the time set of voltages with time indices suppressed.

The covariance matrix (Eq. 47-7) is the product of the voltage matrix \mathbf{v} and its Hermitian transpose \mathbf{v}^H and is normalized by $1/K$ samples:

$$\mathbf{R} = \frac{1}{K} \mathbf{v} \mathbf{v}^H = \frac{1}{K} \begin{bmatrix} \hat{v}_o \hat{v}_o^T & \hat{v}_o \hat{v}_s^T & \hat{v}_o \hat{v}_c^T \\ \hat{v}_s \hat{v}_o^T & \hat{v}_s \hat{v}_s^T & \hat{v}_s \hat{v}_c^T \\ \hat{v}_c \hat{v}_o^T & \hat{v}_c \hat{v}_s^T & \hat{v}_c \hat{v}_c^T \end{bmatrix} \quad (47-7)$$

FIGURE 47-10 Brueninger omni, sine, and cosine DF system

Bartlett correlation uses the covariance matrix \mathbf{R} and the corresponding array manifold $\mathbf{a}(\theta)$ (interpolated to signal frequency) to form a correlation coefficient $C(\theta)$ for every discrete θ in the antenna manifold:

$$C(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{R} \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \mathbf{a}(\theta)} \quad (47-8)$$

The coefficient $C(\theta)$ can be normalized to values 0-1 by multiplying by $1/\text{trace}(\mathbf{R})$. Once $C(\theta)$ is formed, the Bartlett DF process looks for the maximum $C(\theta)$ using standard peak finding and interpolation techniques (see Figure 47-11a). In a simulation, all signal azimuth angles can be examined to create a correlation surface (see Figure 47-11b). With a VHF four-element Adcock array 40 cm in diameter, the bearing error at 150 MHz is about 2° rms.

Commuted Direction Finding Systems

As described earlier in this section, the CDAA and pseudo-Doppler DF systems use antenna element commutation. The Brueninger DF system and other arbitrary DF arrays can also be commuted. One antenna element (usually the “omni”) is selected as the reference element to which all other antenna elements are sequentially compared. Although the array manifold remains the same, the covariance matrix becomes sparse. For example, if antenna element #1 is the reference element, the covariance matrix for an N -element array becomes

$$\mathbf{R} = \frac{1}{K} \begin{bmatrix} \hat{\mathbf{v}}_1 \hat{\mathbf{v}}_1^T & \hat{\mathbf{v}}_1 \hat{\mathbf{v}}_2^T & \cdots & \hat{\mathbf{v}}_1 \hat{\mathbf{v}}_N^T \\ \hat{\mathbf{v}}_2 \hat{\mathbf{v}}_1^T & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ \hat{\mathbf{v}}_N \hat{\mathbf{v}}_1^T & 0 & \cdots & 0 \end{bmatrix} \quad (47-9)$$

The Bartlett Eq. 47-8 is modified to the commuted form

$$C(\theta) = \frac{\mathbf{R}^H \mathbf{a}(\theta)}{[\mathbf{a}(\theta)^H \mathbf{a}(\theta)]^{\frac{1}{2}}} \quad (47-10)$$

FIGURE 47-11 (a) Bartlett correlation with peak finding and (b) Bartlett correlation surface

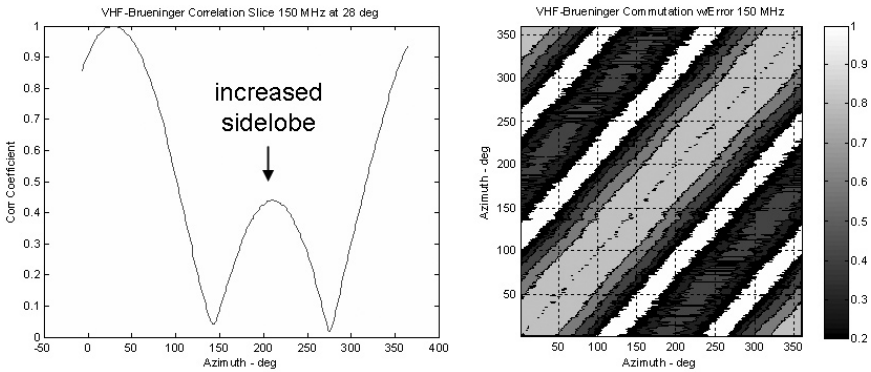

FIGURE 47-12 VHF Brueninger commutated DF (a) correlation with signal at 28° and (b) correlation surface

In spite of what appears to be a paucity of data, DF commutation using the Bartlett algorithm performs nearly as well as the full N -channel solution provided that the total number of voltage samples is the same. However, an N -element commutated array takes N times longer to collect the same number of RF voltage samples. For example, the Brueninger omni, sine, cosine DF system performing three-channel correlation (see Figure 47-11) can be compared to two different commutation variations: a Brueninger commutated system (see Figure 47-12) and a four-element array that is commutated directly without Adcock element combining (see Figure 47-13). As in the previous section, the array example contains four VHF dipoles on a 40-cm circle operating at 150 MHz. Notice that for Brueninger commutation, there is an increase in spatial sidelobes that is not present in four-element sampling.

Why commute? Because it reduces the amount of DF hardware by a factor of $2:N$, which for an 8- or 16-element array can be significant. Regardless of array size, the commutating system only requires two channels of filters, tuners, and A/D converters. Similar efficiencies are gained in digital signal processing. However, the commutation system pays a penalty in time to collect the same number of data snapshots and may totally corrupt the covariance matrix if either the signal transmission is shorter than the commutation cycle time or two or more signals occur at the same frequency during the commutation cycle time.

FIGURE 47-13 VHF four-element commutated DF (a) correlation with signal at 28° and (b) correlation surface

FIGURE 47-14 (a) Fast Fourier transform and (b) Butler Matrix antenna combining

Butler Direction Finding System

When discussing antenna element combining, people often confuse the Brueninger and Butler combiners. The Brueninger, even in its most complex form, only phase reverses antenna elements by 180° before combining, and the result is always three outputs of an omni, sine, and cosine phased beam pattern. Butler combining, most often implemented as a “Butler Matrix” (see Figure 47-14b), is more akin to fast Fourier transform (FFT) and uses combinations of 45° , 90° , and 180° phase shift components.

The FFT example above shows eight inputs and the corresponding eight outputs after “bit reversal” that reorders the output. If the input is time-ordered data, the output is frequency-ordered data with $F(0)$ being the DC component. Butler antenna combining follows the same “butterfly diagram.” Each node creates a sum and difference $(A + B)$ and $(A - B)$ without exponential phase weighting. The phase weighting comes at discrete points in the diagram, requiring 45° and 90° phase shifters. If the input is RF energy from eight equally spaced antennas around a circle, the output is spatial phase shifted modes. Mode 0 has no spatial phase shifting with respect to signal azimuth and is exactly equivalent to an omnidirectional beam combiner. Mode 1 and Mode 7 (referred to as Mode -1) have spatial phase shifting proportional to signal azimuth. Similarly Mode 2 and 6 (Mode -2) have spatial phase shifting proportional to twice the signal azimuth. Mode 3 has spatial phase shifting proportional to three times the signal azimuth.

Figure 47-15a shows a Monte Carlo simulation of Mode 0 and Mode 1 while Figure 47-15b shows the corresponding Butler DF response using the same notional VHF four-element array used earlier in Section 47.3.

FIGURE 47-15 (a) Butler Mode 0 and 1 and (b) resulting DF output

The Butler system uses Mode 0 for signal acquisition and reference to which other modes are phase compared. Mode 1 is typically used for coarse DF with the DF algorithm switching to Mode 2 and even Mode 3 for higher resolution. The DF cascade is necessary because Mode 2 and Mode 3 by themselves are double and triple valued over the full azimuth range and need guidance to signal direction from the previous stage.

47.4 DIRECTION FINDING ALGORITHMS

Modern radio DF systems are dependent upon the direction finding algorithm. Section 47.3 introduced the Bartlett DF algorithm, but it is just one of a host of DF solutions. In this section, we consider several classes of DF algorithms, which include correlation-based, eigen-structured, root-finding, and maximum-likelihood algorithms. We then introduce the Cramer-Rao bound (CRB) that specifies the lower bound for DF error due to additive white Gaussian noise. We then compare various DF algorithms against the CRB. Lastly, we consider the effects of correlated cochannel interference on DF performance.

Basic Correlation Algorithms

We have already introduced the Watson-Watt voltage comparison algorithm and Bartlett correlation for Brueninger and commutated arrays. Here we present a comparison of generic DF algorithms that can be applied to any arbitrary array geometry. Two matrices define the environment that the DF algorithms operate in. The first is \mathbf{a} , the N -element by M -azimuth array manifold that specifies the complex response of each of the N elements over the M azimuths in the field of regard. The second is the sampled signal voltage \mathbf{v} , which is an $N \times K$ matrix, where K is the number of signal samples:

$$\mathbf{a}(\theta) = \begin{bmatrix} a_1(\theta_0) & a_1(\theta_1) & \cdots & a_1(\theta_M) \\ a_2(\theta_0) & a_2(\theta_1) & \cdots & a_2(\theta_M) \\ \vdots & \vdots & \ddots & \vdots \\ a_N(\theta_0) & a_N(\theta_1) & \cdots & a_N(\theta_M) \end{bmatrix}, \mathbf{v} = \begin{bmatrix} v_1(0) & v_1(1) & \cdots & v_1(K) \\ v_2(0) & v_2(1) & \cdots & v_2(K) \\ \vdots & \vdots & \ddots & \vdots \\ v_N(0) & v_N(1) & \cdots & v_N(K) \end{bmatrix} \quad (47-11)$$

The covariance matrix remains defined as $\mathbf{R} = \frac{1}{K} \mathbf{v} \mathbf{v}^H$. Using these definitions, various correlation DF algorithms have been created.^{24,25}

$$\text{Bartlett (Normalized):} \quad C(\theta) = \left(\frac{1}{\text{tr}(\mathbf{R})} \right) \frac{\mathbf{a}(\theta)^H \mathbf{R} \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \mathbf{a}(\theta)} \quad (47-12)$$

$$\text{Capon (Classic):} \quad C(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \mathbf{R}^{-1} \mathbf{a}(\theta)} \quad (47-13)$$

$$\text{Capon (Smooth):} \quad C(\theta) = 1 - \frac{\mathbf{a}^H(\theta) \mathbf{R}^{-1} \mathbf{a}(\theta)}{\mathbf{a}^H(\theta) \mathbf{a}(\theta)} \quad (47-14)$$

$$\text{Maximum Entropy:} \quad C_k(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \mathbf{c}_k \mathbf{c}_k^H \mathbf{a}(\theta)} \quad (47-15)$$

The performance of these algorithms will be given later in the chapter, in the section “DF Algorithm Comparison.” For the Bartlett algorithm, we included the factor $1/\text{trace}(\mathbf{R})$ to ensure $C(\theta)$ varies between zero and one. The Capon algorithm is written in both its classic form and in a smooth (inverted) form that ensures $C(\theta)$ varies between zero and one and allows easier peak interpolation when using discrete array manifold θ steps. For the Maximum Entropy algorithm, \mathbf{c}_k is the k th column vector of the inverse covariance matrix (\mathbf{R}^{-1}) .

Eigen Structured Algorithms

Many DF algorithms depend upon decomposing the covariance matrix into subspaces that comprise the signal and noise. One of the first spectral estimation methods using eigenvectors was developed in 1973 by V. F. Pisarenko,²⁶ whose eigen method originally focused on harmonic decomposition. The Min-Norm eigen approach was developed in 1983 by Kumaresan and Tufts.²⁷ However, the most popular and versatile algorithm is Schmidt’s 1986 MUSIC algorithm.¹⁵ The algorithms are

$$\text{Pisarenko:} \quad C_k(\theta) = \frac{1}{|a(\theta)^H \bar{e}_k|^2} \quad (47-16)$$

$$\text{Min-Norm:} \quad C_k(\theta) = \frac{(u_k^T \mathbf{E}_N \mathbf{E}_N^H u_k)^2}{|a(\theta)^H \mathbf{E}_N \mathbf{E}_N^H u_k|^2} \quad (47-17)$$

$$\text{MUSIC (classic):} \quad C(\theta) = \frac{1}{\mathbf{a}(\theta)^H \{\mathbf{E}_N \mathbf{E}_N^H\} \mathbf{a}(\theta)} \quad (47-18)$$

$$\text{MUSIC (smooth):} \quad C(\theta) = 1 - \frac{\mathbf{a}^H(\theta) \{\mathbf{E}_N \mathbf{E}_N^H\} \mathbf{a}(\theta)}{\mathbf{a}^H(\theta) \mathbf{a}(\theta)} = \frac{\mathbf{a}^H(\theta) \{\mathbf{E}_S \mathbf{E}_S^H\} \mathbf{a}(\theta)}{\mathbf{a}^H(\theta) \mathbf{a}(\theta)} \quad (47-19)$$

The performance of these algorithms will also be given later in the chapter, in the section “DF Algorithm Comparison.” For the Pisarenko algorithm, \bar{e}_k is one or more eigenvectors associated with the smallest (noise) eigenvalues. The span of the eigenvectors is of dimension N , the number of elements in the array. We normally expect only one signal present for DF. Hence the signal eigenvector \mathbf{E}_S is of dimension $N \times 1$, and \mathbf{E}_N , the matrix of noise eigenvectors, is of dimension $N \times (N - 1)$. If D co-channel signals are present in the voltage samples that make up the covariance matrix, \mathbf{E}_S is an $N \times D$ subspace and \mathbf{E}_N is an $N \times (N - D)$ subspace.

For the Min-Norm algorithm, u_k is the k th column of an $N \times N$ identity matrix. The MUSIC algorithm is presented in its classical form in Eq. 47-18, which shows distinctive sharp spectral peaks, and is presented in a smoothed form in Eq. 47-19, which has smoother peaks and is easier to interpolate when using a discrete array manifold. Further, MUSIC is written using either the noise or signal eigenvectors \mathbf{E}_N or \mathbf{E}_S : choose the form that has the smaller subspace for the lowest computational load.

Root DF Algorithms

Root DF algorithms are specialty DF algorithms applicable to only uniformly spaced linear arrays with N elements, where the array manifold can be written using an index to specify the array element of interest. The array manifold is then written as

$$\mathbf{a}(\theta, n) = \exp\left(-jn \frac{2\pi d}{\lambda} \cos(\theta)\right) \quad (47-20)$$

where n goes from $-(N-1)/2$ to $(N-1)/2$ (odd-numbered element arrays), λ is the signal wavelength, and d is the spacing between elements. For a standard linear array, just at the Nyquist limit, $d = \lambda/2$. Then Eq. 47-20 reduces to

$$\mathbf{a}(\theta, n) = \exp(-jn\pi \cos(\theta)) \quad (47-21)$$

The array manifold can further be transformed into a vector of polynomial coefficients z by using the representation

$$z = \exp(j\pi \cos(\theta)) \quad \text{giving} \quad \mathbf{a}_z(z) = [1 \quad z \quad \dots \quad z^{N-1}]^T \quad (47-22)$$

The most common DF approach is the Root MUSIC algorithm using noise subspace eigenvectors. The correlation coefficient is written in terms of the eigenvector noise subspace and the antenna manifold as

$$C(z) = \mathbf{a}^T \left(\frac{1}{z} \right) \{ \mathbf{E}_N \mathbf{E}_N^H \} \mathbf{a}(z) \quad (47-23)$$

The Root MUSIC algorithm computes the roots of $C(z)$ and chooses the D roots, \hat{z}_i , that lie inside a unit circle and are closest to the unit circle. The estimates of signal azimuth $\hat{\theta}_i$ are found by the inverse relation between θ and z for the $i = 1 \dots D$ roots, giving

$$\hat{\theta}_i = \cos^{-1} \left(\frac{\arg(\hat{z}_i)}{\pi} \right) \quad (47-24)$$

From Eq. 47-24 it can be seen that Root MUSIC is not affected by the magnitude of \hat{z}_i . Thus we expect Root MUSIC to provide a better estimate of signal direction than the classical MUSIC algorithm. The performance of these algorithms is given later in the chapter, in the section “DF Algorithm Comparison.”

Since the Min-Norm algorithm also uses eigenvectors of the noise subspace, we expect that there should be a Root Min-Norm algorithm that is a better estimator than Eq. 47-17. While the development of both root MUSIC and Root Min-Norm is developed using a uniformly spaced linear array, these algorithms are applicable to circular arrays as well. The starting point for Root Min-Norm begins by defining a subspace vector \mathbf{d} , of dimension $N \times 1$, that has the property of being orthogonal to the signal subspace. That is, given the array manifold $\mathbf{a}(\theta_i)$ at discrete θ_i for $i = 1 \dots D$ signal directions, \mathbf{d} has the property

$$\mathbf{a}(\theta_i)^H \mathbf{d} = 0 \quad (47-25)$$

The only set of vectors orthogonal to the signal vectors is the set of noise eigenvectors with arbitrary magnitude. Thus the vector \mathbf{d} is found as a weighted noise subspace eigenvector

$$\mathbf{d} = w^{\frac{1}{2}} \mathbf{E}_N = \left(\frac{\mathbf{c}^*}{\mathbf{c}^H \mathbf{c}} \right) \mathbf{E}_N \quad (47-26)$$

where \mathbf{c} is created from the first elements of each of the noise eigenvectors. As with Root MUSIC, Root Min-Norm uses the transform $z_i = \exp(j\pi \cos(\theta_i))$ to represent the $i = 1 \dots D$ signal directions, allowing \mathbf{d} to be written in polynomial form

$$D(z) = 1 + d_1 z^{-1} + \dots + d_N z^{-N} \quad (47-27)$$

The polynomial roots of $D(z)$ provide the estimate of \hat{z}_i , which are selected within and close to the unit circle. The inverse trigonometric transform of Eq. 47-24 converts \hat{z}_i to the Root Min-Norm estimate of signal arrival $\hat{\theta}_i$ for the $i = 1 \dots D$ signals.

Maximum Likelihood DF Algorithms

The Maximum Likelihood (ML) estimator for the direction $\hat{\theta}_i$, for $i = 1 \dots D$ signals, uses a signal subspace that is as close as possible to the data subspace. This is formulated by taking the maximum of

$$\theta_{\text{ml}} = \arg \max_{\theta} \{ \text{tr}[\mathbf{P}_{\theta} \mathbf{R}] \} \quad (47-28)$$

where \mathbf{R} is the covariance matrix of the antenna array voltage data and \mathbf{P}_{θ} is the projection vector of the $i = 1 \dots D$ signals. \mathbf{P}_{θ} is formed from the discrete $N \times D$ steering vectors $\mathbf{a}(\theta_i)$ as

$$\mathbf{P}_{\theta} = \mathbf{a}(\theta_i) (\mathbf{a}(\theta_i)^H \mathbf{a}(\theta_i))^{-1} \mathbf{a}(\theta_i)^H \quad (47-29)$$

To search over the actual N -elements by the M -azimuth array manifold $\mathbf{a}(\theta)$, the computational complexity of the ML algorithm is $O(M^D)$. Fortunately there is a way to reduce computational complexity to find \mathbf{P}_{θ} . The alternating projection maximization (APM) algorithm, invented by Ziskind and Wax,²⁸ replaces the multidimensional maximization problem with a sequence of one-dimensional maximization problems, reducing the computational complexity to $O(MD)$.

The first step of the APM algorithm is an initialization step where θ_i^0 is estimated for $i = 1 \dots D$ signals. θ_1^0 is estimated by finding the angle θ that maximizes Eq. 47-28 assuming only one signal is present. θ_2^0 is found by assuming the first signal is at θ_1^0 and maximizing Eq. 47-28 for the second signal. The initialization is complete after repeating for D signals.

Next, a projection of the manifold is created so that all of the manifold vectors are orthogonal to all of the estimated steering vectors except the steering vector that is being updated. Notationally, $\mathbf{a}(\hat{\theta}_i)$ represents the set of steering vectors for all of the estimated signals except for signal i . APM creates a projected manifold \mathbf{b} such that the vector at each θ , $\mathbf{b}(\theta, \hat{\theta}_i)$ is orthogonal to all of the vectors in $\mathbf{a}(\hat{\theta}_i)$. That is

$$\mathbf{b}(\theta, \hat{\theta}_i) \mathbf{a}(\hat{\theta}_i) = \mathbf{0} \quad (47-30)$$

APM then determines θ_i^{k+1} for iteration $k + 1$ and signal i as

$$\theta_i^{k+1} = \arg \max_{\theta_i} \mathbf{b}(\theta, \hat{\theta}_i^k)^H \mathbf{R} \mathbf{b}(\theta, \hat{\theta}_i^k) \quad (47-31)$$

The iterations are repeated until a criterion δ is reached such that

$$|\theta_i^{k+1} - \theta_i^k| < \delta \quad (47-32)$$

Power Method Algorithms for Eigen Structures

In this section we investigate ways of computing eigenvalues and eigenvectors efficiently. Many computer languages provide a Linear Algebra extension from the LAPACK library to compute eigenvectors and eigenvalues quickly.²⁹ For an N -element array, this requires $O(N^3)$ operations. For many applications, the LAPACK library meets all computational needs. Although efficient, the standard LAPACK library has a highly complex logical structure that cannot be implemented efficiently in pipeline hardware such as Field Programmable Gate Arrays (FPGAs).

The Jacobi algorithm for computing eigenvalues and eigenvectors is not optimal in terms of multiply, divide, and add operations, but it can be implemented using Coordinate Rotation Digital Computer (CORDIC) processes³⁰ that are suitable for pipeline hardware. Ahmedsaid et al³¹ implemented the Jacobi algorithm using CORDIC blocks for an 8×8 covariance matrix. Computing the eigenvectors and values to 14-bit resolution required 16,681 slices and approximately 18,000 clock cycles.

Another pipeline approach is the "power method" by Stewart,³² which shows there is an extremely simple way of estimating the dominant eigenvector, \mathbf{E}_1 , from a covariance matrix \mathbf{R} :

$$\mathbf{E}_1 = \mathbf{R}^k \mathbf{R}(m) = (\mathbf{L}\mathbf{L}^H)^k \mathbf{L}\mathbf{L}(m)^H \quad (47-33)$$

where k is an integer > 0 , $\mathbf{R} = \mathbf{L}\mathbf{L}^H$, $\mathbf{R}(m)$ is a column vector from \mathbf{R} , and $\mathbf{L}(m)$ is a row vector from \mathbf{L} . In the case of a single signal with positive SNR, \mathbf{E}_1 (an orthonormal vector) can be used in place of \mathbf{E}_s in the MUSIC DF of Eq. 47-19 and is quickly solved.

With a modest extension, the power method is able to determine a set of orthonormal vectors and bases to replace the eigenvectors and values of multiple signals. Once \mathbf{E}_1 has been found, the \mathbf{L} matrix is updated as

$$\mathbf{u} = \mathbf{E}_n^H \mathbf{L}_n \quad (47-34)$$

$$\mathbf{L}_{n+1} = \mathbf{L}_n - \mathbf{E}_n \mathbf{u} \quad (47-35)$$

where \mathbf{E}_n is normalized such that $\mathbf{E}_n^H \mathbf{E}_n = 1$. The corresponding basis value λ_n is then estimated as

$$\lambda_n = \mathbf{u}^H \mathbf{u} \quad (47-36)$$

This procedure is repeated to estimate \mathbf{E}_n and λ_n from $n = 1$ to N array elements. In all, the power method requires $(2k + 4)N^3 - (2k + 1)N^2 - 2N$ multiply and accumulate (MAC) operations. Up to $N = 8$ and $k = 2$ MAC operations can be supported using modern FPGAs.

Cramer-Rao DF Error Limit

Before evaluating each of the algorithms given in the preceding section, we would like a baseline that gives the limit of DF performance for any given array and incoming co-channel set

of signals. This can be obtained using the Cramer-Rao bound (CRB) where additive white Gaussian noise (AWGN) corrupts the received signal voltages without bias. A thorough treatment is given by Van Trees.³³

We start with a model of the received signal \mathbf{V} as an $M \times K$ matrix of voltages sampled at each of M antenna array elements over K snapshots. (We use M vice N to avoid confusion with the noise component \mathbf{N} .) \mathbf{V} is the result of D co-channel signals \mathbf{S} received through the array manifold $\mathbf{a}(\theta)$ plus direction independent noise \mathbf{N} . \mathbf{S} is a $D \times K$ matrix, while \mathbf{N} is an $M \times K$ diagonal matrix of AWGN noise samples with variance σ_w^2 .

$$\mathbf{V} = \mathbf{a}(\theta)\mathbf{S} + \mathbf{N} \quad (47-37)$$

Using this separation of signal and noise, the covariance matrix \mathbf{R}_V of measured voltages can be written in terms of signal and noise as well:

$$\mathbf{R}_V = \mathbf{R}_S + \mathbf{R}_N = \mathbf{a}(\theta)\mathbf{S}_f\mathbf{a}(\theta)^H + \sigma_w^2\mathbf{I} \quad (47-38)$$

where \mathbf{R}_S is the signal covariance matrix (equal to $\mathbf{a}(\theta)\mathbf{S}_f\mathbf{a}(\theta)^H$), \mathbf{R}_N is the noise covariance matrix (equal to $\sigma_w^2\mathbf{I}$), and \mathbf{S}_f is the $D \times D$ signal matrix (equal to $\mathbf{S}\mathbf{S}^H$). The resulting Cramer-Rao bound of variance becomes

$$\mathbf{C}_{CR}(\theta) = \frac{\sigma_w^2}{2K} \left\{ \text{Re} \left[\left[\frac{\partial \mathbf{a}(\theta)^H}{\partial \theta} \mathbf{P}_\theta^\perp \frac{\partial \mathbf{a}(\theta)}{\partial \theta} \right] \circ \left[\mathbf{S}_f \mathbf{a}(\theta)^H \mathbf{R}^{-1} \mathbf{a}(\theta) \mathbf{S}_f^T \right] \right] \right\}^{-1} \quad (47-39)$$

where \circ is the Hadamard product of two matrices using element by element multiplication and \mathbf{P}_θ^\perp is the projection matrix of the array manifold onto the noise subspace and is defined as

$$\mathbf{P}_\theta^\perp = \mathbf{I} - \mathbf{a}(\theta)(\mathbf{a}(\theta)^H \mathbf{a}(\theta))^{-1} \mathbf{a}(\theta)^H \quad (47-40)$$

Clearly the CRB decreases with increasing data samples, K , and decreasing noise variance. At high SNR the CRB is proportional to σ_w^2 , but at low SNR, the CRB is proportional to σ_w^4 . The transition from low to high SNR is determined by the signal correlation, spatial separation of the signals, and the beamwidth of the array. As the signals become more correlated, \mathbf{R}_S becomes less diagonal, increasing the CRB. As the separation of the signal steering vectors $\mathbf{a}(\theta)^H \mathbf{a}(\theta)$ becomes less diagonal, CRB likewise increases.

DF Algorithm Comparison

Monte Carlo simulations were run to compare DF performance in which two uncorrelated, equal power signals impinge on a standard linear array with elements spaced $\lambda/2$ apart. The signals were positioned nearly broadside to the array at azimuths of 87.5° and 92.5° . The array SNR (ASNR) was varied from -20 dB to $+30$ dB and resulting DF rms errors were determined from 200 trials per algorithm. Each trial uses 100 data (voltage) snapshots with additive white Gaussian noise.

If only one signal is present in the array manifold (per frequency channel, etc.), all computational methods produce the same directional estimate, with Bartlett correlation the simplest to implement. The Bartlett correlation algorithm can be used on many different array geometries, can handle Brueninger element combining, and can be used in commutating systems. But the Bartlett DF algorithm cannot resolve closely spaced co-channel

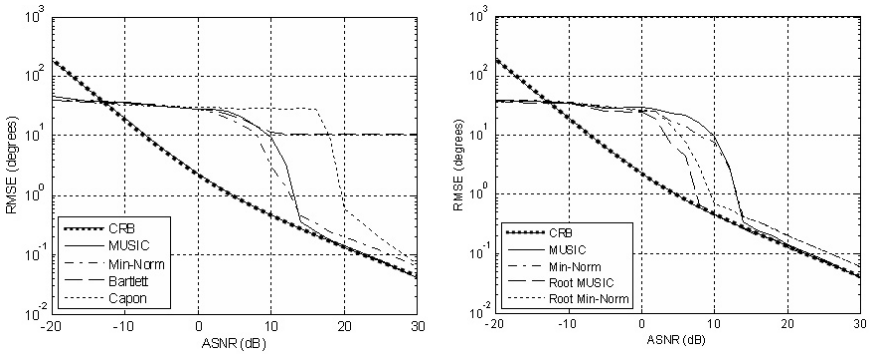

FIGURE 47-16 (a) Basic DF and Eigen algorithm DF performance and (b) Eigen and Root algorithm DF performance

signals. The Capon method provides much better signal resolution than Bartlett, but eigen structure methods provide even more capability. The Min-Norm algorithm provides slightly better performance than MUSIC at low ASNR, but with much more complexity (see Figure 47-16a). For restricted array geometry, Root MUSIC and Root Min-Norm give better DF performance than their general array counterparts MUSIC and Min-Norm. Root MUSIC is slightly better than Root Min-Norm in accuracy and is considerably more efficient to compute (see Figure 47-16b).

The power method creating orthogonal basis vectors and values can be used in the MUSIC, Root MUSIC, Min-Norm, and Root Min-Norm algorithms just as the eigenvectors and values are used. In a DF simulation consistent with the other comparisons in this section, the eigen decomposition required double floating point values (64 bits) while the power method used only 18-bit integer multipliers and 48-bit integer accumulators. The power method thus provides significant computational load savings without loss of accuracy (see Figure 47-17).

FIGURE 47-17 DF performance of Eigen versus power method implementations

Estimating the Number of Co-Channel Signals

For an N -element array, eigen decomposition of the covariance matrix gives N eigenvalues λ and corresponding eigenvectors \mathbf{E} . The eigen subspace is divided into \mathbf{E}_S , a subspace of $1 \dots D$ signal eigenvectors, and \mathbf{E}_N , a subspace of $(N - D)$ noise vectors. These eigenvectors and their eigenvalues are related to the original covariance matrix as

$$\mathbf{R} = \mathbf{E}_S \lambda_S \mathbf{E}_S^H + \mathbf{E}_N \lambda_N \mathbf{E}_N^H \quad (47-41)$$

The problem is to estimate the number of signals D when the noise eigenvalues λ_N can be represented by a span of $(N - D)$ noise terms containing AGWN,

$$\lambda_N = \text{diag}[\sigma_w^2 \dots \sigma_w^2] \quad (47-42)$$

An ad hoc ratio test can be established to compare the smallest eigenvalue with the $(N - 1)$ remaining eigenvalues in a threshold test. An optimal approach uses the likelihood ratio that challenges the hypothesis that the $(N - D)$ smallest eigenvalues are equal against the hypothesis that the $(N - D - 1)$ smallest eigenvalues are equal. Van Trees³⁴ shows that for a covariance matrix \mathbf{R} , created from K snapshots and decomposed into N eigenvalues, the likelihood of D signals, $L(D)$, can be written as

$$L(D) = K(N - D) \ln \left\{ \frac{\frac{1}{N - D} \sum_{i=D+1}^N \lambda_i}{\left(\prod_{i=D+1}^N \lambda_i \right)^{\frac{1}{N - D}}} \right\} \quad (47-43)$$

The term in the brackets is the ratio of the arithmetic mean of the $(N - D)$ smallest eigenvalues to the geometric mean of $(N - D - 1)$ eigenvalues. If the $(N - D)$ smallest eigenvalues are equal (i.e., have the same noise variance σ_w^2) then the arithmetic and geometric means are equal and $L(D) = 0$.

Two common tests use this likelihood ratio to determine the number of signals present: the Akaike information-theoretic criterion (AIC)³⁵ and the minimum description length (MDL) of Wax and Kailath.³⁶ These tests add a penalty function based on the degrees of freedom of the likelihood function. Akaike introduces AIC as

$$D_{\text{AIC}} = \arg \min_D \{L(D) + [D(2N - D)]\} \quad (47-44)$$

while the MDL test uses

$$D_{\text{MDL}} = \arg \min_D \left\{ L(D) + \frac{1}{2} [D(2N - D) + 1] \ln K \right\} \quad (47-45)$$

As with any eigen structure method, the power method of determining orthonormal vectors and values may be substituted. For the antenna array and simulation parameters defined in the preceding section, the AIC test (using eigen structures or orthonormal vectors) has a better probability of signal detection at low ASNR than the MDL test. Both AIC and MDL may underestimate the number of signals present. Above 8 dB, all methods successfully estimate the presence of two signals (see Figure 47-18).

FIGURE 47-18 Estimates of the number of signals present vs. array signal-to-noise ratio (ASNR)

DF when Co-Channel Signals Are Correlated

All of the DF algorithms discussed so far have some ability to separate co-channel signals. But none can separate perfectly correlated or coherent signals. They cannot separate the signals because the signal covariance matrix, S_f , as defined in Eq. 47-38, has a rank of one for coherent signals.

Unfortunately, multiple signal correlation generally occurs in a multipath situation. That is, a single signal travels on multiple paths from the transmitter to the receiving antenna array. If the signal arrives on two paths that are equal length, then the antenna array would see two signals that are 100 percent correlated. As the path length difference increases, the correlation ratio drops. An estimate of the correlation, ρ , is given

$$\rho = 1 - \frac{B \cdot \Delta path}{c} \quad (47-46)$$

where B is signal bandwidth, $\Delta path$ is the path length difference, and c is the velocity of light. For example, if the signal bandwidth is 25 kHz and the path length difference is 600 meters, then $\rho = 0.95$.

A Monte Carlo simulation similar to that used previously in Section 47.4 was used to evaluate MUSIC and Root MUSIC using two signals with 95 percent correlation (see Figure 47-19). At low ASNR, both MUSIC and Root MUSIC are erroneous, randomly determining the DF. Even a moderately strong ASNR of 10–12 dB still produces random DF. Only when the SNR is greater than 15 dB does Root MUSIC begin to determine the correct direction of both signals, while the classic MUSIC algorithm needs ASNR > 25 dB to produce useful DF. Both Root MUSIC and classic MUSIC can resolve highly correlated, closely spaced signals given sufficient ASNR.

FIGURE 47-19 DF performance for two closely spaced signals that are 95 percent correlated

47.5 GEOLOCATION ALGORITHMS

In this section, we present three geolocation algorithms. The Stansfield algorithm is the oldest and has been used successfully in both worldwide HFDF systems and line-of-sight angle-of-arrival systems as well. The Wangness algorithm uses LOBs drawn on a spherical earth and likewise can be used globally or locally for geolocation solutions. A simple 2D TDOA geolocation algorithm is also presented. These three approaches are compared using confidence ellipse containment.

Stansfield AOA Geolocation Algorithm

The Stansfield algorithm³⁷ was developed during World War II for AOA geolocation using a flat (Cartesian) geometry, illustrated in Figure 47-20.

The LOB from a receiving site has a bearing angle β from north (y-axis). Using an arbitrary coordinate system, the LOB is also described by d , the perpendicular distance to the coordinate system origin; m is the LOB miss distance from point $(p_x, p_y)^T$.

The miss distances from a set of K lines of bearing with common Cartesian origin created by some number of DF sites is written in matrix form as

$$\mathbf{m} = \mathbf{A}\mathbf{p} + \mathbf{d} \quad (47-47)$$

where \mathbf{m} is the miss vector, \mathbf{A} is a transformation matrix, \mathbf{p} is the position vector, and \mathbf{d} is the LOB origin offset parameter:

$$\mathbf{m} = \begin{bmatrix} m_1 \\ m_2 \\ \vdots \\ m_K \end{bmatrix}, \mathbf{A} = \begin{bmatrix} -\cos(\beta_1) & \sin(\beta_1) \\ -\cos(\beta_2) & \sin(\beta_2) \\ \vdots & \vdots \\ -\cos(\beta_K) & \sin(\beta_K) \end{bmatrix}, \mathbf{p} = \begin{bmatrix} p_x \\ p_y \end{bmatrix}, \text{ and } \mathbf{d} = \begin{bmatrix} d_1 \\ d_2 \\ \vdots \\ d_K \end{bmatrix}$$

FIGURE 47-20 Stansfield geolocation geometry

The goal is to find a position $\hat{\mathbf{p}}$ that minimizes $\mathbf{m}^T \mathbf{m} = \sum_1^K m_i^2$, which can be done in an iterative approach using the gradient form of Eq. 47-47. The iterative improvement in position is

$$d\mathbf{p} = \text{inv}(\mathbf{A}^T \mathbf{A}) \cdot (\mathbf{A}^T \mathbf{m}) \quad (47-48)$$

and

$$\hat{\mathbf{p}}_{\text{new}} = \hat{\mathbf{p}}_{\text{old}} + d\mathbf{p} \quad (47-49)$$

Inspection of the components of Eq. 47-48 reveals that the $\mathbf{A}^T \mathbf{A}$ and $\mathbf{A}^T \mathbf{m}$ matrices are the classic unweighted least squares normal equations. These should be used on the first iteration from an arbitrary starting point \mathbf{p}_o . Subsequent iterations should use a weighted version of $\mathbf{A}^T \mathbf{A}$ and $\mathbf{A}^T \mathbf{m}$ that account for the LOB a priori DF variance σ_{LOB}^2 and distance r_i from the i th bearing site to emitter. Using a covariance matrix \mathbf{R} whose diagonal elements contain the squared weights $w_i^2 = 1 / (\sigma_{\text{LOB}}^2 r_i^2)$, Eq. 47-48 is modified to be

$$d\mathbf{p} = \text{inv}(\mathbf{A}^T \mathbf{R} \mathbf{A}) \cdot (\mathbf{A}^T \mathbf{R} \mathbf{m}) \quad (47-50)$$

The weighted normal equations are written as

$$(\mathbf{A}^T \mathbf{R} \mathbf{A}) = \begin{bmatrix} \sum_{i=1}^K \frac{\cos^2(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} & -\sum_{i=1}^K \frac{\cos(\beta_i) \sin(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} \\ -\sum_{i=1}^K \frac{\cos(\beta_i) \sin(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} & \sum_{i=1}^K \frac{\sin^2(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} \end{bmatrix} \quad (47-51)$$

TABLE 47-2 Ellipse Confidence Factor

Ellipse Confidence Factor	Scaling Factor (jo)
68%	1
80%	1.79
90%	2.15
95%	2.45

and

$$(\mathbf{A}^T \mathbf{R} \mathbf{m}) = \begin{bmatrix} -\sum_{i=1}^K \frac{m_i \cos(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} \\ \sum_{i=1}^K \frac{m_i \sin(\beta_i)}{\sigma_{\text{LOB}}^2 r_i^2} \end{bmatrix} \quad (47-52)$$

Convergence to $\hat{\mathbf{P}}$ requires only three or four iterations from an arbitrary starting point, making the Stansfield geolocation algorithm fairly efficient. It is customary to estimate a confidence containment ellipse about the location $\hat{\mathbf{P}}$, which can be determined from the eigenvalues of the $\text{inv}(\mathbf{A}^T \mathbf{R} \mathbf{A})$ matrix. Letting the inverse matrix be noted as \mathbf{Q} , the eigenvalues are found by solving the determinate $|\lambda \mathbf{I} - \mathbf{Q}| = 0$. Two eigenvalues result, designated λ_+ (maximum) and λ_- (minimum). The confidence ellipse is scaled by the number of LOBs, K , and by a scaling factor, jo , which establishes the statistical confidence level (see Table 47-2).

The confidence ellipse is then described by the semi-major and semi-minor axes:

$$s \text{ maj} = jo\lambda_+ \sqrt{\frac{K}{K-1}} \text{ and } s \text{ min} = jo\lambda_- \sqrt{\frac{K}{K-1}} \quad (47-53)$$

The unambiguous ellipse orientation (see Table 47-3) requires testing of the terms of the \mathbf{Q} matrix.

A Monte Carlo simulation of LOBs from three bearing sites illustrates the Stansfield algorithm. LOBs with 2° rms error were generated from three sites, producing a best estimate position and 95 percent confidence containment ellipse (see Figure 47-21a). To evaluate 300 trials, the confidence ellipse, normally centered on each estimated position, is shifted to the true emitter location, and allows comparison of the theoretical 68%, 80%, and 95% confidence ellipse containment with the trial estimated positions (see Figure 47-21b).

TABLE 47-3 Confidence Ellipse Orientation

Compare Diagonal Terms	Orientation
$Q_{1,1} \leq Q_{2,2}$	$90 - \frac{1}{2} \text{atan} 2 \left(\frac{y \text{ term}}{x \text{ term}} \right)$
$Q_{1,1} > Q_{2,2}$	$\frac{1}{2} \text{atan} 2 \left(\frac{y \text{ term}}{x \text{ term}} \right)$
where	$y \text{ term} = Q_{1,2} + Q_{2,1}$ $x \text{ term} = Q_{1,1} - Q_{2,2}$

FIGURE 47-21 (a) Stansfield LOBs, geolocation, and 95% confidence ellipse and (b) 300 trials with 68%, 80%, and 95% confidence ellipse centered on the true emitter

Wangness AOA Geolocation Algorithm

In 1973 Dennis Wangness proposed an elegant solution to geolocation on a spherical earth.³⁸ It has the advantage of being a fast, non-iterative eigenvector approach to produce both geolocation and a confidence containment ellipse. Extending the spherical solution onto a geoid allows the algorithm to be WGS-84 compliant.

Wangness recognized that any LOB describes a great circle around the earth and is anchored through the bearing site. These great circles are described by perpendicular normal vectors, \mathbf{n} , which collectively produce an eigenvector solution for best estimate of position and error ellipse.

First, the LOB normal vectors are described in terms of the Earth Centered Earth Fixed (ECEF) coordinate system and are collected into transformation matrix \mathbf{A} for K LOBs:

$$\mathbf{A} = \begin{bmatrix} nx_1 & ny_1 & nz_1 \\ \vdots & \vdots & \vdots \\ nx_K & ny_K & nz_K \end{bmatrix} = [\mathbf{n}_1 \quad \cdots \quad \mathbf{n}_i \quad \cdots \quad \mathbf{n}_K]^T \quad (47-54)$$

where $\mathbf{n}_i = \begin{bmatrix} nx_i \\ ny_i \\ nz_i \end{bmatrix}$ is the i th LOB normal vector in ECEF coordinates.

Once the $\mathbf{A}^T\mathbf{A}$ matrix is formed, the Wangness algorithm solves for the three eigenvalues and associated eigenvectors using $|\lambda\mathbf{I} - \mathbf{A}^T\mathbf{A}| = 0$. The normalized eigenvector associated with the smallest eigenvalue is a unit vector that points toward the best estimate of emitter position. This unit vector can be transformed into spherical latitude and longitude and further transformed into geodetic latitude and longitude using a standard geoid such as WGS-84.

Although the eigen solution is not iterative, once an approximate emitter position is found, a weighted solution using the covariance error matrix $\mathbf{R} = \text{diag}(1/r_i^2)$, where r_i is the arc distance between the i th-LOB bearing site and the estimated location. The $\mathbf{A}^T\mathbf{A}$ matrix now becomes the weighted matrix $\mathbf{A}^T\mathbf{R}\mathbf{A}$.

The three eigenvalues of $|\lambda \mathbf{I} - \mathbf{A}^T \mathbf{R} \mathbf{A}| = 0$ are sorted smallest to largest (λ_1 , λ_2 , and λ_3) to provide the confidence ellipse equations:

$$s_{\text{maj}} = \frac{a_e \cdot jo}{\sqrt{K-2}} \cdot \sqrt{\frac{\lambda_1}{\lambda_2}} \quad \text{and} \quad s_{\text{min}} = \frac{a_e \cdot jo}{\sqrt{K-2}} \cdot \sqrt{\frac{\lambda_1}{\lambda_3}} \quad (47-55)$$

where K is the number of LOBs, jo is the ellipse scaling factor for confidence of containment, and a_e is the earth's radius to convert arc distances into meters. Ellipse orientation is derived from the arc cosine of the dot product formed by the eigenvector associated with λ_2 (the eigenvalue associated with semi-major axis) and a unit vector at the estimated location that points east.

A similar Monte Carlo simulation was run for the Wangness algorithm with the same LOB error and site geometry of the Stansfield simulation. LOB, best position, and confidence ellipse were computed (see Figure 47-22a) and 300 trials were made (see Figure 47-22b). Again, the confidence ellipse was shifted to the true emitter location, for comparison of the theoretical 68%, 80%, and 95% confidence containment ellipses.

TDOA Geolocation Algorithm

When the LORAN hyperbolic location system was first developed by MIT in 1942, it was computationally intensive and highly classified.³⁹ Now TDOA geolocation can be done with small radio tuners and inexpensive computer chips. The algorithm presented here is consistent with the two-dimensional Stansfield approach, but can be easily extended to a three-dimensional solution on a spherical earth or WGS-84 geoid.^{40,41}

The time difference of a signal arriving at two sites s_1 and s_2 from an emitter at s_o can be written in terms of the two distances D_1 and D_2 between the sites and emitter, scaled by the speed of light, c :

$$\text{TDOA}_{ik} = \frac{D_i - D_k}{c} \quad (47-56)$$

where D_i is the distance between site s_i and emitter at s_o

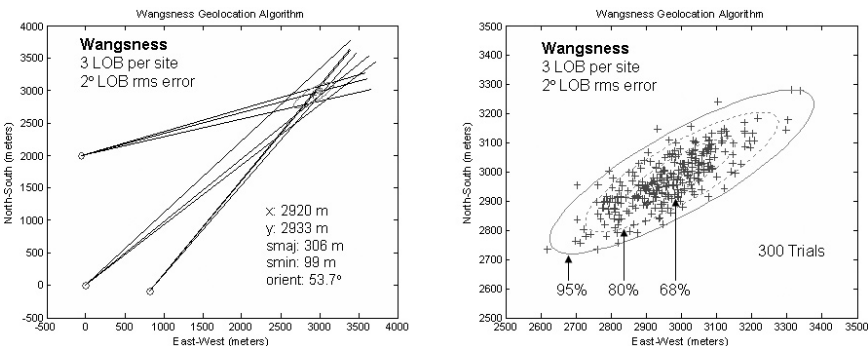

FIGURE 47-22 (a) Wangness LOBs, geolocation, and 95% confidence ellipse and (b) 300 trials with 68%, 80%, and 95% confidence ellipse centered on the true emitter

$$D_i = |\mathbf{s}_i - \mathbf{s}_o| = \left\{ (x_i - x_o)^2 + (y_i - y_o)^2 \right\}^{\frac{1}{2}} \quad (47-57)$$

The hyperbolic TDOA solution of location is written in an iterative, gradient form similar to the Stansfield approach of Eqs. 47-48 and 47-49:

$$d\mathbf{s}_o = (\mathbf{A}^T \mathbf{A}) \cdot d(\mathbf{TDOA}) \quad (47-58)$$

and

$$\hat{\mathbf{s}}_{\text{new}} = \hat{\mathbf{s}}_o + d\mathbf{s}_o \quad (47-59)$$

The matrix $d(\mathbf{TDOA})$ is a $K \times 1$ vector of K observed minus calculated TDOA values from the i - k site pair, where the calculated TDOA_{ik} and its derivative are based on the current estimate of emitter position $\hat{\mathbf{s}}_o$. The $\mathbf{A}^T \mathbf{A}$ matrix is a $K \times 2$ transformation matrix of partial derivatives of TDOA_{ik} with respect to $\hat{\mathbf{s}}_o$. The fundamental $d(\mathbf{TDOA})$ vector and \mathbf{A} matrix are written as

$$d(\mathbf{TDOA}) = \begin{bmatrix} \text{TDOA}_{ik}(\text{measured})_1 - \text{TDOA}_{ik}(\text{calculated})_1 \\ \text{TDOA}_{ik}(\text{measured})_2 - \text{TDOA}_{ik}(\text{calculated})_2 \\ \vdots \\ \text{TDOA}_{ik}(\text{measured})_K - \text{TDOA}_{ik}(\text{calculated})_K \end{bmatrix} \quad (47-60)$$

$$\mathbf{A} = \begin{bmatrix} \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial x_o} dx_o \right\}_1 & \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial y_o} dy_o \right\}_1 \\ \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial x_o} dx_o \right\}_2 & \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial y_o} dy_o \right\}_2 \\ \vdots & \vdots \\ \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial x_o} dx_o \right\}_K & \left\{ \frac{\partial \text{TDOA}_{ik}}{\partial y_o} dy_o \right\}_K \end{bmatrix} \quad (47-61)$$

The partial differential of TDOA_{ik} with respect to the current estimate of emitter position is further expanded using the definitions of time delay from Eqs. 47-56 and 47-57:

$$\frac{\partial \text{TDOA}_{ik}}{\partial x_o} = \frac{1}{c} \left(\frac{\partial D_i}{\partial x_o} - \frac{\partial D_k}{\partial x_o} \right) = \frac{1}{c} \left(\frac{(x_o - x_i)}{D_i} - \frac{(x_o - x_k)}{D_k} \right) \quad (47-62)$$

and

$$\frac{\partial \text{TDOA}_{ik}}{\partial y_o} = \frac{1}{c} \left(\frac{\partial D_i}{\partial y_o} - \frac{\partial D_k}{\partial y_o} \right) = \frac{1}{c} \left(\frac{(y_o - y_i)}{D_i} - \frac{(y_o - y_k)}{D_k} \right) \quad (47-63)$$

At least two different site pairs are required for geolocation convergence, and care must be taken to avoid ambiguities, since, unlike LOB observations, the hyperbolic TDOA isochrones have left-right symmetry about a line between the measuring i - k site pair.

FIGURE 47-23 GDOP for TDOA geolocation from three sites. Lightest color indicates lowest GDOP and area of best geolocation.

A useful concept in evaluating the geolocation geometry is a quantity called the Geometric Dilution of Precision (GDOP), defined as

$$\text{GDOP} = \text{trace}(\text{inv}(\mathbf{A}^T \mathbf{A})) \quad (47-64)$$

A low value of GDOP indicates good geometry for the geolocation solution, while a high GDOP indicates poor geometry (see Figure 47-23).

A Monte Carlo simulation with a geometry similar to Stansfield and Wangsness was run for TDOA geolocation (see Figure 47-24). Each TDOA has $\sigma_{\text{TDOA}} = 50\text{-ns}$ rms error.

FIGURE 47-24 (a) TDOA hyperbolic isochrones, geolocation, and 95% confidence ellipse and (b) 300 trials with 95% confidence ellipse centered on the true emitter

Although the TDOA algorithm estimates position entirely in the time domain, the simulation also drew hyperbolic isochrones for comparison with the LOB geolocation approach (compare Figure 47-24a with Figures 47-21a and 47-22b). Four TDOA measures were made from each site pair (shown as dotted lines connecting the sites). The calculation of the confidence error ellipse closely parallels that of the Stansfield algorithm described by Eq. 47-53 and Table 47-3. In Figure 47-24b, the confidence ellipse is shifted to the true emitter location to examine the 95% containment of 300 geolocation trials. The TDOA geolocation error is distributed very differently from the LOB geolocation error (compare Figure 47-24b with Figures 47-21b and 47-22b).

48.1 INTRODUCTION

ESM and ECM Systems

The use of electronic countermeasures (ECM) against opponents' communications systems started with the use of wireless communications in military operations at the beginning of the 20th century. Extensive electronic monitoring/interception of nonfriendly signals and countermeasures against both communications links (primarily high frequency [HF] at that time) and newly developed radar systems began during World War II (1939–45). The use of the electromagnetic spectrum in military operations was defined as “electronic warfare.” Soon these activities were classified as electronic support measures (ESM). ESM consisted of passive measurements of emitted signals by nonfriendly emitters, and ECM systems, which included the emission of signals to confuse or deceive the communications and radar sensor systems of opposing forces.

Extensive use of passive ECM techniques, such as chaff (a large number of dipole elements spread into the air), began toward the end of WWII. Electronic counter-counter measure (ECCM) techniques are aimed to overcome or decrease the ECM threats of friendly communications and sensor systems. To this day, ECM and ECCM techniques are in a continuous competition.

The design and development of antennas intended to serve the needs of ESM and ECM systems poses unique requirements, as compared to communications or radar antennas, such as

- Ultrawide spectral bandwidths
- Low weight and size
- Full polarization control
- Very high isolation between transmit and receive in collocated antennas

The last requirement is of particular significance, since the ability to receive weak signals while transmitting countermeasure (jamming) signals is of primary importance. Achievement of this goal provides superior ECM abilities. Indeed, the capability to regenerate threat signals improves the efficiency of ECM systems to a high degree.

General Properties of ESM and ECM Antennas

In treating the ESM/ECM antennas the spectral region of interest has primary importance. In tactical communications systems the frequency region 1–2500 MHz (HF, VHF) is used predominantly, while radars use microwave (1–30 GHz) and millimeter wavelength (30–100 GHz) spectral regions. The wideband antenna technologies, which started to appear during the mid-1950s, are widely used in both ESM and ECM applications concerning both communications and radar systems. The extensive use of multiple communications networks at the same geographical place and jamming-resistant wideband systems forces the use of wideband systems, thus requiring ultra wideband (UWB) ESM and ECM antennas. Furthermore, especially in low-frequency ESM and ECM systems, the relatively large size of antennas necessitates the use of the same antenna aperture for various needs such as signal interception and emission at various frequency bands almost simultaneously.

The development of monolithic integrated circuits (based on GaAs or Si technologies) after the 1980s enabled the use of phased-array principles in ESM and ECM systems.

The availability of true time-delay, digitally controlled, two-port networks allowed the development of wideband phased-array antennas, which provide superior operational characteristics such as the following:

- Highly dynamic beam agility in one or two planes
- Ability to modify outgoing wavefront to effect monopulse radars
- Use of nulling at the direction of arrival energy jamming signals without significant degradation of radiation pattern at other angles
- Highly effective irradiated power toward threats

In specifying and designing ESM and ECM antennas, the standard quantities used in general antenna theory are used, such as directivity (D), gain (G), bandwidth (BW), and radiation patterns at various levels.

In ECM and ESM system antennas, the polarization properties of antennas are of paramount importance to performance. The polarization behavior of ECM systems, and to some extent ESM systems, has essential effects on the ability of radars to resist jamming and deception phenomena (ECCM). Furthermore, the level of isolation between receiver and transmitter antennas in an ECM system, either for communications or radar, is of fundamental importance because it affects to a significant degree the countermeasure capabilities.

In this chapter, the ESM and ECM systems antennas are reviewed independently concerning the communications and radar systems. The presentation reflects the practical use of antennas in the corresponding applications based on generic concepts. In the case of communications systems, attention is focused on the low frequencies (1–2500 GHz), while for radar applications the microwave (1–30 GHz) and millimeter wavelength (30–100 GHz) bands are considered. In all the considered cases, the mechanical, environmental, and radar cross-section implications are also considered in practical terms. In both cases, the direction-finding antenna principles are also discussed and investigated based on various monopulse principles. At the end of the chapter, the important issue of transmit-receive antenna isolation in ECM systems is analyzed and general rules to achieve maximum isolation are suggested.

48.2 COMMUNICATION ESM AND ECM SYSTEM ANTENNAS

Mission of Communication ESM and ECM Systems

Communication ESM Systems The operational mission of communication ESM systems is to detect-receive incident, usually very weak, signals and convey them to sensitive wideband receivers. There are two fundamental operational missions of ESM systems: (a) acquisition and analysis of incoming signals and (b) measuring direction of arrival (direction finding, or DF) at the horizontal plane with respect to the Earth's surface. In the former case, signal parameters are measured without determining the angle of arrival in the horizontal plane.

Usually, omnidirectional antennas are utilized to receive signals without measurement of angle of arrival. Near the earth's surface, at the low radio frequencies (RF), 1–500 MHz, only vertical polarization is a matter of interest, while at higher frequencies, reception horizontal polarization should also be taken into account.

In the case of DF systems, monopulse antenna principles based on the simultaneous measurement and comparison of received signal amplitudes or phases is utilized (see Chapter 47). The DF systems are required to measure wideband signals such as the case of frequency-hopping and/or spread-spectrum modulated carriers, which pose serious difficulties in achieving azimuth angle measurement accuracies on the order of a few degrees. Furthermore, a dynamic range of at least 80 dB is required. The extensive use of digital signal processing techniques during recent years has enabled simultaneous measurement of DF and signals tracking of frequency-hopping and spread-spectrum signals. The combination of DF measurement techniques and use of signal processing techniques such as FFT and wavelet transform has provided the capability of efficient multiple signals processing and de-interleaving. Therefore, the modern trend is to have combined DF and signal acquisition-analysis ESM receivers, which require a single antenna for both missions.

Communication ECM Systems The primary role of an ECM antenna in communications applications is to direct the radiated countermeasure signals toward the enemy receivers to achieve degradation or complete loss of signal reception at the opponent's receiver units. This means that the azimuthal orientation of the victim receiver (or receivers) should be known with an accuracy of at least 10° in tactical communications using VHF (30–90 MHz) or UHF (200–2500 MHz) frequencies. In such cases, mobile ECM systems are usually used, placed inside a shelter for land-based systems. Ships or airplanes (manned or unmanned) are also used to a lesser degree. A significant difficulty arises because of the large antennas needed for ECM tactical systems required to cover the low VHF region, corresponding to this wavelength $\lambda = 3\text{--}10\text{ m}$.

Concerning HF communication ECM systems, usually land-based systems, antenna arrays with wideband properties are used. In this case, large-size fixed-array installations are used. In mobile, land-based HF ECM systems, usually omnidirectional or medium-directivity antennas with wideband characteristics are used.

Omnidirectional Antennas To achieve wideband reception of signals omnidirectionally, the most commonly used antennas are based on conical type structures, as shown in Figure 48-1, which also shows the corresponding critical design parameters.

FIGURE 48-1 Family of conical antennas

In practice, the geometric size restrictions pose difficulties in achieving low-frequency coverage. The use of conical monopole or disccone antennas usually is preferable since the required antenna heights are $h = \sqrt{2} \lambda/8$ and $h = \lambda/8$, respectively. In the case of VHF and UHF frequencies, to reduce the antenna weight and wind load, radial conductors are used as shown in Figure 48-2. The number of radials should be at least 16 peripherally to achieve sufficiently dense current distributions.

A significant issue in omnidirectional antennas is the ability to receive and transmit both polarizations simultaneously, especially in the case of microwave signals and radar signals. The simplest approach is to polarize the incident-outgoing waves by using a grid of parallel wires, as shown in Figure 48-3. The distance between the two parallel running wires should be less than $\lambda_M/20$, where λ_M is the maximum wavelength of the radiation. Usually, printed strips of approximately $\lambda_M/100$ on a low-permittivity substrate are used. The drawback of this method is the 3 dB insertion loss, concerning either vertical or horizontal polarization.

In the case of HF (wavelength $\lambda = 100\text{--}10\text{ m}$) and VHF ($\lambda = 10\text{--}1\text{ m}$) frequencies, reception of both polarizations rarely is needed. Therefore, in the case of UHF ($\lambda = 1\text{--}0.1\text{ m}$) and SHF, EHF ($\lambda = 10\text{--}1\text{ cm}$) frequencies, in order to receive both polarizations with an omnidirectional radiation pattern, one can use independent antennas and then use either independent analog summation of the two signals or independent signal processing channels.

Figure 48-4 depicts two techniques to achieve reception and transmission for both polarization antenna systems. In Figure 48-4a the printed and slot triangular butterfly antennas

FIGURE 48-2 Disccone antenna made of radial conductors

FIGURE 48-3 Polarized discone conical antenna

are placed collinearly to simultaneously radiate both polarizations. Another example is shown in Figure 48-4b where orthogonal conical dipoles are used to receive at all possible polarizations and incident angle signals.

Directional Antennas The antenna type that has been used, and still is widely used, in ESM and ECM communications systems is the logarithmic periodic antenna (LPA), which

FIGURE 48-4 Combination of electric-magnetic wideband dipoles

was invented by Raymond H. Du Hamel.¹⁻³ The following are the critical design parameters in LPAs:

- Maximum and minimum operation frequency
- The required directivity and gain
- Polarization characteristics

The basic structure of an LPA is shown in Figure 48-5. The basic design equations of the structure of an LPA are also given. Although numerous variations of LPAs have been developed and used during the last 50 years, the structure with multiple dipole elements has been the most commonly used ECM and ESM wideband antenna in practice. LPAs could provide antenna gains on the order of 7-10 dBi depending on the number of elements (N) and apex angle (α). If more directivity is required, use of multiple LPAs proved to be a useful technique, such as shown in Figure 48-6, where the two LPAs are placed parallel with their axis forming the angle β and the distance between the largest dipole is equal to the largest dipole (half wavelength $\lambda_M/2$ at the largest frequency).

$$\frac{l_n + 1}{l_n} = \frac{h_n + 1}{h_n} = \tau$$

$$\tan(\alpha/2) = \frac{l_n - l_{n+1}}{h_n}$$

Maximum operation wavelength = $\lambda_M = 4l_1$ (largest dipole double length)

$$\sin\left(\frac{\beta}{2}\right) = \frac{\lambda_M/4}{L}$$

where

$$L = \sum_{n=1}^N h_n$$

N = number of elements

FIGURE 48-5 Array of log-periodic arrays

Communication Systems Direction Finding Antennas The simultaneous reception of signals with different radiation pattern antennas—a principle known as *monopulse*—is used to measure the angle of incidence of communications and radar signals. Usually the azimuth angles of the incident signals are measured. In this case, an even number of wideband antennas, such as $n = 4, 6, 8$, etc. directive antennas, are used, as shown in Figure 48-6. For low frequency communications systems, only vertical polarization reception is typically required, simplifying the antenna element construction. A commonly used wide antenna type is the transverse electromagnetic mode (TEM) horn antenna, shown in Figure 48-6a, in which log-periodic elements are also used (see Figure 48-6b). Analog signal processing techniques consisting of hybrid circuits (sum and difference) and down converter units are employed to drive the A/D conversion circuits for direction finding (see Chapter 47) using the two signals $X(\varphi)$ and $Y(\varphi)$. Assuming each individual antenna in Figure 48-6 has a radiation pattern function described by an even function $F(\varphi) = F(-\varphi)$ with respect to the $\varphi = 0$ axis, the $X(\varphi)$ and $Y(\varphi)$ functions are computed as follows:

$$X(\varphi) = F(\varphi) - F(\varphi - 180^\circ)$$

$$Y(\varphi) = F(\varphi - 90^\circ) - F(\varphi - 270^\circ)$$

By comparing the two signals $X(\varphi)$, $Y(\varphi)$ we can then obtain the φ angle as a function of the X and Y signals on the assumption of a monotonically decreasing function. Calibration techniques should be used to account for any frequency dependence of the $F(\varphi)$ radiation pattern function. Increased bandwidths and conversion rates of the A/D converters provides opportunity for eliminating the necessity of using analog processing units to obtain the $X(\varphi)$ and $Y(\varphi)$ signals by digital processing.

Instead of using directive antenna elements, many systems use a more simplified technique, known as the Watson-Watt technique, shown in Figure 48-6c, where four dipole elements are used to obtain the $X(\varphi)$ and $Y(\varphi)$ functions. The distance between the two antipodal dipole elements should be less than half a wavelength at the maximum operation frequency. This condition guarantees the unique dependence of φ to X and Y voltages. To cover wide bandwidths, three or four sets of collinearly placed quadrant dipole or monopole elements are used along the vertical axis.

FIGURE 48-6 Wideband direction-finding antennas

48.3 RADAR ESM AND ECM SYSTEM ANTENNAS

Mission of Radar ESM and ECM Systems

Detection of radar signals with high-sensitivity receivers provides the opportunity of sensing the presence of radar emitters at large distances. The introduction of low probability of intercept (LPI) radars, which use very low peak power levels (few watts) with coded signal emissions, poses challenges in detecting such emitters with conventional noncoherent ESM receivers. Traditionally, because of the high peak power of pulsed radars, crystal video principle “envelope detection” receivers have been utilized. Furthermore, it is highly important to measure the direction of arrival of signals at the azimuth plane. Both direction and direction finding operations are always carried out simultaneously at many octave bandwidths (1–100 GHz). The required dynamic range of the receivers should be even more, at least up to 100 dB.

In ECM systems, depending on the platform to be protected (self) or the required effective radiated power to be emitted toward the victim radar, antennas ranging from moderate gain (10 dBi) to high gain (30 dBi) are used. In designing ECM antennas, the operational requirements as well as installation restrictions should be taken into account. In case of radar systems, since high microwave frequencies usually are employed, isolation levels between receive-transmit antennas as high as 90 dB could be achieved, which increases the capability of ECM systems.

ESM-DF Antennas to Detect Radar Signals To cover multi-octave bandwidths, inherently wideband antennas such as conical dipole/monopoles, spirals, and spiral conical structures are utilized. In traditional ESM-DF receivers, an omnidirectional antenna is separately used to drive an analysis channel while six to eight cavity-backed spiral antennas are used to measure the direction of arrival of the incoming signals. Figure 48-7 shows the architecture of an ESM-DF system (see also Chapter 47). To achieve wideband coverage (2–18 GHz or 0.5–40 GHz in many cases), direct detection receivers based on instantaneous frequency measurement correlators and amplitude detection have been used in the past. However, a serious drawback of these approaches has been the inability to detect continuous wave emitters and even more low probability intercept radars that incorporate encoded low power signals.

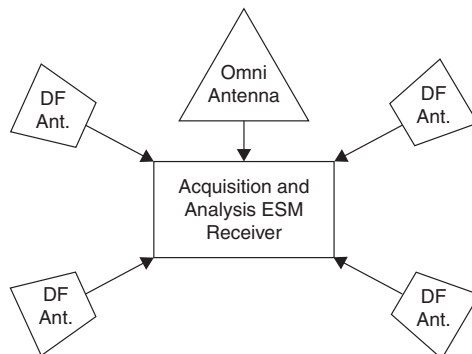

FIGURE 48-7 Radar signal ESM-DF system

FIGURE 48-8 Spiral antennas used in DF antennas

Omnidirectional antennas with conical type structures, previously shown in Figure 48-1, are usually used to achieve wideband coverage. For the DF antennas, spiral antennas are commonly used, such as cavity-backed or conical spiral antennas. Figure 48-8 shows structures commonly used in direction finding spiral antennas.

In ECM systems against radars, in the case of medium-gain antennas, wideband horn-type antennas are used, as shown in Figure 48-9, where loading of conventional horn antennas by strips is used. To achieve higher gains, parabolic reflector antennas using wideband horns are utilized. Phased-array antennas using wideband properties are also used extensively to achieve high gains and fast control of radiation beams.

The development of high-speed analog to digital (A/D) converters achieving up to several Giga-Sample/second (GS/s) rates, can allow the development of fully coherent receivers using wideband down-converters prior to digitization using A/D converters operating at 1–2 GS/s. In these systems, either a spinning antenna or, again, a circular array of wideband antennas (i.e., cavity spiral spiro-conical or even wideband horn antennas) is used. Figure 48-10 shows the architecture of this type of system. The use of a rotating passive reflector excludes the use of a rotational joint, which causes reliability problems and difficulties in achieving wideband properties.

49.1 RADIO-TELESCOPE INTRODUCTION

In contrast to optical telescopes, which produce visible light images, a radio telescope detects radio waves emitted by radio sources, typically by means of a large reflector antenna, or arrays of them. The first extraterrestrial radio source was detected by Karl Jansky, an engineer with the Bell Telephone Laboratories, and announced in *The New York Times* on May 5, 1933:

NEW RADIO WAVES TRACED TO CENTRE OF THE MILKY WAY. Mysterious static reported by K. G. Jansky, held to differ from cosmic ray. Direction is unchanging. Recorded and tested for more than a year to identify it as from Earth's galaxy. Its intensity is low. Only delicate receivable able to register—no evidence of interstellar signaling.

Today, we view this announcement of Jansky's paper, entitled "Electrical Disturbances Apparently of Extraterrestrial Origin," presented at the meeting of the U.S. Committee of the International Union of Radio Science (URSI) in Washington, D.C., as the beginning of radio astronomy. In Jansky's honor, astronomers named the unit of radio flux the jansky (which equals $10^{-26} \text{ W m}^{-2} \text{ Hz}^{-1}$).

Grote Reber was one of the pioneers of radio astronomy. Using a 9-m telescope constructed in 1937, he was instrumental in repeating Karl Jansky's pioneering but somewhat simple work, and conducted the first sky survey in the radio frequencies. After World War II, substantial improvements in radio astronomy technology were made by astronomers in Europe, Australia, and the United States, and the field of radio astronomy began to blossom.

One of the most notable radio astronomy developments came in 1946, with the introduction of radio interferometry (see, for example, "Solar Radiation on 175Mc/s "¹ by Martin Ryle's group at Cambridge University, which was awarded a Nobel Prize for this, and later aperture synthesis work). Another major development was the Lloyd's mirror interferometer, developed independently in 1946 by Joseph Pawsey's group at the University of Sydney.²

In the early 1950s, the Cambridge Interferometer mapped the radio sky to produce the famous *Second Cambridge Catalogue of Radio Sources (2C)* and *Third Cambridge Catalogue of Radio Sources (3C)*³ surveys of radio sources. In the late 1950s and early 1960s, the largest single-dish radio telescope in the world was the 76-m telescope at Jodrell Bank, England, which became operational in 1957. It was one of many radio telescopes constructed during the middle of the 20th century, and has been surpassed by more modern telescopes and arrays of telescopes.

This chapter describes the basic types and functions of modern radio telescopes and highlights several of the more notable instruments.

Position and Coordinates

The accurate position of a radio source is necessary to distinguish the source from others and to assist in its identification with optical objects when possible. The position is conveniently expressed in *celestial equatorial coordinates*: *right ascension*, α ; and *declination*, δ . The poles of this coordinate system occur at the two points where Earth's axis, extended, intersects the celestial sphere. Midway between these poles is the *celestial equator*, coinciding with Earth's equator, expanded.

The declination of an object is expressed in degrees and is the angle included between the object and the celestial equator. It is designated as a positive angle if the object is north of the equator and negative if south. For example, at the Earth's equator, a point directly overhead (the zenith) has a declination of 0 deg, while at a north latitude of 40 deg, the declination of the zenith is +40 deg.

The *meridian* is a great circle passing through the poles and a point directly overhead (the zenith). The *hour circle* of an object is the great circle passing through the object and the poles. The *hour angle* of the object then is the arc of the celestial equator included between the meridian and the object's hour circle. This angle is usually measured in hours.

A reference point has been chosen on the celestial equator. It is called the *vernal equinox*. The arc of the celestial equator included between the vernal equinox and the object's hour circle is termed the *right ascension* of the object. It is measured eastward from the vernal equinox and is usually expressed in hours, minutes, and seconds.

The right ascension and declination of an object define its position in the sky, independent of the Earth's diurnal rotation. However, because of the slow wobble (precession) in the direction of Earth's rotation axis, there is a gradual change in these coordinates for a fixed object in the sky, the change completing one cycle in 26,000 years. Thus, the right ascension and declination of an object will again be the same as they are now in 26,000 years. To be explicit, it is necessary to specify the date to which the right ascension and declination refer. This date is called the *epoch*. At present, the *epoch* 2000.0 is commonly used in catalogs of source positions (that is, the right ascension and declination are those of January 1, 2000, which are then precessed to the current date).

Polarization and the Stokes Parameter

Any monochromatic wave is elliptically polarized, i.e., the end point of its electric vector at each point in space periodically traces out an ellipse or one of its special forms, viz. a circle or straight line. On the other hand, a polychromatic wave can be in any state of polarization, ranging from the elliptically polarized state to the unpolarized state, where the end point of the electric vector moves quite irregularly. Cosmic radio waves are generally in neither of these two extreme states but rather in an intermediate state containing both elliptically polarized and unpolarized parts. Such a wave is said to be "partially polarized" and is described by four parameters first introduced by Sir George Gabriel Stokes in 1852.^{4,5}

Given a specific coordinate system, it is possible to express the Stokes parameters in terms of the orthogonal electric field components of the incident radiation. Considering the simplest case of a monochromatic completely polarized wave, the orthogonal components of the incident radiation can be written as

$$\begin{aligned} E_x &= E_1 \sin(\omega t - \delta) \\ E_y &= E_2 \sin(\omega t) \end{aligned} \quad (49-1)$$

where δ is the phase difference between E_x and E_y , and E_1 and E_2 are real amplitudes. The four Stokes parameters are

$$\begin{aligned} I &= E_1^2 + E_2^2 \\ Q &= E_1^2 - E_2^2 \\ U &= 2E_1E_2 \cos(\delta) \\ V &= 2E_1E_2 \sin(\delta) \end{aligned} \quad (49-2)$$

A telescope measures radiation over a finite bandwidth so that the net polarization is the result of averaging many monochromatic components with independent

polarization properties. In that case, we can only measure average polarization properties. Thus, for partially polarized waves, the quantities E_1 , E_2 , and δ are time dependent, so time averages must be taken to find the Stokes parameters:

$$\begin{aligned} I &= \langle E_1^2 \rangle + \langle E_2^2 \rangle \\ Q &= \langle E_1^2 \rangle - \langle E_2^2 \rangle \\ U &= 2 \langle E_1 E_2 \cos(\delta) \rangle \\ V &= 2 \langle E_1 E_2 \sin(\delta) \rangle \end{aligned} \quad (49-3)$$

The I parameter is a measure of the power of the polarized radiation, Q and U are measures of linear polarization, and V is a measure of circular polarization. For a completely unpolarized wave, $Q = U = V = 0$.

Since the trigonometric functions above can never be greater than 1, and since waves can add in and out of phase (interfere constructively or destructively), we see that

$$I^2 \geq Q^2 + U^2 + V^2 \quad (49-4)$$

We now define the degree of polarization as

$$H = \frac{\sqrt{Q^2 + U^2 + V^2}}{I} \quad (49-5)$$

For the monochromatic wave $I^2 = Q^2 + U^2 + V^2$, the four parameters are not independent.

For fully polarized waves, the degree of polarization is 1, and for unpolarized waves the degree of polarization is 0.

Stokes parameters are particularly useful for describing the cosmic microwave background radiation (CMBR) as it is largely unpolarized, with a small polarized anisotropy on the order of one part in 10^6 . Thus, the partial polarization of the CMBR is expressed in terms of the Stokes parameters (I , Q , U , and V), which constitute the observables for most CMBR polarization experiments. Note that the CMBR is not expected to have circularly polarized anisotropies, so the measure of V can actually be used as a null test in polarimeter calibration.

Stokes parameters have units of power although CMBR experiments measure the Stokes parameters as a temperature at points on the sky (the two units are related by a constant conversion factor). Thus, polarization experiments usually refer to the temperature Stokes parameters Q_T , U_T , I_T , and V_T . The Q and U parameters are separated by 45 deg, and a 90-deg rotation of either parameter results in its inverse (so Q rotated by 90 deg gives $-Q$). It is possible to redefine the linear polarization Q and I Stokes parameters as

$$\begin{aligned} I &= \frac{T_x + T_y}{2} \\ Q &= \frac{T_x - T_y}{2} \end{aligned} \quad (49-6)$$

where T_x and T_y are the temperature measurements of the x and y orthogonal polarization components. Note that U can be derived by rotating the detection axes by 45 deg. There are a number of experiments under way to measure the polarization properties of the CMBR (see, for example, Leitch et al and Piacentini et al^{6,7}).

49.2 SINGLE-APERTURE RADIO TELESCOPES

The basic properties of single-aperture radio telescopes are described here, including common antenna geometries and feed systems.

Beamwidth and Sidelobes

The beam of a single-aperture telescope is the Fourier transform of the aperture illumination. Consequently, one of the major requirements in the design of telescope feeds and geometries is to control the illumination of the primary reflecting surface to produce a beam with the desired characteristics. There is a fundamental conflict between maximum sensitivity along the main beam axis and the level of sidelobes, because the Fourier transform of a function with sharp edges will contain power over a wide range of spatial frequencies.

For example, maximum telescope sensitivity occurs when the power received by each unit of collecting area is added equally, i.e., none of the power falling on the telescope aperture is wasted. This is equivalent to saying that the aperture is uniformly illuminated by the feed. In one dimension, uniform illumination is a rectangular function that is zero outside of a width equal to the diameter of the telescope's primary reflector. But the Fourier transform of a rectangular function is a sinc function whose central peak has a width inversely proportional to the width of the rectangle.⁸ However, a sinc function also has significant power outside of the main peak in the form of gradually decreasing oscillations (ringing). Thus, a telescope with uniform illumination has maximum sensitivity along the main beam (the central peak of the sinc function) but also has large sidelobes (the multiple maxima of the sinc function on either side of the central peak) that respond to radiation from other directions.

For applications where main-beam sensitivity is the primary goal, such as observations of point sources (spacecraft or natural radio sources whose angular size is much smaller than the telescope's beamwidth), uniform illumination is the proper goal. An aperture illumination pattern with perfectly sharp edges is not possible, but with careful design of the feed and reflector shapes, a good approximation to this can be achieved.

In many radio astronomy observations, the radio emission comes from a region that is not angularly small compared to the width of the telescope beam. In this case, large sidelobes can cause serious confusion, since the telescope is responding simultaneously to multiple areas of the radio source. For observations where this is a concern, such as mapping of extended emission regions or observing a weak radio source with stronger sources nearby in the sky, it is worth trading some sensitivity for much lower sidelobes.

As an extreme example of this, consider a telescope illuminated using a Gaussian function. The Fourier transform of a Gaussian is just another Gaussian whose width is inversely proportional to the width of the first Gaussian. Here we have a telescope beam whose amplitude decreases smoothly to a very low level with no ringing. Of course, true Gaussian illumination is not possible because the function will be cut off at some point by the edge of the telescope aperture. On the other hand, the Fourier transform of a more realistic truncated Gaussian contains some high spatial-frequency components, but if the truncation occurs far enough from the central peak so that the Gaussian amplitude is already very small, the resulting telescope beam will be a reasonable approximation of a Gaussian. In this case, however, much of the telescope collecting area is being used very inefficiently; the power received by the surface near the edge of the primary reflector is largely rejected by the feed.

Compromises between the extreme cases of aperture illumination described above have been implemented. In many cases, a cosine-squared illumination function has been adopted because it provides higher main-beam sensitivity than Gaussian illumination and lower sidelobes than uniform illumination.

In general, illumination functions that drop quickly and smoothly to zero at the edge of the primary reflector are desirable not only because they reduce sidelobes but also because they do not see radiation coming from beyond the edge of the dish (thermal emission from the ground, for example). Illumination patterns that do not drop to zero at (or inside) the reflector edge are said to spill over the reflector, and will respond to radiation from the ground. This, in turn, increases the background noise level of the observations.

Directivity, Gain, and Effective Aperture

The directivity and gain of a radio telescope are both measures of the ratio between the telescope's response to radiation from the direction of the main beam to the response to radiation from other directions. This ratio depends on the width of the telescope's main beam, which in turn is inversely proportional to the width of the telescope aperture in units of the observing wavelength. The constant of proportionality depends on the aperture illumination function but is normally close to 1.

If the telescope beam is described as a normalized power pattern in spherical coordinates, then the beam (or pattern) solid angle in steradians is the integral of the power pattern over a sphere (4π steradians). If sidelobes in the power pattern are negligible, the beam solid angle is equal to the main beam solid angle. In many cases, the beam solid angle will be close to the solid angle of the main beam within the half-power points. Directivity is equal to $4\pi/\text{beam solid angle}$. Thus, the directivity of a telescope is proportional to its diameter squared. For an isotropic antenna, directivity = 1 for all directions. (This corresponds to the Fourier transform of a delta function.) The gain of a telescope is the directivity converted to logarithmic units (usually dB with respect to an isotropic antenna, or dBi).

The half-power beamwidth of a telescope whose reflector diameter is N wavelengths will be approximately $1/N$ radians (in one dimension). This corresponds to a beam solid angle of $\pi/(4N^2)$ steradians in two dimensions. Since the beam solid angle is also equal to $4\pi/\text{directivity}$, we have directivity = $16N^2 = 16 (\text{diameter/wavelength})^2 = 4\pi (\text{area})/(\text{wavelength})^2$. Here, the area is the effective area of the telescope.

The effective area is equal to the geometric area in the case of perfect uniform illumination and no losses, but in reality, the effective area will be smaller than the physical area. The ratio of effective area to physical areas is the aperture efficiency. Typical radio telescopes have aperture efficiencies of 0.5–0.7, but lower values can occur near the low- or high-frequency ends of their designed frequency range.

Common Antenna Geometries

The vast majority of telescopes used for radio astronomy are axially symmetric reflectors. A number of other designs such as cylindrical parabolic reflectors, fixed spherical and parabolic reflectors, and large arrays of low-gain antennas are described in Section 49.5.

The main differences between symmetric reflecting telescopes are the number of reflecting surfaces and the location of the focal point(s). The simplest geometry is a single parabolic reflector with a feed located at the focal point. This is commonly referred to as a prime-focus telescope. It is used chiefly at low frequencies, where the long wavelengths require a physically large reflector to avoid significant diffraction effects. In this regime, any additional reflecting surfaces would also need to be physically large.

At higher frequencies, either the dual-reflector Cassegrain or Gregorian geometry can be used. In both cases, a secondary reflector (also called a subreflector) is used in the optical path between the feed and the primary parabolic reflector. The main difference in the two geometries is the shape of the subreflector: In Cassegrain geometry, the subreflector is a hyperbola with the feed at one focal point of the hyperbola (the secondary focus) and the other focal point of the hyperbola at the primary parabola focal point. In Gregorian geometry, the

subreflector is a concave ellipse with the feed at one focal point and the other focal point at the ellipse focal point. Gregorian geometry allows a low-frequency feed to be placed at the first focus and operated in prime-focus mode without removing the subreflector. Cassegrain geometry requires that the subreflector be removed for a prime-focus feed to be used.

It is possible to improve the efficiency of such systems by changing the shape of the subreflector to optimize the primary aperture illumination (for example, to make it more uniform for maximum telescope gain). If this is done, the primary reflector shape must also be changed to compensate for the additional phase changes caused by the new subreflector shape and to restore uniform phases across wavefronts. Telescopes that have been optimized in this way are called shaped antennas and can achieve aperture efficiencies of about 0.8.

A variation on the two-reflector geometries is a nonsymmetrical, offset section of a parabola for the primary reflector shape. This allows the subreflector (and the prime focus) to be located out of the beam path and thus avoids blockage and scattering of incoming radiation. Figure 49-1 shows one of the Allen Telescope Array antennas (under construction in Northern California) before the feed and ground shield are mounted. The feed will go near the bottom of the main reflector, pointing towards the subreflector. The ground shield will be below the feed, to prevent sidelobes from seeing radiation from below.

Some telescopes use multiple reflectors to steer the beam from the subreflector to a location where the feeds and receivers can remain stationary and can be changed rapidly. These beam-waveguide (BWG) geometries are particularly appropriate when high power transmission is needed, since the heavy transmitter does not need to be mounted on the moving telescope structure. An example of the BWG design used by NASA's Deep Space Network is shown in Figure 49-2.

FIGURE 49-1 The ATA offset Gregorian optics before the addition of the feed and ground shield

FIGURE 49-2 Deep Space Network research and development antenna

Radio telescopes designed for very high frequencies (millimeter and submillimeter wavelengths) often use additional reflecting surfaces to allow receivers to be located along the elevation axis and thus remain fixed as the telescope moves in elevation. At very high frequencies, the subreflector can be physically small and, consequently, it is practical to move it rapidly to switch the telescope beam between on-source and off-source positions. This allows better calibration by canceling slowly varying atmospheric effects.

Common Feed Types

There are four broad classes of feeds: (1) narrowband, (2) multiband, (3) wide-band, and (4) phased-array. Traditionally most telescopes for radio astronomy have been equipped with narrowband conical horn feeds. These feeds can provide very high performance but at the expense of flexibility. The frequency range covered by horn feeds is usually no more than a factor of 2. Horn feeds are usually designed with ridges or corrugations along the inside of them to control the profile of the radiation pattern. They can have high gain (narrow beamwidths), which makes them a natural match to high-frequency telescopes with small subreflectors. They can also be designed to have low gain (for prime focus) by making the output matching section a very-wide-angle cone. However, at low frequencies, all horn feeds tend to be physically large, which makes them unsuitable for cryogenic cooling. At high frequencies, horn feeds can be placed inside Dewars and cooled to reduce noise associated with ohmic losses in the feed material. For high-gain feeds, the vacuum window in the Dewar needs to be only slightly larger than the diameter of the feed. An alternative type of narrowband feed for low frequencies is a pair of crossed dipoles or a set of four dipoles in a square configuration, mounted over a ground plane (and sometimes also surrounded by a short, cylindrical cavity wall). These feeds are appropriate for prime-focus mounting, are smaller than a horn feed for the same frequency, but have higher sidelobes and consequently lower performance.

A special case of a narrowband feed is a line feed, which can be used to compensate for spherical aberration caused by using a spherical primary reflector. Line feeds are designed so that the propagation of velocity of signals along the feed is equal to the speed of signal convergence along the linear focus of a spherical reflector. Line feeds are intrinsically very narrowband and are insensitive directly along their axis.

Multiband feeds are usually combinations of two or three narrowband conical feeds that are mounted coaxially. An example of this type of feed is shown in Figure 49-3.

FIGURE 49-3 Multiband feed

Wide-band feeds sacrifice some performance in exchange for exceptional flexibility. Most wide-band feed designs are based on log-periodic structures of some sort, in which radiation at a given frequency couples with the part of the structure that is resonant at that frequency and then travels along the structure as a balanced feedline to the amplifier input. Log-periodic feeds can cover frequency ranges exceeding 20:1, with a nearly constant beamwidth throughout the whole range. However, the beamwidth is normally very large (60–90-deg full opening angle), and sidelobe levels are relatively high. Log-periodic feeds can be made to have higher gain if they have a small opening angle (i.e., are tall and slender). In this case, several elements are nearly resonant at the same frequency and can interact like the elements of a Yagi antenna. However, the phase center in this type of feed moves along the structure with frequency, so some of the wide-band advantage is lost because only part of the feed structure can be near the telescope focal point at a given time. Newer designs avoid this problem by using a very large opening angle for the log-periodic antenna (short and wide structure). The change in phase center with frequency is kept small because the entire structure is very short. In this case, very low feed gain is unavoidable.

Phased-array feeds are composed of many antenna elements whose signals are combined with appropriate phase shifts to create a desired beam profile. Because the signal from each element can be combined with other signals an arbitrary number of times, phased arrays can create multiple beams simultaneously and thus cover a much larger area of sky than a single feed can. The ability to control phases can also be used to correct for wavefront distortions caused by errors in the telescope's reflecting surfaces. The main limitations of phased array feeds are that they require separate low-noise amplifiers for each antenna element, thus increasing the cost. And they are difficult to use over wide frequency ranges because the physical spacing between elements is optimal for only a narrow range of frequencies.

Most feeds are inherently linearly polarized, while most radio astronomy observations use circular polarization to eliminate the effects of Faraday rotation in the ionosphere. Circular polarization can be obtained from a pair of orthogonal linear feeds by combining the signals from them with a 90-deg phase difference. With this approach, the useful frequency range may be limited by the polarizer more than by the feed. Some feeds, such as helical feeds, are inherently circularly polarized.

Calibration of Telescope Sensitivity

For radio astronomy, the important parameter for telescope sensitivity is system equivalent flux density (SEFD), which can be calculated by observing a radio source of known flux density and measuring the increase in system temperature due to the source. The ratio of the temperature increase over the source flux density is the telescope sensitivity in K/Jy , which depends only on telescope size and efficiency.

The increase in system temperature caused by a radio source is the antenna temperature of the source. This can be measured in kelvins if the system temperature is calibrated using hot and cold loads in front of the first amplifier. If the off-source system temperature is T_{sys} , the antenna temperature T_{ant} is

$$T_{ant} = (P_{on} - P_{off} / P_{off}) \times T_{sys} \quad (49-7)$$

where P_{on} and P_{off} are the receiver output power level with the telescope on source and off source. Having the antenna temperature in kelvins for a radio source of known flux density, we can determine the aperture efficiency of the telescope.

To include the effect of system temperature on sensitivity, we can use the K/Jy value to convert the system temperature T_{sys} into flux density units (Jy). This is the SEFD, and it combines

the effects of telescope size, efficiency, and receiver performance (system temperature). It is a useful way to compare the sensitivities of different telescopes; smaller values of SEFD are better because they imply higher sensitivity (a combination of high K/Jy and low T_{sys}).

49.3 THE TWO-ELEMENT INTERFEROMETER

The basic characteristics of the two-element interferometer are described here. The two-element interferometer provides the fundamental building block for astronomical observations.

Electric Field Correlations

An interferometer is an instrument that measures the correlation of electric fields at spatially separate locations. These correlations contain information about the sky brightness distribution on angular scales that are inversely related to the spatial scale over which the field correlation between points is measured. Thus, an interferometer that measures the cross-correlation of electric field received at points separated by a small physical distance is sensitive to emissions from the sky on large angular scales, and an interferometer that measures cross-correlations between points physically far apart is sensitive to small angular-scale structures in radiation from the sky.

The cross-correlation of two electric fields, E_1 and E_2 , is $\langle E_1 E_2 \rangle$ so it is equivalent to multiplying the received signals from one telescope by the received signals from a second. However, the cross-correlation will be significant only if it is the product of samples from different parts of the same wavefront. That means that any propagation delay between the time a given wavefront reaches one telescope and the time it reaches the second telescope must be compensated for before the signals from the two receivers are multiplied by each other.

Let T be the geometric delay between the two telescopes (equal to the dot product of the baseline vector between the two telescopes and a unit vector in the direction of the radio source being observed), and let H be the Hilbert transform (corresponding to a 90-deg phase shift). Then the cross-correlation between voltages E_1 and E_2 from telescopes 1 and 2 is

$$C = \langle E_1(t) E_2(t + T) \rangle + i \langle H[E_1(t)] E_2(t + T) \rangle \quad (49-8)$$

Note that the cross-correlation defined here is a complex function. In practice, it is obtained by delaying the signal from telescope 1 by the geometric delay, T ; multiplying (and averaging) the delayed E_1 with E_2 ; and simultaneously multiplying (and averaging) E_1 shifted by 90 deg with E_2 . The circuit that performs these tasks is called a complex correlator, and it is a basic component of all modern interferometers. The complex sum of the two independent outputs of a complex correlator is the visibility function, which differs from the complex cross-correlation function only in details of amplitude calibration.

The Visibility Function

The visibility function is the Fourier transform of the sky brightness distribution. As mentioned above, it is a complex function. Because sky brightness is a positive real function, its Fourier transform must be a Hermitian function: (1) the visibility function is complex, (2) the real part is symmetric about the origin, and (3) the imaginary part is antisymmetric about the origin. The visibility measured by an interferometer is a function of sky brightness distribution and the projected length and orientation of the interferometer baseline. It is *not* a function of the absolute positions of the telescopes but only of the

projection of the baseline vector between the telescopes in the direction of the source. Each observation with an interferometer provides one sample of the visibility function. From a number of such measurements, the strength and position of radio sources can be deduced.

At this point, it is useful to recall a few mathematical properties of Fourier transforms. These include linearity (the visibilities of multiple radio components add), shift (changing the position of a source on the sky produces a phase gradient in the visibility function), and similarity (larger radio sources have more compact visibility functions).

It is traditional, and also helpful, to imagine that measurements of the visibility function are all made on a plane. Then we can define a coordinate system that has one axis orthogonal to this plane. The coordinates of this system are (u, v, w) , with w orthogonal to the plane in which the visibility measurements are made. In other words, w points toward the radio source being observed. By convention, u points east, and v points toward the north celestial pole.

$$V_v(u, v) = \iint \frac{I_v(l, m)}{\sqrt{1 - l^2 - m^2}} e^{-2i\pi(ul + vm)} dl dm \quad (49-9)$$

The sampling of the visibility function by interferometers can be quantified by specifying the position in the projected baseline vector in the (u, v) plane. The more thoroughly the (u, v) plane is sampled, the more completely the visibility function is known, and the more accurate our knowledge of the sky brightness distribution becomes. Recall that the amplitude of the visibility function tells us about the radio source structure, and the phase tells us about the source position on the sky.

Geometric Delay

The geometric delay of an interferometer depends only on the length and orientation of the baseline with respect to the direction of the radio source being observed. If \mathbf{B} is the baseline vector between two telescopes, and \mathbf{S} is a unit vector in the direction of the source, the geometric delay is just the dot product $(\mathbf{B} \cdot \mathbf{S})/c$. As the interferometer tracks a source across the sky, $\mathbf{B} \cdot \mathbf{S}$ changes and, consequently, the geometric delay changes. For a perfect system, we can introduce an exact delay correction to keep the fringe phase constant as a function of time.

In real instruments, there is always some error in our knowledge of the baseline vector, and often there is also some uncertainty in the position of the radio source. These errors contribute to an uncertainty in the calculated geometric delay of

$$\Delta\tau = \sqrt{(\sin\theta/c)^2 \Delta B^2 + (B \cos\theta/c)^2 \Delta\theta^2} \quad (49-10)$$

If the uncertainty in delay is large compared to the Nyquist sampling⁹ interval in delay (the inverse of twice the observing bandwidth), then a search over multiple delays is needed to determine the delay that produces the highest visibility amplitude. This is called fringe searching and is most often needed when the separation between telescopes is very large (hundreds to thousands of kilometers).

If we know the sky positions of several radio sources very well, we can use this knowledge to determine the baseline vector of an interferometer. Let ΔB be the error in our assumed baseline vector \mathbf{B} (in wavelengths), let δ be the declination of a radio source, and let H be the hour angle of the radio source (the distance in right ascension from transit, where $H = 0$). The interferometer phase as a function of hour angle is $\phi(H) = 2\pi(\mathbf{B} \cdot \mathbf{S})$ for a perfect system. The baseline error $\Delta B = \Delta B_x, \Delta B_y, \Delta B_z$ causes a change in the baseline phase of

$$\Delta\phi(H) = 2\pi \Delta B_x \cos(\delta) \cos(H) - 2\pi \Delta B_y \cos(\delta) \sin(H) + 2\pi \Delta B_z \sin(\delta) \quad (49-11)$$

We are ignoring any constant instrumental phase. By measuring $\Delta\phi(H)$ for sources at multiple declinations, we can solve for ΔB_x , ΔB_y , and ΔB_z (and a constant instrumental phase as well).

Fringe Rotation

Radio interferometers normally convert the received high radio frequencies to a lower, intermediate frequency for transmission to the correlator. As a result, when the geometric delay compensation is applied as part of the cross-correlation process, it is applied at a different frequency than the frequency the geometric delay occurred at. The result is a phase error, which can be corrected by adjusting the phase of the local oscillator at the telescope whose signal undergoes the geometric delay compensation.

Phase Switching

Systematic errors at very low fringe rates can limit the accuracy of interferometer measurements. These errors include interference picked up at the intermediate or baseband frequencies, offsets in digitizer thresholds, or cross-talk between correlators. By applying 180-deg phase shifts using orthogonal switching waveforms to the signals from the telescopes, we can suppress this type of error. An example of orthogonal digital waveforms are the Walsh functions, which are used for phase switching of the local oscillators at the Very Large Array (New Mexico) telescopes.^{10,11} When integrated over many phase switching cycles, signals entering the system before the first mixer (where the local oscillator signal is applied) are unaffected by phase switching, while signals that enter the system after the first mixer are suppressed.

Digital Cross-Correlation

Nearly all modern correlators are digital, but the process of digitizing an analog signal causes loss of information. For wide-bandwidth signals, it is often impractical to use many bits per sample when digitizing and, consequently, it is necessary to correct the measured visibility amplitudes for the loss in signal-to-noise ratio (SNR) caused by the sampling. For 1-bit sampling, as used for interferometers in which the widest possible bandwidth is desired, the sampling loss is a factor of about 1/3. Even for 2-bit (4-level) sampling, the loss is greater than 10 percent.

It is also necessary to make a digital correction to both the visibility amplitude and phase, which depends on the signal-to-noise ratio (SNR) and the number of bits used to digitize the signal. Van Vleck¹² first noted that digitization causes an increase in correlation at low correlation levels and a predictable nonlinearity at high correlation levels. The correction is applied separately to the real and imaginary output of a complex correlator, so the correction affects the visibility phase as well as the amplitude.

Calibration

Possibly significant error sources, in the order they occur along the signal chain, are

- **Ionospheric Faraday Rotation** The linear polarization angle of radiation passing through the ionosphere is rotated by a difference in propagation velocity between left and right circular polarization (birefringence). This effect is proportional to wavelength

squared and, consequently, can be measured and corrected by using widely spaced frequencies to measure the frequency dependence of the polarization angle. It is also possible to determine ionosphere electron density from Global Positioning System measurements.

- **Troposphere Effects** Variations in water vapor in the troposphere cause changes in amplitude due to opacity, and changes in phase due to excess path length. These changes can be a dominant error source at high frequencies. Water vapor radiometers, which measure the strength of water line emission, can help to calibrate these changes, but the best solution is usually antenna-based self-calibration (discussed in Section 49.4).
- **Parallactic Angle** This is a time-varying angle between the feed polarization response and the sky; it is important for polarization measurements. It can be calibrated by observing radio sources with known linear polarization position angles. The parallactic angle is defined as

$$\chi(t) = \arctan \left(\frac{\cos(l) \sin(h(t))}{\sin(l) \cos(\delta) - \cos(l) \sin(\delta) \cos(h(t))} \right) \quad (49-12)$$

l = latitude, $h(t)$ = hour angle, δ = declination

- **Antenna Voltage Pattern** The antenna voltage pattern is important only for wide-field observations. It can be determined from direct measurement or from modeling of the feed and mechanical structure of the telescope.
- **Electronic Gain** This includes a large number of amplitude and phase effects introduced by imperfect electronics (in amplifiers, mixers, filters, digitizers, etc.) but excluding frequency-dependent effects. Calibration usually requires a stable broadband noise source that can be added to the signal path before the first active device. Measurement of the total system temperature combined with the telescope sensitivity in units of K/Jy allows the amplitude of interferometer fringes (i.e., the amplitude of the visibility function) to be determined.
- **Bandpass Response** Both amplitude and phase response can vary across the observed bandwidth due to instrumental or—at millimeter and submillimeter wavelengths—atmospheric effects. The bandpass response can be calibrated by observing a strong continuum radio source.
- **Geometric Compensation** Errors in the baseline vector can be corrected using observations of radio sources having well-known positions. If the calculated geometry is imperfect, there will be a residual baseline phase that varies with the angle between the source direction and the interferometer meridian. After the residual phases of sources are measured as they move across the sky, the resulting data can be used to solve for corrections to the baseline vector via a least-squares fit.

Sensitivity

The root-mean-square (rms) noise level in the output of an interferometer (in janskys) is given by

$$\Delta S = \frac{1}{\eta_s} \times \frac{\text{SEFD}}{\sqrt{2 \times \Delta \nu \times \tau_{\text{acc}}}} \quad (49-13)$$

where SEFD is the system equivalent flux density of the interferometer, η is the efficiency, $\Delta \nu$ is the observing bandwidth, and τ is the integration time.

Model Fitting

A single baseline interferometer cannot produce sufficient sampling of the visibility function to result in a true radio image of the sky. However, it is still possible to determine the basic characteristics of a radio source with model fitting. This technique involves relatively simple geometric modeling for one- or two-point sources, Gaussian or uniform disks, edge-darkened or edge-brightened disks, as examples.

The model parameters (flux density, position, diameter, axial ratio for elliptical sources, etc.) are adjusted to minimize the difference between the Fourier transform of the model and the observed visibility data.

With accurately calibrated fringe amplitudes, it is possible to determine source flux densities and sizes (and sometimes shapes) with model fitting. The orientation and angular separation of double sources can also be found and changes monitored in this way. With the addition of fringe-phase data, the sky positions of sources can be found with model fitting (although it is much more difficult to accurately calibrate interferometer phase data than amplitude data).

Astrometry

Positional information is contained in the phase part of the visibility function. The residual phase on an interferometer baseline tells us how far the true signal delay between the two telescopes differs from the calculated delay. If the interferometer baseline is well known, this in turn tells us how far the radio source is from its assumed position. Because baseline phases can be difficult to calibrate and use directly, it is sometimes advantageous to use instead the phase differences between different frequencies. This observable is immune to ambiguities in total phase values.¹³ The derivative of phase with frequency is the group delay, and the accuracy with which it can be measured depends on the total range of frequencies used. If the total bandwidth that can be observed is too small for a good group delay measurement, it can be split between two narrower bands that are spaced farther apart in frequency. This is called bandwidth synthesis, and is used for position measurements on long baselines, where it is very hard to avoid ambiguities in the total number of turns of baseline phase.

Baseline phases can be used directly to measure angular separations between sources. These phase-referenced measurements do not provide absolute source positions but can provide very precise relative positions. In phase referencing, one source is used to determine instrumental and atmospheric effects, and the phase difference of the second source gives us the position difference. This approach works well when the sources are angularly close enough that the two lines of sight from each telescope pass through the same regions of the atmosphere and ionosphere and if at least one of the sources is strong enough that the integration time needed to obtain a high SNR is shorter than the time scale of atmospheric propagation changes. All other instrumental errors cancel in the differencing.

If, however, the second source is too weak to detect in a short integration time, the measured phases from the stronger source can be used to extend the coherent integration time on the weak source. In this mode of phase referencing, the coherent integration time can be extended to hours instead of the usual seconds to minutes.

The limitation to this technique is the lack of precision with which the phases on the strong source can be interpolated to the times when the weaker source is being observed.

The precision of astrometric position measurements is the angular resolution of the interferometer (the observing wavelength divided by the baseline length) divided by twice the SNR. It is possible to obtain high precision with long-baseline interferometers and moderate SNR or with short baseline interferometers and high SNR. Ideally, of course, one has both. Current intercontinental interferometers can measure relative positions with a precision better than 0.5 nanoradians for sources producing a signal only 10–20 times the thermal noise level.

49.4 APERTURE SYNTHESIS

The term *aperture synthesis* refers to the fact that a multibaseline interferometer can produce radio images with an angular resolution equal to that of the longest baseline. In other words, the interferometer can synthesize the resolution of an aperture with the same diameter as the array of telescopes. This section describes how aperture synthesis is used to form images.

(u, v) Plane and the Synthesized Beam

The (u, v) plane was introduced in Section 49.3. It is a plane orthogonal to the line of sight to a radio source in which the location of the projected baseline vector shows where the visibility function is being measured. Because the visibility function is Hermitian, a single baseline interferometer measures two points on opposite sides of the origin in the (u, v) plane.

A multitelescope interferometer with N telescopes has $N(N-1)/2$ simultaneous baselines (the factor of 2 is because the baseline between telescope 1 and 2 samples the same (u, v) points as the baseline between telescopes 2 and 1). The Fourier transform of the sampled points in the (u, v) plane, with each sampled point weighted equally, is the synthesized beam of the interferometer. This is the same as the point spread function in optical terminology. If N is large enough or the telescopes are moved to allow the baselines to sample the (u, v) plane reasonably well, the synthesized beam will have a well-defined peak along with a complex pattern of sidelobes. A synthesized beam with a single clear peak is necessary for aperture synthesis imaging.

Earth Rotation Aperture Synthesis

The position of the sampled points in the (u, v) plane moves as Earth rotates because the projected length and orientation of the baseline changes. The curve of sampled points in the (u, v) plane will be a section of an ellipse whose origin and axial ratio depend on both the baseline geometry and the position of the radio source.

The importance of Earth rotation aperture synthesis is that the constantly changing baselines of a multitelescope interferometer can, over a period of several hours, sample the visibility function (u, v plane) so well that an inverse Fourier transform of the visibility function can be calculated to produce an initial radio image of the region of sky being observed. The usual practice is to place the measured (u, v) points onto a uniform two-dimensional grid that extends at least a factor of 2 beyond the measured points to accommodate the fast Fourier transform (FFT) algorithm. This “gridding” of the measured data can be done by shifting, averaging, or interpolating, depending on the density of measurements and the spacing of points in the grid.

There are many options for weighting gridded visibility data. The most obvious is to weight every gridded data point equally. This provides a synthesized beam with maximum angular resolution, as it corresponds to uniform illumination in the single-aperture case. However, it also produces a beam with relatively high sidelobe levels (for the same reason), and lowers beam sensitivity somewhat because grid points in which several independent visibility measurements were averaged together have the same weight as grid points based on single measurements. The alternative is to weight each grid point by the number of measurements that it is based on—in effect, weighting all of the original measurements equally. This provides maximum sensitivity since no data are reduced in weight, but because most interferometers produce much denser sampling near the origin of the (u, v) plane than farther out in the long-baseline regions, the resulting synthesized beams are usually much broader than the angular resolution of the longest baseline. Weighting all visibility measurements equally does tend to

produce a synthesized beam with lower sidelobes and is often a better choice for the detection of extended radio emissions. If the goal of an observation is to detect or image very extended, low-surface brightness emissions, the synthesized beam can be further broadened by applying a Gaussian weighting function to the (u,v) data. This is called “tapering”; it effectively reduces the weight of data points far from the (u,v) origin. These points provide high angular resolution information, but they are insensitive to very extended emissions.

Of course, there will always be regions in the (u,v) plane that are not sampled and for which we will consequently have no observational constraints on the visibility function. These unsampled regions, if they are a significant fraction of the overall area of measurements in the (u,v) plane, can cause serious artifacts in the image produced by Fourier transforming the gridded visibility data. Historically, unsampled (u,v) points were set to zero before the Fourier transform was done. This was a computationally simple and often surprisingly effective solution, but it was certainly not an optimal way to approximate the visibility function at unmeasured grid points. More often, a convolving function is used to fill in missing values, but choosing this approach implicitly assumes that the unsampled regions are relatively small. Furthermore, in nearly all cases, the lack of dense and uniform measurement of the visibility function leads to image artifacts that need to be removed.

Instrument Calibration

Another cause of errors in radio images produced by aperture synthesis is imperfect calibration of the measured visibility function amplitude and phase. The correlator output can be calibrated to produce fringe or visibility amplitudes in janskys if the telescope sensitivities and signal processing losses are known. If C is the fraction of signal power from two antennas that is correlated (the correlation coefficient, or the fraction of bits correlated – $1/2$), then the calibrated fringe amplitude is given by

$$\begin{aligned} S_{\text{corr}} &= Cb \sqrt{(T_{\text{sys1}} T_{\text{sys2}}) / (T_{\text{ant1}} T_{\text{ant2}})} S_{\text{total}} \\ &= Cb \sqrt{(\text{SEFD}_1 \text{ SEFD}_2)} \\ &= Cb \sqrt{(T_{\text{sys1}} T_{\text{sys2}}) / (\text{DPJY}_1 \text{ DPJY}_2)} \\ &= Cb 2k \sqrt{(T_{\text{sys1}} T_{\text{sys2}}) / (A_{\text{eff1}} A_{\text{eff2}})} \end{aligned} \quad (49-14)$$

where T_{sys} and T_{ant} are the system and antenna temperatures at a given telescope, S_{total} is the total flux density of the radio source in janskys, SEFD is the system equivalent flux density at a telescope, DPJY (degrees per jansky) is telescope sensitivity expressed in K/Jy , and A_{eff} is the effective area of a given antenna (the physical collecting area \times the aperture efficiency). Note that the antenna temperature is just the source flux density $\times K/\text{Jy}$ for the telescope ($K/\text{Jy} = A_{\text{eff}} / 2k$). The correction factor, b , accounts for system losses due to a number of causes, including nonrectangular bandpasses, mismatches in feed polarizations, phase fluctuations between local oscillators, signal digitization, and discrete steps in delay compensation; b is typically between 1 and 2 in well-designed interferometers and can be determined from observations of sources that are completely unresolved by the interferometer (for which $S_{\text{corr}} = S_{\text{total}}$).

The rms noise in a measurement of S_{corr} is given by

$$S_{\text{rms}} = b S_{\text{total}} \frac{1}{\sqrt{2BW \Delta\tau}} \sqrt{\frac{T_{\text{sys1}} T_{\text{sys2}}}{T_{\text{ant1}} T_{\text{ant2}}}} \quad (49-15)$$

where BW is the observing bandwidth in Hz, and $\Delta\tau$ is the coherent integration time in seconds. The value of $\Delta\tau$ is limited by either the atmospheric coherence time or the local oscillator coherence time. In terms of fractional frequency stability ($\Delta f/f$), the coherence time can be estimated $\Delta\tau = 1/[(\Delta f/f) \times \text{observing frequency in Hz}]$.

Phase calibration is more difficult than amplitude calibration because the baseline phase can change very rapidly due to propagation effects in the ionosphere (at low frequencies) or troposphere (at high frequencies). These phase fluctuations increase as baseline length increases, up to several kilometers, and saturate at longer baselines.

Self-Calibration

The most effective way to remove phase fluctuations from interferometer data is to remember that all of the major contributions to the phase errors are telescope based. That is, changes in the propagation along one telescope's line of sight—or local oscillator phase changes, or mispointing, or mechanical changes in the telescope structure, or receiver performance variations—all affect the signal from an individual telescope but have no effect on the signals from any other telescope. This means that errors in interferometer baseline data can be modeled as a product of errors associated with the individual telescopes^{14,15}:

$$V_{\text{obs}}(1,2) = V_{\text{err1}} \times V_{\text{err2}} \times V_{\text{src}}(1,2) \quad (49-16)$$

where V_{obs} is the observed complex visibility on the baseline between telescopes 1 and 2, V_{err} is a complex error associated with a given telescope, and $V_{\text{src}}(1,2)$ is the visibility due to the radio source that would have been measured in the absence of any telescope-based errors. (More correctly, we would use the complex conjugate of V_{err2} because the baseline phase is the difference of the telescope phases.) For a perfect interferometer, $V_{\text{obs}}(1,2) = V_{\text{src}}(1,2)$.

Now consider just the phase part of the visibilities and telescope errors:

$$\phi_{\text{obs}}(1,2) = \phi_{\text{err1}} - \phi_{\text{err2}} + \phi_{\text{src}}(1,2) \quad (49-17)$$

If we sum the observed baseline phases around a triangle of baselines between telescopes 1, 2, and 3, we get a quantity called the closure phase:

$$\begin{aligned} \phi_{\text{closure}}(1,2,3) &= \phi_{\text{obs}}(1,2) + \phi_{\text{obs}}(2,3) + \phi_{\text{obs}}(3,1) \\ &= [\phi_{\text{err1}} - \phi_{\text{err2}} + \phi_{\text{src}}(1,2)] + [\phi_{\text{err2}} - \phi_{\text{err3}} + \phi_{\text{src}}(2,3)] + [\phi_{\text{err3}} - \phi_{\text{err1}} + \phi_{\text{src}}(3,1)] \\ &= \phi_{\text{src}}(1,2) + \phi_{\text{src}}(2,3) + \phi_{\text{src}}(3,1) \end{aligned} \quad (49-18)$$

Note that the sum contains information about the radio source, but all the telescope-based error terms cancel. This means that the closure phase is a very robust observable, although it contains less total information than the individual baseline phases.

A similar trick can be used to produce a quantity that is independent of telescope-based amplitude errors:

$$A_{\text{closure}}(1,2,3,4) = \frac{|V_{\text{obs}}(1,2)| |V_{\text{obs}}(3,4)|}{|V_{\text{obs}}(1,3)| |V_{\text{obs}}(2,4)|} = \frac{|V_{\text{src}}(1,2)| |V_{\text{src}}(3,4)|}{|V_{\text{src}}(1,3)| |V_{\text{src}}(2,4)|} \quad (49-19)$$

Again, the telescope-based errors cancel in the ratio, and we are left with a closure amplitude that contains only information about the radio source.

For an array containing N radio telescopes, the number of independent closure phases and closure amplitudes is $\frac{1}{2}(N-1)(N-2)$ and $\frac{1}{2}N(N-3)$, respectively. These are both smaller than the number of baselines $\frac{1}{2}N(N-1)$. But it is clear that as N increases the amount of information contained in the closure, quantities becomes nearly equal to the information in the baseline amplitudes and phases. The only fundamental information loss associated with the closure phase and closure amplitudes is the absolute sky position and the absolute flux density of the radio source; the closure quantities are independent of these parameters.

The fact that major error sources in radio interferometers are telescope based and thus can be removed without destroying the information we want in the visibility function is the basis for self-calibration. For N telescopes, there are only $(N-1)$ complex errors to solve for (one telescope can be arbitrarily defined as a reference) and there are $\frac{1}{2}N(N-1)$ complex visibility measurements to constrain the solutions. Thus, we can use least-squares to adjust the telescope errors so that the resulting visibilities are as close as possible to the expected visibilities. But what should we expect the visibilities to be? Here we are helped by the fact that the sky is mostly empty at all but the lowest radio frequencies. Consequently, a model of the sky that consists of only a single source is often a good approximation. The Fourier transform of a point source is a visibility function with constant amplitude and zero phase everywhere. This is the usual starting point for self-calibration.

After a least-squares adjustment of the telescope errors, there will most likely be residual differences between the corrected visibilities and the assumed visibilities. This tells us that our model of the sky is imperfect. To achieve a better result, we can Fourier-transform the corrected visibilities to produce a more accurate model of the sky brightness, and then repeat the self-calibration process. Each iteration of self-calibration will produce both more accurate telescope calibration and a more accurate image of the sky. Eventually, the residual differences between the corrected and model visibilities will be so small and random that an image made from the residual visibility data will look like two-dimensional Gaussian noise with an rms amplitude close to the expected thermal noise limit. At that point, self-calibration has converged, and no further improvement in the telescope calibration of the radio image is possible.

Non-Closing Errors

We have seen that self-calibration of an interferometer array can remove telescope-based, or closing, errors. But are there errors that are really baseline dependent and that do not vanish in the closure quantities? There are, although in a well-designed interferometer nonclosing errors can be kept to a very low level. Nevertheless, they can limit the dynamic range of very high-quality radio images made with modern interferometers.

Examples of nonclosing errors are mismatched bandpass and polarization responses between telescopes. These produce additive errors instead of multiplicative errors, so the effect on all baselines to a given telescope will not be identical—it will depend on the telescopes at the other ends of the baselines. There are also subtle correlator errors that can be baseline dependent.

Nonclosing errors can be removed by observing a very strong radio source and measuring the bandpass response (for example) of each telescope accurately and then determining a bandpass calibration function for each telescope to produce a uniform response. Ideally, a very strong unresolved source can be used to calibrate the entire system at once because such a source should produce identical visibility amplitudes on all baselines. However, for interferometers with very long baselines, there are few, if any, radio sources that are completely unresolved.

Image Formation

The basic process of radio-image formation has been described already: grid, weight, and Fourier-transform the visibilities measured by an array of interferometers and, if necessary, use self-calibration to remove errors in the measured visibilities and repeat. The initial images produced by this process are a convolution of the actual sky brightness distribution with the synthesized beam of the array. Since the synthesized beam can be complex with high sidelobes, except for arrays with a very large number of telescopes, the resulting convolved image is usually not a good approximation of the sky brightness distribution. Indeed, the usual term for the synthesized beam is a “dirty beam,” which in turn produces a “dirty image” of the sky. This undesirable state of affairs can be remedied by removing the image artifacts created by the sidelobes of the dirty beam, as described below. Once a deconvolved image or model of the sky is produced, it can be convolved with a “clean beam”—the main peak of the synthesized beam without any of the sidelobes—to produce a cleaned image.

There is a fundamental relationship between the spacing of grid points in the (u,v) plane used for the Fourier transform and the angular separation between pixels in the image plane. To properly represent the radio source morphology, we need at least two pixels (and preferably three to five pixels) across the width of the main peak in the synthesized beam. This is another way of saying we need the image plane sampling to be finer than the angular resolution of the longest interferometer baselines. Otherwise, we are effectively wasting the long baselines in the array. Similarly, the image must contain enough pixels in each direction to cover the full extent of the radio emission. Otherwise, the large-scale structure information from the short baselines in the array will be wasted.

A given spacing in the image plane (ΔX) implies a grid spacing in the (u,v) plane of $1/(M * \Delta X)$, where M is the size of the grid along the axis in question. (The FFT need not use equal numbers of grid points in both dimensions, but this is the usual default.) Note that grid spacing in the (u,v) plane can be adjusted by changing the size of the FFT. There is a lower limit for M , based on the maximum size of the radio source being observed. In fact, $M * \Delta X$ must be at least twice the width of the radio emission to avoid aliasing in the FFT. Is there an upper limit? There is, because very fine sampling of the (u,v) plane means that a larger fraction of grid points is far from an actual measurement of the visibility function. Ideally, the distance between (u,v) grid points should be similar to the average spacing between visibility measurements.

The important point here is that there is a relationship between the range of angular structure that an interferometer array is sensitive to and the range of baseline lengths in the array. If there is a mismatch between the actual (u,v) sampling provided by the interferometer baselines and the range of angular resolutions needed, one side of the FFT or the other will be inappropriately spaced, with unfortunate consequences for the quality of the image produced. A useful rule of thumb is that the maximum angular resolution is determined by the width of the synthesized beam peak (which in turn is determined mainly by the length of the longest baselines in the array), and the maximum angular size of the radio source that can be imaged is determined by the synthesized beamwidth multiplied by the total range of baseline lengths in the array.

In practice, it is necessary to average the correlator output in both time and frequency, and this also sets a limit on the angular extent of radio emission that an interferometer array can image. Averaging visibilities in time results in an azimuthal smearing of the measurements, resulting in suppression of emission far from the image center. Averaging in frequency has a similar effect in the radial direction (this can be understood as an effective change in baseline length, in wavelengths, as the frequency changes across the bandpass).

Image Deconvolution

The dirty image produced by an interferometer array can be cleaned by deconvolving it with the dirty beam. This removes the effects of the dirty beam's sidelobes and results in an image with higher dynamic range (i.e., weaker features can be detected). There are a number of approaches to the deconvolution process, none of them straightforward because the existence of (u,v) points with zero amplitude prevents deconvolution via a simple division of Fourier transforms.

The two more common deconvolution algorithms in radio astronomy are CLEAN¹⁶ and maximum entropy.^{17,18} The CLEAN approach iteratively subtracts the dirty beam centered on the brightest pixel in the image until no pixels much higher than the noise level remain. During each dirty-beam subtraction, a delta function is placed at the location of the center of the dirty beam. Thus, after the subtractions we have an image consisting of many delta functions located at some of the image pixel centers. This array of delta functions is then convolved with a clean beam to restore an appropriate angular resolution (consistent with the actual (u,v) sampling by the array), but without adding back any sidelobes. This approach is simple, intuitive, and usually produces dramatic improvements in image dynamic range. It can fail to converge in some cases, but usually only on very extended sources. The CLEAN algorithm assumes that the sky can be modeled as a finite number of point sources (the delta functions), which is reasonable for compact radio sources surrounded by empty sky. However, for very extended sources, most of the field of view may contain radio emission, and then the assumption that delta functions are a good approximation can break down.

For extended sources, an algorithm with the opposite assumption of the one for CLEAN is commonly used. This is the maximum entropy algorithm, which assumes that the sky is uniformly bright (featureless) and tries to produce an image as close to featurelessness as the data allow. In other words, this algorithm produces an image with the minimum amount of structure (and thus the maximum entropy) consistent with the visibility data. It tends to image very extended radio emission more successfully than CLEAN does. It also has the interesting feature that the images it produces have higher angular resolution in areas of higher SNR, since no equivalent of a clean beam is used directly. Sometimes it is instructive to use both approaches to image a given set of observations. The differences between images produced using such different starting assumptions can be a useful indicator of the true uncertainties in the image plane.

Multifrequency Synthesis Imaging

It is always desirable to have more complete sampling of the visibility function, but there are limits to the number of telescopes and to the observing time available. A relatively new technique to improve (u,v) sampling is to observe in several separate frequency bands simultaneously. This has the effect of sampling a number of (u,v) points along a radial direction in the (u,v) plane simultaneously for each baseline. If the total fractional frequency range spanned by the observations is comparable to the fractional spacing of baselines in the array, a large reduction in the size of unsampled (u,v) regions can be obtained in this way. Consequently, the synthesized beam will have much lower sidelobes, improving the speed and probably the ultimate quality of image deconvolution. The limitation is that over a wide frequency range, the structure of the radio source could change, which would make it inappropriate to combine all of the visibility data into a single image. In principle, it is possible to solve for the spectral characteristics of the source in addition to other parameters, but this is a significant complication to the imaging process.

Wide-Field Imaging

Throughout this chapter, we have been discussing interferometers and imaging in terms of two-dimensional arrays (the (u,v) plane, the image plane, and two-dimensional Fourier transforms). This is appropriate for the usual applications of radio interferometers, which are normally used to image relatively small regions of the sky and which (except for very-long-baseline arrays) are built with the telescope approximately in a plane.

For imaging large regions of the sky, the two-dimensional assumption is not adequate. Instead, it is necessary to replace the (u,v) plane with a (u,v,w) volume in which the visibility function is measured. Similarly, the image (sky) plane must be replaced by a spherical surface in a three-dimensional image volume. Then, it is also necessary to use a (computationally intensive) three-dimensional transform to move between these volumes.

A number of techniques have been developed to avoid the need for three-dimensional transforms in wide-field imaging, the most common of which involves dividing the field of view into many smaller regions that can each be approximated as two-dimensional. A newer and more efficient approach developed by T. Cornwell¹⁹ is to use Fresnel diffraction theory to calculate the visibility sampling that would be obtained if all antennas were in a single plane orthogonal to each source. This approach is called w projection.

Wide-field imaging can also complicate the calibration of interferometer data. Up to now we have assumed that propagation effects (ionospheric and atmospheric attenuation and phase fluctuations) could be represented by a single time-variable error term per telescope. However, emission from a large area of sky could pass through regions of the ionosphere or atmosphere containing different, uncorrelated conditions. This implies that we need multiple simultaneous direction-dependent error terms per telescope. The number of error terms could now exceed the number of available visibility measurements, violating the basis for self-calibration.²⁰ These are areas of active research, and new approaches are likely to be offered within the next few years.

49.5 MAJOR RADIO TELESCOPES

Single-Aperture Telescopes

This section gives a brief description of a few of the world's great single-aperture telescopes.

Arecibo Radio Telescope The Arecibo Observatory (Puerto Rico) is one of the world's largest radio telescopes.²¹ Its main reflector is a spherical surface 305 m in diameter and nearly 51 m deep. Forty thousand perforated aluminum panels compose the surface of the telescope. The panels are supported by a network of steel cables strung underneath them. The Arecibo feed system consists of both narrowband line feeds and Gregorian optics to correct for spherical aberrations, as shown in Figure 49-4. The feed system is suspended 137 m above the reflector and attached to a triangular frame supported by cables strung from three towers. Immediately below the frame, a 100-m-long azimuth arm moves on a circular track. The curved part of the azimuth arm is another track. On one side of this track is a carriage house that supports

FIGURE 49-4 Arecibo feed system

the narrowband line feeds; on the other side, a large dome houses the optics. Inside the dome, two subreflectors (secondary and tertiary) direct radiation to a set of wide-band horns. Either the Gregorian optics or line feeds can be positioned up to 20 deg from the vertical.

Green Bank Telescope The largest clear-aperture telescope is the 100-m-diameter Robert C. Byrd Green Bank Telescope (GBT) in West Virginia.²² A clear aperture is significant because clear apertures prevent reflection and diffraction from the telescope's feed support structure. The clear-aperture design was achieved by implementing an offset reflector geometry that could be used in a prime-focus mode or a dual-reflector Gregorian mode. The main reflector is composed of 2004 panels mounted at their corners on actuators, which are small motor-driven pistons that enable a surface adjustment for both thermal- and gravity-induced surface distortions. The antenna's wheel-and-track design allows it to scan the entire sky above 5 deg of elevation. The track measures 64 m in diameter; to ensure precise pointing, it is level to less than .01 cm.

Effelsberg Radio Telescope Until the Green Bank Telescope was built, the largest fully steerable telescope was the 100-m-diameter reflector in Effelsberg (Germany), which began operating in 1972.²³ The telescope uses dual-reflector Gregorian optics at both the primary and secondary focus to observe radio emission in the wavelengths from 90 cm down to 3.5 mm. Because of the homology of the design and a special support structure, the deviation of the dish surface from the ideal parabolic form is at most 0.5 mm despite the flexing of the steel members of up to 10 cm due to gravity. The shift in the focus position due to surface flexure accompanying the tilting of the dish is compensated for by means of an electronic control mechanism.

The receiver systems are mounted either at the focal point of the main reflector, just beneath the prime-focus cabin suspended on four support legs, or at the secondary focus located at a central point just above the surface. There, in the secondary focus cabin, it is possible to use many additional receiver systems, some even simultaneously.

Parkes Radio Telescope The 64-m Parkes Radio Telescope (Australia) began operations in 1961.²⁴ It was then one of the first large movable dishes in the world. Today, Parkes frequently operates together with the Australia Telescope Compact Array at Narrabri and a single dish at Mopra, to form a very-long-baseline interferometry array.

The original surface of the telescope was metal mesh but was later upgraded to smooth metal panels on the central part of the antenna, allowing for operation at both centimeter and millimeter wavelengths (see Figure 49-5). The receiving cabin is located at the focus of the parabolic dish, supported by three struts 27 m above the dish. The cabin contains multiple feed systems, which can be switched into the focal point for different science observations.

NASA applied the basic design concept of the Parkes Radio Telescope when developing the Deep Space Network. Subsequently, almost identical 64-m antennas were built at Goldstone (California), Madrid (Spain), and Tidbinbilla (Australia). In 1987, NASA extended the Tidbinbilla antenna from 64 m to 70 m, surpassing Parkes as the largest steerable radio telescope in the Southern Hemisphere.

Major Interferometers

This section gives a brief description of three of the world's largest interferometers.

The Very Large Array The Very Large Array (VLA) consists of 27 reflector antennas in a Y-shaped configuration located 80 km west of Socorro, New Mexico.²⁵ Each antenna is

FIGURE 49-5 The Parkes Radio Telescope

25 m in diameter. Each reflector has multiple narrowband feed systems covering the range of frequencies from 70 MHz to 43 GHz. The elements can be respaced in their Y pattern in four configurations: A array, with a maximum antenna separation of 36 km (which has the sensitivity of a 130-m antenna); B array, with a maximum separation of 10 km; C array of 3.6 km; and D array of 1 km. The telescopes are switched between these configurations approximately every four months. The resolution of the VLA is set by the size of the array—up to 36 km across. At the highest frequency, resolution is 0.04 arcsec.

With a view to upgrading the 1970s technology used to build the VLA, recent funding has been allocated for the conversion of the VLA into the Expanded Very Large Array (EVLA). The upgrade will enhance the instrument's sensitivity and frequency range by installing new hardware at the San Agustin site.

Giant Metrewave Radio Telescope The Giant Metrewave Radio Telescope (GMRT) was established by the National Centre for Radio Astrophysics (NCRA) of India to do research using the meter wavelengths range.²⁶ The site is about 80 km north of Pune, India. GMRT consists of 30 fully steerable 45-m-diameter parabolic antennas. The main reflector is lightweight and of low solidity because the conventional backup structure was replaced with a series of rope trusses (made of thin stainless steel wire) stretched between 16 parabolic frames of tubular steel. The wire ropes are tensioned suitably to create and maintain a mosaic of plane facets approximating a parabolic surface. A lightweight thin wire mesh (made of 0.55-mm-diameter stainless steel wire) with a grid size varying from 10×10 mm in the central part of the dish to 20×20 mm in the outer parts, and stretched over the rope truss facets, forms the reflecting surface of the dish. Making the reflecting surface of a porous mesh cuts down the wind forces by a large factor and is particularly suited to the local climate conditions of the plains.

The number and configuration of the dishes were optimized to achieve sensitivity at high angular resolution as well as the ability to image radio emission from diffuse extended regions. Fourteen of the 30 dishes are located randomly in a compact central array in a region about 1 km². The remaining 16 antennas are spread out along the three arms of an approximately Y-shaped configuration over a much larger region, with the longest interferometric baseline at about 25 km.

The array operates in six frequency bands centered at 50, 153, 233, 325, 610, and 1420 MHz. All feeds provide for dual polarization outputs and, in some configurations, dual-frequency observations are possible.

The Atacama Large Millimeter Array The Atacama Large Millimeter Array (ALMA), in Chile, is a millimeter-wavelength telescope planned to consist of about sixty-four 12-m antennas located at an elevation of 5000 m.²⁷ ALMA functions at between 10 mm and 350 μ m, with array configurations from approximately 150 m to 10 km. The spatial resolution is 10 milliarcsec; ALMA will be able to image sources arcminutes to degrees across at 1-arcsec resolution.

An important requirement for the ALMA project was the capability to rapidly switch positions in order to achieve phase-stable observations a large fraction of the time. To achieve this goal, in 1992, work began on a “slant-axis” antenna design, whose stiffness enabled very fast switching.

Later, the slant-axis design evolved into an off-axis paraboloid whose advantages included good gravitational performance, lack of counterweights, and the high sensitivity of an unblocked aperture. However, a minimum-blockage conventional antenna design, patterned after the Berkeley Illinois Maryland Association (BIMA) 6-m antennas (in California), proved to be more cost effective and provided better field-of-view and polarization performance and was the design chosen for development.

In 1998, ALMA was formed as an international partnership consisting of both the North America and European radio astronomy communities. Each partner had its own antenna design concepts. The international partnership decided that the best way to determine the antenna design would be for each organization to produce a prototype antenna for testing (see Figure 49-6). In 2001, the Japanese joined the ALMA partnership and offered a third antenna design for testing. The three prototypes were tested at the VLA site; all three designs were selected for use in the ALMA array.

49.6 CONCLUSIONS

Radio telescope antennas have produced dazzling science covering meter-to-submillimeter wavelengths. The next generation of telescopes such as ALMA, the Square Kilometer Array (SKA),²⁸ Low-Frequency Array (LOFAR),²⁹ and the Allen Telescope Array (ATA)³⁰ promise even more wondrous science. Perhaps, with the ATA or SKA, we may even discover that we are not alone in the universe.

Acknowledgment

This research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

50.1 INTRODUCTION

Over the last few decades, there has been great progress in the development of indoor measurement facilities; and as a result, many outdoor facilities are closing in lieu of going indoors. This has been made possible because of the development of enhanced measurement hardware and facilities. This chapter attempts to describe how one can take advantage of these modern measurement systems in order to perform various types of antenna measurements.

There have been major enhancements in terms of network analyzers such that one is now able to quickly and easily collect both impedance and pattern data using these very powerful devices. These measurements are normally done in CW mode, but more and more applications have increased bandwidth such that time domain measurements can also be taken with most modern network analyzers. This can be done using the time domain option in the network analyzer by acquiring broadband (amplitude and phase) data and then transforming from the frequency to the time domain. Once in the time domain, it's possible to software time gate the desired time response and, therefore, gate out the undesired time terms. This will be shown to be very useful later, when the various antenna measurements are considered in more detail.

Besides using a network analyzer, one can also consider many other source and receiver systems. These options include time domain hardware that can be used to directly gate out undesired time responses using pulse hardware. There are two rather inexpensive hardware options that are considered here: 1) a *chirp system* and 2) a *pulsed/CW system*.

The *chirp system* uses a linear frequency sweep for the transmitted signal. This chirp signal is received by the antenna-under-test (AUT), where it is then sent to a mixer that correlates it with a sample of the linear chirp coming directly from the source. The output of this mixer is then a low-frequency harmonic that is directly related to the difference in frequency between the AUT received signal and the present frequency of the swept source. To isolate the desired frequency harmonic, simply filter the desired AUT term. These systems are rather inexpensive because they consist of a swept source, a mixer, and a low-frequency digital filter system for selecting the desired frequency response. In order to properly use a chirp system, one must understand and maintain the amplitude and phase linearity requirements and must also create the proper amplitude weighting to control range sidelobes.

An inexpensive *pulsed/CW system* can be built using a network analyzer and pulse hardware. Just about any network analyzer can be considered for use with this application. The pulse hardware consists of a single-pull-single-throw (SPST) high-speed transmit switch, which creates the pulse waveform, and a power amplifier to increase the radiated signal. This hardware goes between the network analyzer transmit port and source antenna. At the AUT, which is considered as the receiver in this example, one then adds another SPST high-speed switch to select the desired time response. This received pulse signal is then input to the network analyzer using the receive port. Because this is a broadband signal that consists of pulsed harmonics, one has to be careful to choose a pulse repetition rate so that pulse harmonics are not related to the receiver harmonics. Otherwise, the network analyzer received response will be corrupted by the pulse harmonics. Recall that the network analyzer is used to transmit and receive a CW signal. So, the pulsed/CW hardware is used to time gate out undesired time responses, while maintaining the CW response as seen by the network analyzer. In designing these systems, one has to be very careful to avoid ringing within the pulsed hardware.

In times past, one had to worry about the transceiver hardware as much as the facility issues associated with his or her measurement. As stated earlier, that is no longer the case. Modern network analyzer and transceiver systems are extremely linear, have excellent IQ circularity, are very stable, and provide huge dynamic ranges. As a result, modern antenna measurements can now focus on the facility capability as opposed to the hardware that is used to collect the desired data. These same conclusions were pointed out by Dybdal.¹

Since indoor facilities are limited to reasonable dimensions, the effective distance between the transmitter and receiver is not that large. That being the case, there is not a need to transmit much power. Thus, the normal output provided by a network analyzer is usually sufficient for most indoor antenna measurements. If more power is needed, one does not have to typically use more than a solid-state amplifier, which is very nice because solid-state units are readily-available, reasonably priced, and stable.

Before going into the details of the different facilities, let's think about the topic in general. First, any antenna measurement should be done in such a way that the actual antenna application is simulated as well as can be accomplished within the confines of an indoor environment. For example, one cannot simulate a full satellite antenna measurement including all the associated satellite features. That can only be done within certain limits. Second, the indoor environment creates undesired scattering that must be understood and controlled to the degree necessary for meeting the desired measurement goals. These two issues tend to mean that the facility will be extremely large. Obviously, on the other side, building costs force the size the facility to be smaller. As a result, one has to make compromises between cost and performance. That being the case, present-day facilities are not normally perfectly designed for any specific measurement; therefore, they must be evaluated to determine how well they can actually perform any given measurement.

Since modern antenna measurement facilities are not ideal for any given measurement, they must be carefully thought out before they are even purchased in the first place. Furthermore, the burden of properly selecting and designing these facilities has to be carried out in such a way that the facility procurer plays a very active role along with the vendors. Therefore, it's important to get smarter in terms of measurement facilities. In that regard, one should not think of the measurement as a separate and distinct task when compared to numerically simulating the antenna. If one understands the full volumetric pattern of the antenna, it's possible to predict a measured response for any known complex signal illuminating the AUT. This being the case, one can determine the specific fields in the test zone by collecting high-quality probe data. These probe fields can then be transformed to determine the incident field plane wave spectrum, which describes the actual illumination of the AUT within the facility. With this information, one can then take this incident plane wave spectrum and compute the expected measured results that are achievable within a specific facility. If these simulated measured results show that the resulting error exceeds the desired measurement goals, then that facility is not appropriate for the proposed AUT tests. In fact, this concept should be adopted as a standard practice for any proposed antenna measurement in order to justify that a given facility can actually meet or exceed the desired measurement goals. More will be said about this topic later.

To become more familiar with these measurements or to get a better basic understanding of them, refer to the IEEE Standard Test Procedures for Antennas.² This chapter can then be used to bring these concepts up-to-date. Note that each of the measurement topics are briefly described in the following sections along with appropriate references to allow the reader to examine this material in as much detail as desired.

50.2 IMPEDANCE OR S11 MEASUREMENTS

As stated in the introduction, impedance or S11 measurements have been greatly improved with the advent of modern network analyzers and the development of accurate loads needed for proper calibration. Using the calibration procedures fully described in the network analyzer documentation, one can easily achieve precise impedance results provided that an

appropriate antenna environment for the measurement is used. In other words, the measurement hardware is typically not the limiting factor in these measurements. It is the operator and the measurement environment that can limit S11 measurement performance.

In order to understand how well an S11 measurement is performed, one should use the time domain option. This is very useful because the time domain can be used to ascertain the amplitude and placement of the various time responses relative to the desired AUT response. If the network analyzer calibration is correctly performed, the time responses before the AUT response should be very small compared to the AUT S11 term since this response involves cabling and connectors. The environment can be evaluated in terms of the time responses after the AUT term or terms. If all the time responses, before and after the AUT term or terms, are negligibly small compared to the AUT responses, then the calibration should be correct and the AUT environment is sufficiently controlled for a successful S11 measurement. Therefore by deleting these early and late time responses through time gating, the gated response that has been transformed into the frequency domain represents the desired AUT response, except near the frequency end bands, which are corrupted by the time gate. Therefore, one should use a wider bandwidth than is needed for the actual measurements so that the end band corrupted values do not impact the desired data.

Recall that a gain measurement requires a very accurate calibration relative to some type of gain standard. Since one can perform very accurate impedance calibrations, it is very interesting to think of ways to take gain measurements using an S11 measurement. Such a concept will be presented in the section discussing gain.

50.3 PATTERN OR S12 MEASUREMENTS

For pattern measurements, one can again use the various measurement hardware systems described in the introduction. These systems will all perform accurate pattern measurements, provided that one can achieve the desired signal-to-noise ratio needed for the measurements. Recall that antenna patterns can have a huge dynamic range, especially for low-sidelobe antenna systems. Even so, the hardware can typically achieve a dynamic range of say 80 dB as long as the peak pattern level is adjusted so that it is close to the saturation level of the receiver system. Across this 80 dB dynamic range, the measurement should be very linear and provide excellent IQ performance. If more dynamic range is needed, the pattern should then be taken in terms of two patterns with the second pattern taken with more amplification added in order to measure the lower levels. Note that low-noise solid-state amplifiers should typically be used in this situation. In these cases, a preliminary link budget and attention to the receiver noise floor and saturation is very useful.

Clearly with antenna patterns, one must deal with an antenna motion control system. This issue is oftentimes implemented in terms of massive hardware that is needed to meet or exceed some rotational accuracy requirements. These requirements tend to get very convoluted in the sense that one defines the maximum weight and angular accuracy together. This places a very stiff set of specifications on the whole rotational system independent of the measurement being taken. For example, there are facilities that take low-gain horn pattern measurements using massive elevation-over-azimuth rotational hardware. In these cases, it is often difficult to see the small antenna in comparison to the very large rotators and associated support structure. So what can be done to correct this undesirable situation? This will be examined next.

One must remember that the antenna pattern should be measured as though it is mounted in its natural environment, which in most cases means that it is surrounded by free space. Thus, the rotation hardware has to be configured based on the antenna being measured. One must use a small low-scattering mount for low-gain light-weight antennas, whereas

large metal mounts should be used for high-gain heavy antenna systems. That being the case, the rotational hardware has to be designed to be multifunctional. In fact, a high-quality antenna measurement facility needs to have different rotational hardware that has been specifically developed to treat small, medium and large antenna systems. It is interesting to note here that the rotational hardware used for a small antenna obviously does not need the rotational accuracy that a high-gain antenna needs. This is very important because it implies that one can use a much smaller mount and encoder and yet achieve or exceed the necessary rotational motion control and accuracy.

For cases where one wishes to measure the complete volumetric pattern for a low-gain antenna, it is important to use a mount structure that is virtually transparent. This can be done using a foam column sitting on an azimuth rotator, keeping in mind that the cable remains as a potential scatterer. To minimize the impact of the cable, one should consider a fiber-optic cable solution. In any event, one can collect a full azimuth cut with very little impact caused by the foam column as compared to a massive elevation-over-azimuth approach. However, one cannot easily collect a full volumetric pattern. To overcome this limitation, one can add a small roll axis rotator on top of the foam column. This will result in a roll-over-azimuth system that can be used to collect the full volumetric pattern for low-gain light-weight antennas. For medium sized antennas, one can replace the foam column with a light-weight foam and plastic pole. Then, a medium-sized roll axis rotator can be mounted on top of this pole to again provide roll-over-azimuth motion. Thus, it is specifically-designed for medium gain and weight antennas. For the largest antennas, one can use the massive rotational equipment stated earlier. This way, one is able to take measurements using a very versatile set of rotational hardware that can be effectively used for all types of antenna measurements.

In order to achieve a given rotational step size, one must realize that the encoder must provide much more resolution than specified by the angular pattern step size. For example, let's suppose that one wishes to measure a low-gain antenna pattern every 1 degree. The encoder cannot have a resolution of 1 degree. Its resolution should be three to ten times finer or 0.3 to 0.1 degrees. This way, the pattern control software can start to watch the encoder readout until the encoder reaches the desired angular position to within its resolution. So the better the resolution, the better and more uniform the actual angular steps will be. Once at the desired angle, the receiver system will then collect the measured data, which will be stored in the computer. The software will then repeat this process until the whole pattern is measured. Putting it another way, if the control software does not have an angular readout resolution finer than the desired pattern accuracy, the precision of the data collection will be very poor. This can cause a problem if one needs precise IQ measured data versus angle. In fact, it will be shown that precise angle data is necessary if one wishes to do image processing of the measured data and is collecting data at the sampling theorem rate. If interested in learning more about antenna pattern image processing, refer to Lee and Burnside.³

So, it has been shown here that one can properly design the rotational hardware to obtain the various antenna pattern measurements performed indoors today. That being the case, one has to now focus on the pattern measurement facility. Since there are a wide variety of such facilities, each one will be examined separately.

Traditional Spherical Range

Traditional spherical ranges consist of a source antenna usually mounted in the transmit wall of a rectangular chamber. The source directly illuminates the AUT mounted in the center of the test zone. The size of this chamber is determined based on the size of the test zone and the frequency of operation. The distance between the source and the center of the test zone is normally defined as $R = 2D^2/\lambda$, where D is the maximum diameter

of the AUT and λ is the wavelength. Note that this requirement means that there will be a 22.5 degree phase taper across the test zone for the frequency that was used to define the wavelength in the definition of R . Clearly, this definition has come from an attempt to approximate a plane wave using a spherical radiator as the illuminator of the AUT. The range (R) must also be several wavelengths long to avoid inductive coupling between the source and AUT. This is the limiting factor at low frequencies for these designs.

The spherical range chamber dimensions are shown in Figure 50-1. The length of the chamber is $L = R + X + D/2$, where D is again the diameter of the test zone. The width and height of the chamber is $W = 2X + D$. The dimension is $X = D$ provided that D is greater than the maximum wavelength across the full operational bandwidth of the chamber. If the maximum wavelength is larger than D , then X is defined as the maximum wavelength.

Note that all these dimensions are measured inside the absorber and represent an initial chamber layout guideline. The absorber will be studied in a later section.

This type of chamber is normally used to measure the antenna patterns for low to medium gain antennas. The test zone size is obviously a function of frequency. The diameter of the test zone versus frequency is given by $D = \sqrt{R * \lambda / 2}$, provided that one wishes to simulate plane wave illumination. Thus, the test zone size reduces with increasing frequency, which means that this type of chamber is not really appropriate for high gain antenna pattern measurements.

One of the major issues associated with the spherical range is that one tends to build them as long narrow tunnels in order make the range (R) as long as possible. This is very problematic as will be seen in the section discussing absorbers. As the chamber becomes long and narrow, the source will tend to illuminate the absorber near grazing incidence. As one would expect, the absorber reflection level is very sensitive to the angle-of-incidence and in fact approaches unity at grazing incidence. Consequently, one should always question using an absorber when the angle-of-incidence is approaching grazing incidence. It is best to think of the absorber as working well for normal incidence or 0 degrees to no more than about 50 degrees. With this 50 degree angle-of-incidence limitation for absorber, one cannot think of making a spherical range chamber that is really that narrow and long.

To get around this absorber limitation, it's possible to design a spherical chamber using a tapered R-Card fence concept. This type of fence will block the undesired absorber scattering near grazing incidence without creating an undesired fence diffraction term. Therefore, one can make a long narrow spherical range chamber, provided that the appropriate tapered R-Card fence or fences are used. These fences are described in the section discussing tapered R-Card fences.

Tapered Chamber

A tapered chamber is actually a spherical range that is housed in a chamber that looks much like a horn, as shown in Figure 50-2. This chamber works very well provided that the source antenna is located at the throat of the horn section. If that is the case, the source energy simply propagates outward from the source to illuminate the test zone. The dimensions of this chamber follow the same formulas listed earlier for the spherical range chamber.

Until recently, the major limitation associated with the performance of a tapered chamber has been the need for an ideal source antenna. The problem is that the

FIGURE 50-1 Spherical range chamber dimensions

source antenna phase center must be located at the vertex of the throat section, which means that the antenna's phase center is surrounded by an absorber. Thus, the absorber tends to attenuate the radiated energy. There have been two antennas that have been specifically-designed to solve this problem: a tapered R-Card horn antenna⁴ and a quad-ridge antenna.⁵

The quad ridge antenna is most appropriate because it is dual-polarized and it can be permanently integrated into the throat section. It also has very good bandwidth properties so that it can typically provide complete performance across the full operational bandwidth of the tapered chamber.

The tapered chamber is used for low and medium gain antenna patterns because of the range (R) requirement. Furthermore, it is most appropriate for low frequency measurements because it has been designed to handle the absorber grazing incidence problem. Recall that the absorber must get thicker for lower frequencies. Thus, a spherical range chamber will grow in size as the frequency is decreased. That is not the case for the tapered chamber in that the absorber is illuminated at grazing incidence; so therefore, it does not have to be very thick. Consequently, one should always think of a tapered chamber as the best approach for low frequency, low and medium gain antenna pattern measurements. One should refer to Burnside et al⁶ to determine the proper layout and absorber treatment for a modern tapered chamber.

FIGURE 50-2 Tapered chamber dimensions

Compact Range

A *compact range* is used to create a plane wave field in the test zone as presented in "Compact Range Techniques and Measurements."⁷ This is done by using a parabolic reflector with the feed antenna located at its focus. As a result, the reflected field from the parabola that illuminates the test zone typically has a very uniform phase; while, the amplitude varies slightly caused by the feed pattern and range variation related to the distance between the feed antenna and the reflector surface. In this case, the test zone lies within the near field of the compact range reflector providing two advantages. The first advantage is that the test zone fields are not spherically attenuated so that the power density in the test field for a given source power is increased enhancing measurement dynamic range. The second advantage is that the collimated near field of the compact range reflector minimizes the illumination of the facility's side walls, floor, and ceiling. As a result, one finds for well-designed compact ranges that the amplitude taper is about 1 dB, the amplitude ripple is about one tenth of 0.1 dB, and the phase variation is typically less than 6 degrees even at its highest operational frequency.⁸

The major issue associated with a well-designed compact range is again the issue of stray signals. As stated earlier, the reflected field creates the desired illumination of the test zone. However, the reflecting surface must be terminated properly to fit within a finite chamber. There have been many attempts to find the best compact range reflector termination concept. This challenge has been going on for more than 20 years and everyone has learned a lot about the different approaches since all of them have been built in one form or another. The blended rolled edge reflector, as designed in Gupta et al,⁹ clearly performs better than any other approach but it is also the most expensive. For example, it is not unusual for a blended rolled edge compact range to have no more than a few tenths of a dB ripple in the test zone fields. This implies that the stray signal levels are nearly 40 dB below the desired plane wave illumination.

Let's suppose that one wishes to measure a low sidelobe antenna. It means that when the main beam of the AUT points toward the stray signal direction, it will be boresighted with the stray signal term. Consequently, the main beam gain will amplify a weak stray signal and create an undesired sidelobe in the resulting measured pattern. This is an issue for all reflector termination designs, but the rolled-edge reflector will still provide about 15 dB better performance. The full impact is actually more significant than just the 15 dB. For serrated edge reflectors, the serrations typically cover a significant portion of the overall reflector surface. So, their stray signals are seen from the AUT point-of-view for a relatively wide angular region. The blended-rolled edge reflector discontinuity comes from the junction between the parabola and blended-rolled edge. This junction is normally designed to be about halfway from the center of the reflector to outside rolled edge; therefore, it has much less angular impact on a pattern measurement. If one is interested in a very thorough discussion of the differences between blended-rolled edge and serrated-edge reflectors, refer to Lee and Burnside.¹⁰⁻¹¹

All compact range systems have another significant stray signal that must be properly handled. This is the feed spillover into the test zone. Since this undesired term takes a much shorter path than the desired plane wave, it can be easily time gated out. Thus, it is important to use some type of time domain technique to minimize the impact of this undesired error term. There have been many attempts to remove this feed spillover term by using various types of absorber panels that hide the feed antenna as seen from the test zone. This is not a good approach because it adversely blocks the wavefront coming from the reflector. This, in turn, results in additional scattering that cannot be gated out because it has nearly the same time delay as the desired plane wave term.

Beside these issues, it has been noted that absorber fences have been used in many compact range applications to hide the large antenna mount structures and to provide a convenient access area to insert or remove the AUT. These fences are typically a simple plywood structure to which absorber panels are added and tend to run across the full width of the chamber. This seems most appropriate for production applications because one can quickly mount or dismount the AUT using massive rotational hardware. Unfortunately, these fences cause very serious stray signal errors that come from the top edge of the fence. Since the absorber does its job, it creates a very significant shadow directly behind the fence. This shadow region is very similar to the one caused by a metal plate. As a result, the fence edge diffraction can be thought of as coming from the incident shadow boundary associated with a metal plate. With this in mind, the fence causes a stray signal that can severely degrade the test zone fields and ultimately the desired antenna pattern measurements. So, it is better not to use a fence at all. But if a fence is absolutely necessary, then one should use a tapered R-Card fence as described in the tapered R-Card fence section.

A compact range reflector system can be defined in a generic sense as shown in Figure 50-3. The reflector focal distance is defined as F , the reflector size is H , the range from the reflector to the center of the test zone is R , and the test zone diameter is D . Typically, one finds that $H = 2D$, $F = H/2 = D$, and $R = 2F = 2D$. Thus, the compact range reflector system can initially be approximated based on the size of the test zone.

Now that the reflector system has been roughly laid out, one can start to define the chamber dimensions that are needed to house this compact range reflector system. The chamber geometry is shown in Figure 50-4. The length of the chamber is approximately given by $L = D/2 + R + 3D/2 = R + 2D = 6D$.

FIGURE 50-3 Compact range system dimensions

The width and height of the chamber are roughly given by $W = 3D$. Again, these are only meant as initial layout dimensions to get the whole design process started. Even so, they are very valuable in terms of estimating initial costs. Furthermore, these dimensions do not include the absorber.

The compact range is the best approach to create a plane wave field across a large test zone, because the reflector is basically acting as a lens to transform an incident spherical wavefront into a reflected plane wave. This planar wavefront is about half the size of the reflector, so it is many wavelengths across. Consequently, it is ideal for measuring the patterns of high gain antennas. Remember that the reflector should be at least 10 wavelengths across in order to actually act as a proper lens.

Because the compact range is complementary to a tapered chamber, many organizations have a tapered chamber to measure low frequency, low to medium gain antennas and a compact range to measure higher frequency, high gain antenna patterns. It is very typical to use a tapered chamber below 1 GHz because of far field limitations and a compact range above 1 GHz. Of course, one can design a compact range to function well for much lower frequencies than 1 GHz and a tapered chamber that works reasonably well above 1 GHz. Nevertheless, the 1 GHz crossover is very typically found in practice.

FIGURE 50-4 Compact range chamber dimensions

Near Field Scanner Systems

A near field scanner measurement system is used to collect near field probe data in the close vicinity of the AUT. This probe data is then used to predict a user-desired field result such as far field patterns through the transform between the fields on a surface and the far field values. Each of these systems collects sufficient data that satisfies the sampling theorem for that particular measurement scenario. There are three major near field scanner systems that are commonly used today: 1) planar, 2) cylindrical, and 3) spherical. An overview of these near field systems is presented in Yaghjian.¹²

The planar scanner collects its data across a planar scan region; thus, it is used mainly for radiators that are designed to create a plane wave in the near field, which is indicative of a high gain antenna. The cylindrical scanner is used to collect the near fields over a cylindrical surface; thus, it is most appropriate for cylindrical radiators, such as cell phone basestation antennas that are long and narrow. The spherical scanner is used to collect near field data over a spherical surface; thus, it is most appropriate for low gain radiators that tend to create a spherical phase front close to the AUT. Therefore, the scanner system used for a given measurement is selected based on the radiation characteristics of the AUT. Of course, these systems can be used for a wide variety of applications even beyond the preferred applications for which it is most appropriate. Because of the versatility of these systems, many papers have been written that compare measured results using these different scanners (see Hess,¹³ for example).

These systems have been very carefully evaluated to ascertain the quality of the collected data. They have typically been characterized in terms of an uncertainty table and a resultant measurement uncertainty such as shown in Newell.¹⁴ This table contains all the expected error mechanisms that can occur during a scanner measurement. For each of these error mechanisms, a special test is defined that allows the system designer to determine the impact of that specific error mechanism on a given measurement. Once this is done, each of the error terms is assumed to be random such that they can be summed as random errors. In other words, they are not

coherently related to one another. In fact, it is assumed in this table that each term will have a random error impact during a given measurement much like the impact of noise.

As might be expected, most error terms in the uncertainty table are very small. However, two error mechanisms tend to dominate these uncertainty tables. These two terms are the chamber scattering and probe mutual coupling. The chamber error comes from the fact that the scanner is surrounded by some type of finite chamber. As a result, the measurement will contain chamber effects such as the scattering from the absorber walls. The probe mutual coupling is related to the interaction between the probe used to collect the near field data and the AUT. This term is typically evaluated by moving the probe antenna a quarter wavelength farther away from the AUT and then repeating the measurement. As a result, the AUT mutual coupling term coming back to the probe antenna will change phase by about 180 degrees for the second measurement. This phase change will cause the received signal to be composed of the desired response minus the mutual coupling error term. Thus, the difference between these two measurements tends to isolate this mutual coupling mechanism. Of course, this argument is not exactly true, but it does provide some useful results that give one at least an order of magnitude improvement in this error term. Using a similar approach, the chamber errors can also be studied by moving the measurement setup relative to a given scattering term that one wishes to investigate. At high frequencies, leakage components (waveguide flanges, mixers and so on) can also be troublesome and attention to possible leakage sources is required. In any event, this type of information is used to form an uncertainty error bound for the scanner system. That being the case, one can then use this error bound to determine if a given scanner system can meet the objectives of a given measurement or not.

The planar scanner system is the most popular and has been greatly enhanced over the years.¹⁵ Because the uncertainty table defines the measurement error terms and its associated impact on a given measurement, it has been used to investigate various ways to enhance its performance. This has resulted in very powerful systems that can scan in extremely precise planes at very precise increments even at high speeds and for wide bandwidth applications. However since the scan plane is finite, the resulting pattern is normally used to simply determine the main beam and first few sidelobes. In many cases, the main beam and first few sidelobes are all that is needed; thus, the planar scanner is ideal for these applications. On the down side, all of the scan data must be collected across the full scan plane before the desired far field pattern results can be computed.

The planar scanner is a very important solution for antenna systems that cannot be moved, such as very expensive satellite structures that are composed of multiple antenna systems. In this case, the planar scanner can be placed in front of satellite radiators and then used to probe the near field of each radiating system without moving the satellite structure. With these results, it's possible to determine the far field patterns of each radiating system and verify the boresighting of each system relative to the others. This boresight data can then be related back to the satellite coordinate system to insure that all the radiating systems are radiating properly.

The cylindrical scanner is mainly used for radiators that are long and narrow. These antennas are used to create fan beams, for example. Much like the planar scanner, these systems have also improved over the years because of the developments in planar scanners as well as through the development of high quality rotational hardware. Note that this scanner typically makes a linear scan followed by a rotation of the AUT or vice versa. In that regard, a planar scanner can be converted to a cylindrical one by adding an azimuth positioner to provide the rotation of the AUT.

The spherical scanner has increased in popularity because it can be used to investigate the volumetric pattern performance of low-gain radiators, such as cell phone antennas. In some situations, it is implemented by using two rotating systems to provide the spherical motion of the AUT, while the probe antenna is held stationary. In other cases, it is important that the AUT remains fixed. Thus, the probe antenna is rotated around the AUT.

In any case, all the probe data must be collected before the desired field pattern results can be obtained. In cases where the full spherical surface is scanned, the measured probe data can be used to provide the complete volumetric pattern. This is the only scanner system that can provide the full pattern, which makes it an important asset.

50.4 ABSORBER

The previous chamber dimensions did not include the absorber, because that is a major topic in its own right. To get a better understanding of the early absorber work, refer to Emerson's very good summary.¹⁶ Today, most engineers are familiar with microwave absorber in terms of its look-and-feel, but not as familiar with absorber performance limitations. As a result, this is the focus of this section.

Microwave, carbon-loaded, foam absorbers should be designed to have a low front face reflection and good attenuation as the incident electromagnetic energy propagates through the material and bounces off its back surface. To achieve these objectives, flat absorber material is typically constructed of multilayers. The first layer is very lightly-doped and does not attenuate the propagating wave very well, but it does have a descent front face reflection level. The next layers get more-and-more lossy such that the attenuation increases as the wave propagates through these layers. For this type of absorber, one typically measures the normal incidence reflection level at about -22 dB, which can be achieved with a traditional three layer design.

To control the front face reflection and still use lossy material, one can shape the front surface. The most popular shape has been pyramidal absorber. The front face reflection for this type of material is greatly reduced by the pyramidal shape. If the pyramidal absorber is properly designed and at least 2 wavelengths thick, it can achieve a -40 dB reflection level for normal incidence. Since wedge material is formed out of long 2D straight wedges and valleys as opposed to 3D pyramid tips, it does not transition as smoothly into free space. Therefore, it typically has a normal incidence reflection level that is between a flat and pyramidal absorber as one might expect. For a complete theoretical description of absorber scattering, refer to Yang et al.¹⁷⁻¹⁸

Normally, one will use a pyramidal absorber in antenna chambers, so let's focus on this type of material. Note that if pyramidal absorber is 2 wavelengths thick, it can achieve a -40 dB reflection level for normal incidence. Furthermore, the lowest reflection level achievable for a single pyramidal absorber panel is about -55 dB. It has been found through experimental studies that the lack of quality control in making the material leads to random variations within the material. These variations cause the -55 dB limit for a single panel. However, that does not mean that the total reflection level for a whole wall of absorber is limited to -55 dB. That is certainly not the case for a back or terminating wall in a chamber. It has been shown many times that the backwall scattering for a compact range chamber can be as low as -80 to -90 dB. This occurs because the absorber scattering comes from different random features within each absorber panel. That being the case, the scattering from individual absorber panels adds in power as opposed to adding in voltage. Therefore, the backwall scattering will drop to very low levels for a large backwall. Refer to DeWitt and Burnside¹⁹ for more details on this topic.

Before examining the angle of incidence performance, it is important to consider the low frequency performance of the absorber. Note that for normal incidence the reflection level degrades rather rapidly when the absorber is less than two wavelengths thick. This happens because the pyramidal shape is used to transition between free space and the absorber material media. For less than two wavelengths, this transition is too abrupt and the tips and valleys of the absorber are clearly seen in a time domain evaluation of the material. So at the low frequency end of the absorber operational bandwidth, the scattering appears to come from specific positions within the material. This means that one can place

the absorber tips and valleys into a Chebyshev height layout.²⁰ This height layout causes the various absorber tips and valleys to destructively interfere with each other.

Let's examine this approach using a one wavelength pyramidal absorber that is laid out in a Chebyshev pattern, which will reduce the reflection level by roughly 15 dB. So, a one wavelength pyramidal absorber in a Chebyshev pattern will have about a -50-dB reflection level. This is getting very close to the high frequency limit of -55 dB. As a result, the Chebyshev concept can be used to increase the low frequency bandwidth of pyramidal absorber. This will be especially important for low frequency chamber backwalls, which have traditionally used very thick pyramidal material. Taking another example, a 4' pyramid in a Chebyshev layout will result in a normal incidence reflection level of about $-30 - 15 = -45$ dB at 200 MHz. That means that it will work as well as a 12' pyramidal absorber panel, which is a huge reduction in cost and space. In addition, all the droop problems associated with using 12' pyramidal absorber can be avoided.

Absorber has been a mainstay in the design of chambers. As a result, the absorber companies have continually sold large volumes of this material. However, they have not provided new materials. That is a shame because antenna measurement requirements are continually getting more and more stringent and really require enhanced chamber designs. One area that has been very troubling is associated with the reflection performance level versus angle of incidence. Note that present-day materials degrade very rapidly after about 50 degrees. The only way to overcome this poor performance is to make the material thicker. Well, that solution is really good for the absorber companies but not for the antenna measurement community. Furthermore, one needs to really understand what is happening here.

As an incident field starts to approach grazing incidence, the material begins to look like a material media that is different than free space. Since a wavefront cannot propagate along this interface between the two media, it has to be totally reflected or nearly so. Thus, the basic physics causes this degraded performance, which means that some other material or design concept must be used to solve this situation. To make matters even worse, one has to measure the angle of incidence from the front face of the absorber because that face is where this undesired reflection occurs. Therefore if one increases the thickness of the absorber, the angle-of-incidence will reduce even further and the material will have to be made thicker and thicker. Therefore, traditional pyramidal absorber does not work well for wide angle incidence unless the undesired absorber scattering can be designed to miss the test zone and be absorbed in the backwall material.

Recently, there has been great interest in using the Chebyshev concept to help this angle-of-incidence problem. Since the absorber front face is causing this poor reflection level at lower frequencies, one can create a Chebyshev pattern for this situation. In this design, the area of concern is, for example, the sidewall scattering that is reflected into the test zone. Since this area is illuminated at say 60 degree, it will scatter a significant amount of energy into the test zone. If this sidewall material is then laid out in a Chebyshev pattern, it can be used to decrease this scattering by an additional 15 dB. That is very important in that it can greatly reduce the size of the chamber needed to perform a desired set of measurements. The details associated with the design of the Chebyshev absorber layouts can also be found in Gau et al.²⁰

If there is still too much sidewall scattering left because of this near grazing situation, consider a tapered R-Card fence approach, which is described in a later section.

Chamber Absorber Treatment

This section will describe how the absorber treatment should be determined for the various chambers. First, pyramidal absorber should be used in all regions of the chambers except for the sidewalls, ceiling, and floor of a tapered chamber. This special case will be examined later.

The first step is to determine the full operational frequency range for the chamber. Then the lowest frequency is used to determine the thickness of the absorber. For example,

suppose that the chamber operates down to 1 GHz, in which case, the wavelength is roughly 12". Therefore, one should use $2 \times 12"$ or 24" pyramidal absorber, which is the proper choice for the front or transmit wall, sidewalls, ceiling, and floor. The back or receive wall should be lined with thicker material because it must completely terminate the very strong incident wavefront. This thicker material could be 36" standard pyramidal absorber or better yet, 24" pyramidal material laid out in a Chebyshev pattern.

Once the chamber is laid out with these materials, one needs to examine the angle-of-incidence question. Perhaps the sidewall, ceiling, and floor are too close to grazing. If that is the case, then one should see if the Chebyshev sidewall layout would provide the desired performance. If that is not good enough, then one has to use R-Card fences or increase the width and height of the chamber. In any event, make sure that all these issues are examined before the facility has been placed under contract.

Now, let's return to the tapered chamber absorber treatment. In this case, the source field basically propagates from the vertex of the tapered chamber to the test zone. That means that the field is propagating in a radial direction or at grazing incidence on the sidewall absorber. Since this field cannot propagate along the absorber boundary, the major issue is the excitation of the tapered chamber near the vertex. This excitation must be done in such a way that the source phase center is located at or near the vertex, which is surrounded by absorber. It has been done in at least two ways, one method has been to place a TEM horn at the vertex formed near the front face of the absorber. The TEM horn has straight walls that allow the source field to expand outward from the throat of the horn and the vertex of the tapered chamber. This TEM horn cannot be terminated abruptly into the absorber because that is too harsh a transition. To solve this problem, the TEM horn can be terminated in a tapered R-Card surface.⁴ Using this approach, the TEM horn metal walls slowly disappear and the presence of the absorber is transitioned in a much more gradual sense. Thus using this tapered R-Card TEM horn, the source field emanates from the vertex of the tapered chamber and propagates between the TEM metal walls that slowly disappear. This results in a very smooth transition of the source fields as they continue to propagate toward the test zone. So this causes the field within the tapered R-Card TEM horn to transition from a basic TEM horn mode to a fundamental horn mode with absorber walls.

The second antenna concept to successfully feed a tapered chamber has been a quad-ridge approach.⁵ This is a better approach because it is dual-polarized. With this method, the quad-ridge throat is placed near the vertex of the tapered chamber. The ridges are formed as extended elliptic ridges that are terminated into the absorber. For low frequencies, the ridges are not that long in terms of the wavelength so the absorber acts as a smooth termination. At higher frequencies, the energy naturally radiates off each curved shaped ridge as a normal creeping wave mechanism. As a result, the quad-ridge antenna is a very broadband radiator that can be used to properly excite a tapered chamber.

So from the previous discussion, one can see that the major issue is the proper excitation of the tapered chamber itself. Once the proper excitation is created, the field strength along the sidewalls is very weak and one can use much thinner material. Since this field is propagating along the down range direction of the chamber, one should use wedge material on the sidewalls, ceiling, and floor. Note that the wedge material is specifically designed for energy to propagate along its length provided that the edges of the wedge material are aligned with the direction of propagation. Near the throat of the tapered chamber and surrounding the feed antenna, one does not want to use wedge material because it is polarization sensitive. Thus, flat material should be integrated around the feed antenna. Naturally, this flat material must slowly transition into the wedge material. Note that the wedge material should extend from this transition region to the back or receive wall. The backwall should be lined with pyramidal material in a Chebyshev layout as done for the other chambers.

Before leaving this topic, there has been one other major issue associated with tapered chambers. Because the AUT can interact with the sidewalls, ceiling, and floor, many tapered chambers have been lined with pyramids laid out in a diamond shape and surrounding the

test zone. It is true that this material will reduce the interaction term between the AUT and surrounding walls, but it causes other problems that can be even more serious. Recall that the source radiation is propagating down the chamber and that the chamber becomes rectangular in the vicinity of the test zone region. This means that these pyramids surrounding the test zone will be illuminated at nearly grazing incidence. This is serious because each of these absorber tips will scatter energy into the test zone. This will create not only a stray signal but will significantly impact the polarization performance of the chamber. As a result, one needs a better solution to solve this AUT/wall interaction issue.

So what can be done to reduce the AUT/wall interaction term without causing these undesired stray signal affects? Recall that the wedge material was used on the sidewall in the horn section because it forms straight lines that align with the incident propagation direction. Therefore, it is very important that this straight-line flow of the absorber continues all the way to the backwall. To reduce the AUT/wall interaction term, one can again resort to the Chebyshev concept as described in Gau et al.²⁰ In this case, the edges of the wedges are laid out to form different heights. This causes the scattering for normal or nearly normal incidence to be greatly reduced in that the individual wedges tend to destructively interfere with each other. Thus, the wedge edges form continuous lines all the way down the chamber to the backwall and the AUT/wall interaction term is reduced by about 15 dB, which is about the difference in scattering levels for normal wedge and pyramidal material. Therefore, the Chebyshev wedge layout provides an ideal solution for this problem. In order to learn more about this tapered chamber layout concept, one should refer to Burnside et al.⁶

50.5 TAPERED R-CARD FENCES

As stated earlier, absorber does not work well at or near grazing incidence because the reflection coefficient approaches unity. In fact, normally, one should not use pyramidal material beyond about 50 degrees. In some situations, one can use pyramidal absorber in a Chebyshev layout to achieve reasonable performance out to about 60 degrees. But whatever the angular limit, one can clearly not use a traditionally available absorber at wider incidence angles. So again, what does one do for these wide angle situations? This is the focus of this section.

The traditional approach to solve grazing incidence and strong wide angle scattering has been to use an absorber fence. By using an absorber fence, the nearly grazing incidence signal on the original absorber is now nearly coming at normal incidence in terms of the absorber on the fence. Since it is nearly at normal incidence, the fence absorber works very well. So, the undesired grazing incidence scattering from the wall, floor, or sidewalls is removed by the fence. However this is basically a tradeoff of one problem for another. Let's assume that the fence absorbs all the incident energy. That means that the incident field that hits the fence is completely absorbed but the field that does not hit the fence is not absorbed. This creates a very harsh discontinuity in the incident field that is virtually the same as seen for a metal plate as discussed earlier. This undesired scattering is basically a diffraction that comes from the terminating edge of the fence. Since these fences are usually placed across the width of the chamber, the diffraction cone coming from the terminating edge of the fence will diffract a very strong signal into the test zone. Thus, the diffraction associated with the edge of the fence must be controlled. This can be done using a tapered R-Card fence.

A sample tapered R-Card fence is shown in Figure 50-5. This fence is formed out of a resistive material that varies from a perfect conductor at the bottom to a very large resistance at the top. This variation in the resistance means that the incident field will be perfectly reflected at the bottom of the fence; however, the reflection level will decrease as the resistance increases. At the very top of the R-Card fence, the resistance is usually on

FIGURE 50-5 Tapered R-Card fence showing the resistance values for a sample design

the order of 3000 ohms per square. For such a large resistance level, the incident field is hardly impacted by this portion of the fence. Therefore, the incident signal transitions in a very smooth manner from being completely transmitted at the top of the fence to being completely reflected at the bottom. As a result, the R-Card fence is basically a fence that can block the grazing or nearly grazing signals on the absorber without diffracting. Thus, it has countless applications in chambers and outdoor ranges.

It has been shown by Gupta and Burnside²¹ that one can use these tapered R-Card fences to block the ground bounce in a ground bounce range. One might ask, why is that so significant? Well, it allows the set up of an outdoor measurement facility without being impacted by the ground bounce, which means that the measurement can be taken over extreme bandwidths. That cannot be done easily using a traditional ground bounce range unless the source height above the ground is varied versus frequency.

Before leaving this topic, there is one other modification of this concept that has been found to be very useful, especially for indoor applications. Recall that an R-Card fence is basically a reflecting surface that does not diffract. Well for most applications, one would really like an absorber fence that does not diffract. This can be done as well. The tapered R-Card fence is basically constructed of resistive material. It has been known for many years that one can take resistive sheets and form an absorber, such as a Salisbury screen. Using this idea, one can construct a five layer design such as shown by Lee and Burnside.²² This design provides at least a -22-dB reflection level for normal incidence from 2–18 GHz. So this absorber consists of a bottom metal layer and then four resistive layers separated by free space or foam.

So now, it is understood how one creates an absorber out of these resistive sheets. To make the absorptive R-Card fence that absorbs but does not diffract, one has to take each of the resistive layers and taper the resistivity going from the original resistance level to a very high resistivity, say 3000 ohms per square. Such a design is also shown in Lee and Burnside.²² Note that the fence is about 5 wavelengths tall at the lowest frequency and can be used very effectively to remove the wide angle scattering associated with traditional absorber. This concept will be shown in the next section to be extremely useful for hardware-in-the-loop chambers.

50.6 HARDWARE-IN-THE-LOOP CHAMBERS

Hardware-in-the-loop chambers are widely used to examine the performance of real operational hardware when it is illuminated by a wide variety of radiators. In these chambers, the real hardware is inserted into the test zone and illuminated by various sources mounted on a transmit wall. These are typically rectangular chambers with fixed antennas mounted

at various locations on the transmit wall or moving antennas that can be used to simulate various real-world scenarios. The antennas on the transmit wall typically come very close to the sidewall; thus, they potentially illuminate the sidewall absorber at or near grazing incidence. In evaluating a wide variety of these chambers, it has been found that one should use a rectangular chamber with absorber to handle the antenna locations near the center of the transmit wall. If an antenna comes close to the sidewall and the angle-of-incidence on the sidewall absorber is greater than 50 degree, then the Chebyshev layout can be used. If the angle-of-incidence is greater than 60 degrees, then R-Card fences are needed. The placement of the fences is typically located at the specular reflection position assuming that the reflection comes from the tips of the absorber. Since there can be many antenna positions that are close to sidewalls, one may need more than one R-Card fence. A typical sidewall design for a hardware-in-the-loop chamber is shown in Figure 50-6. Note that the sidewall absorber is laid out in a Chebyshev pattern and that absorptive R-Card fences are triangular in shape and positioned to remove the specular reflections for each of the antennas close to the sidewalls. The same treatment should be done on the floor and ceiling if the antennas come close to those surfaces as well.

Note that the tapered R-Card fences can be used to hide the junction associated with absorber being thinner closer to the source antennas and thicker farther away. Also, the fences become larger away from the source antennas because they need to block more energy coming from the antennas farther from the sidewalls.

Besides the chamber issues, hardware-in-the-loop testing involves using real-world systems that are not meant to be mounted in a chamber. Furthermore, to simulate the real-world operation of these systems, they must appear to be moving at high speeds and placed in very demanding situations. That being the case, the motion control hardware must be massive and yet not impact the measurement. This can only be done to a certain degree because of the size of the equipment needed to properly hold and move the hardware being tested. First, the mounting structure has to be designed to keep the motion control system as far as possible from the AUT. Because the hardware must remain in the test zone, it must be close to the center of rotation. To accomplish all these desires at the same time, one should use a mount structure that places the very large azimuth rotator as close to the floor as possible. The azimuth rotator then holds a tilted boom arm that extends vertically into the region just

FIGURE 50-6 Typical hardware-in-the-loop chamber showing the R-Card fences on the sidewall along with the pyramidal absorber laid out in a Chebyshev pattern

behind the test zone. This tilted arm holds the elevation rotational hardware. The tilt in this arm causes the incident signal to be reflected downward away of the test zone, much like a pylon that is used for RCS testing. In fact, this tilted arm could be designed to have an ogival cross-sectional shape that is pointed in the front and back. Using this approach, one minimizes the impact of the very large azimuth rotator and associated vertical arm that is normally used to hold the real-world hardware in the center of the test zone.

The last item that must be hidden is the very large elevation rotation hardware that is mounted directly behind the radiating system. This is done by attempting to model the actual hardware mounting structure. Note that this mounting hardware is probably metal, or least conducting. So a conducting shroud should be placed between the radiating system and the elevation rotational equipment. It will hide the elevation rotational hardware but will have an exposed trailing edge. The potential edge diffraction from this edge could also impact the desired measurement. This diffraction can again be minimized by using a tapered R-Card concept for the trailing edge of the shroud. Using all these techniques, the rotational hardware is pretty well hidden and the measured data should be as realistic as possible considering the size of the rotational hardware needed to safely maneuver real-world hardware during these hardware-in-the-loop tests.

50.7 GAIN, EFFICIENCY, AND BORESIGHT MEASUREMENTS

For small antennas, the efficiency is the major concern.^{23–24} On the other hand, for most antennas, the gain is typically the parameter that must be measured. This is normally done by comparing the gain of the unknown antenna with the gain of a known antenna. The first step in this process is to find the boresight direction, which is typically determined by measuring the main beam pattern at several selected levels and then assuming that the true boresight direction is half-way between the angular locations of a given selected level. The use of several pattern levels provides averaging to refine the boresight location. Once the boresight direction and gain are known for the AUT, one then measures the boresight direction and gain for a standard gain antenna using the exact same measurement hardware. From these two measurements, one can then determine the difference in gain between the known and unknown antennas. This difference is then added to the known gain to determine the gain of the unknown antenna. This seems rather simple, but it has many pitfalls.

First, it must be assumed that the field quality is perfect across the whole test zone used to measure the two antennas. That is typically not possible for a high gain antenna because it is illuminated by a field that varies somewhat in amplitude and phase. For a compact range, this could be as much as a dB or more in some larger applications. Next, there is the question of polarization. The AUT may be circularly polarized, but the known antenna is linearly polarized. All of these potential issues must be resolved before one can accurately determine the gain of an unknown antenna.

In recent years, there has been a great interest in knowing the gain to within tenths of a dB. That means that one must account for every possible error term in their gain measurement. The measurement uncertainty is assessed through an error budget projection comprised of the arithmetic sum of the mean error components and an RSS sum of the standard deviations. As a result, it is very difficult to verify that the desired gain level has actually been achieved. To overcome this situation, it is very useful to have different ways to make these gain measurements. If the desired level of performance is achieved, one should be able to verify the results using dramatically different gain tests.

Let's consider that it is our desire to measure the gain through an RCS measurement in that it is well-known that the antenna-mode backscatter term is directly proportional to the

gain of the antenna squared.²⁵ Since the RCS level can be very accurately calibrated, one does not need to use a standard gain antenna. Therefore, this method removes the potential errors associated with a second antenna measurement.

That being the case, how does one measure the antenna-mode RCS scattering level of a high gain antenna. First, one needs to understand that the total scattering is made up of two terms: 1) the antenna-mode scattering and 2) the structure scattering. These two terms can be separated by matching the antenna port. In this case, the antenna-mode signal is fully absorbed in the matched load and the total scattering comes from the structural scattering. So this offers one way to isolate the antenna-mode scattering from the structural scattering. But this approach is not very useful in practice, because it is often times very difficult to find a perfectly-matched condition. That is especially true for broadband applications. So, it is strongly suggested that a time domain method be used, which is often the preferred measurement approach for high-quality RCS measurements.

Using the time domain, it's possible to separate out the various time responses, because the structural scattering comes at certain times and the antenna-mode scattering at others. In fact, the antenna-mode scattering can be moved in time by changing cable lengths. This is done by attaching a length of cable to the antenna port. At the other end of the cable, it is connected to a multi-throw switch that has its output ports connected to a set of different length cables terminated in short circuits. The RCS of the antenna is then measured with the antenna in the boresight direction. This measurement is performed over the available bandwidth of the antenna. The same measurement is then repeated with the multi-throw switch connecting different lengths of cable. This measurement is repeated a number of times so that one can clearly separate the structural scattering term from the antenna-mode term. Once the antenna-mode term is isolated, it can be calibrated by a flat plate of the same aperture size as the AUT. This means that both apertures are exposed to the same exact field. This will provide the desired antenna-mode RCS level. Once the cables connected to the antenna port are calibrated using very accurate network analyzer techniques, the only unknown is the AUT gain. This RCS gain measurement technique is described in Rudduck et al.²⁶

This RCS method is very useful for high-gain antennas. In addition, the large plate that is used for the RCS calibration can also be used to boresight the high-gain antenna. This is done by using the mechanical alignment of the plate relative to some feature on the mounting structure that will ultimately hold the antenna. So, this plate is used as a mounting standard for boresighting the antenna in a mechanical sense. The high-gain antenna is then boresighted so that its beam is fully aligned with the flat plate peak scattering. This is done by appropriately shimming the antenna to get the antenna radiated main beam to align with the flat plate RCS main beam. Note that the plate can be mounted some distance behind the high-gain antenna so that an absorber can be added to make sure that it does not interfere with the forward radiation from the antenna. Thus, the flat plate serves two functions. It is used to very accurately align the boresight direction of the main beam with the mounting structure and to also provide a very accurate RCS calibration standard. Since the potential errors in this method are dramatically different than those in the substitution method, it is an excellent way to either measure the gain or verify the substitution method results. Finally, one should realize that the RCS calibration and boresight plate should be removed before any full patterns are attempted, especially in cases where the backlobe pattern region is of interest.

This RCS method is not very useful for medium or low-gain antennas. Thus, another method is needed for these cases. One can use an S11 measurement technique.²⁷ Using this approach, one takes the AUT and mounts it in front of a very large polished flat plate. The flat plate reflection then re-illuminates the AUT. This illumination comes from the perfect image of the AUT. In other words, one is measuring the S12 transmission between two identical antennas. Since the S11 port can be very accurately calibrated and this S12 coupling term can be separated in time, one can obtain the S11 measured results that are

fully calibrated and the gain is the only unknown provided that the antenna's phase center is accurately determined using standard pattern measurement techniques. Consequently, this method again does not need a standard gain antenna, so it is not susceptible to errors related to the substitution method. Thus, it is a wonderful method to obtain gain data quickly and accurately for low or medium gain antennas.

Traditionally, gain measurements have focused on the magnitude alone. For most applications, that is all that is needed. However, there are new broadband applications that are becoming more important all the time. That being the case, one is also very interested in the main beam phase behavior versus frequency. Recall that for broadband systems, the magnitude and phase variations can cause undesired modulation responses. Thus, the phase measurements cannot be ignored. There are many standard gain antennas that one can use to perform normal gain magnitude measurements; however, gain phase tests for standard gain horns have not been done to any great degree. Thus, new methods must be developed to perform these broadband phase tests.

Since neither the RCS nor flat plate reflection tests require a secondary gain standard, one can use either of these tests to collect both the magnitude and phase. Let's consider the flat plate test. In this test, the S_{11} response associated with the flat plate reflection term is isolated in the time domain. From this data, one knows both the magnitude and phase data. The phase data is related to the path length between the horn and its image, plus the phase variation associated with AUT. The path length between the AUT and its image can be determined. This leaves the AUT phase as the only unknown. Thus, this method can be used for future broadband phase tests as well. Note that similar concepts can be used to extract the AUT phase variation using the RCS test.

50.8 POLARIZATION MEASUREMENTS

In order to take any pattern measurement, one must also be concerned with the polarization of the AUT. To fully understand the polarization properties of the AUT, it has been found most useful to measure both linear polarization patterns because it is generally easier to achieve high polarization purity with a linear state. If these patterns are taken so that they are phase coherent, then one can combine these two polarization results in any way that is needed to fully characterize the AUT's polarization performance. The difficulty in measuring these two patterns is to insure that they remain stable in magnitude and coherent in phase. To properly insure the stability and coherency, one can take advantage of the rotational hardware used to hold the AUT during these measurements. This will be discussed in more detail later.

As shown by Ludwig,²⁸ the third polarization definition is most useful and found to be consistent with how one should take the measurement in terms of keeping the AUT in the middle of the test zone. Let's suppose that a measurement facility has a roll-over-elevation-over-azimuth motion control system. Using this hardware, there should be a tall vertical pole between the elevation-over-azimuth rotator, which is mounted on the floor. This pole should then be oriented perpendicular to the direction of plane wave propagation within the chamber. Then, the elevation rotator should be used to boresight the AUT. This boresight procedure is done using the azimuth and elevation rotators. Once the antenna is boresighted the elevation rotator angular position is fixed for all subsequent measurements. Now, the polarization or roll axis is adjusted to align with a desired linear polarization state and the pattern is taken by rotating the azimuth positioner from 0 to 180 degrees in step sizes that satisfy the sampling theorem. Once this azimuth pattern is collected, the azimuth axis should return to 0 degrees going in the opposite direction to the pattern motion. Next, the

polarization axis is rotated to a desired step size and the azimuth pattern is taken again. This process is continued until the full volumetric pattern is obtained. Recall that this set of patterns is taken for one linear polarization. So, the source antenna should then be rotated by 90 degrees to obtain the orthogonal polarization pattern. Thus, the full volumetric pattern is repeated for this new source antenna polarization. This approach will provide the complete pattern description for the AUT provided as stated earlier that the two polarization pattern sets are stable in magnitude and coherent in phase.

To insure that the two polarization patterns are stable and coherent, one simply needs to recall the data collection process. First say that the source polarization is horizontal and the AUT is also horizontally polarized for the initial roll axis angle of 0 degrees. That being the case, the source and AUT polarizations are aligned at 0 degrees. Now consider the second polarization measurement, the source polarization is now vertically oriented and at a roll axis position of 90 degrees, the AUT polarization is also vertical. That means that the same boresight measurement is being repeated using either the horizontal and vertical source polarizations. Therefore, these two measurements can be used to insure that the two polarization patterns are stable in magnitude and coherent in phase.

Before leaving this topic, it's important to consider one more aspect associated with this measurement approach. The concern here is that the large AUT remains in the test zone during the full measurement. As shown earlier, the test zone size is a very important parameter in the design of a measurement system, in that the cost of the measurement facility tends to be directly correlated to the test zone size. As a result, it is very important to keep the test zone size as small as possible. That being the case, one should also want to make sure that the AUT remains centered in the test zone; otherwise, the AUT will go outside the test zone resulting in undesired measurement errors. With this in mind, the roll-over-azimuth approach is ideal because the AUT can be mounted on the support structure to insure that it is always located inside the test zone boundaries.

50.9 ANTENNA TEMPERATURE MEASUREMENTS

Normally, receiver noise dominates over antenna generated or received external noise. However for low-noise systems or systems that tend to look toward the sun or other hot spots, one must understand how to take proper antenna temperature measurements. Normally, these measurements are not taken indoors because it involves having the AUT illuminated by the appropriate real-world external noise sources, whereas a chamber has an ambient 290K background. Even so, one can still gain great insight into antenna temperature measurements by properly characterizing the antenna properties. First, one needs to fully measure the volumetric pattern of the AUT. Then each of the losses in the antenna system must also be identified. In most cases, it is much easier to measure these parameters indoors. Of course, there are measurements that can be done outside using known temperature sources. Once these parameters are fully understood, one can then create various scenarios to investigate the impact of certain real-world situations and the impact on system performance.²⁹⁻³⁰

One parameter that is very important to understand is the volumetric pattern. This must be known to very low levels because any real-world system can be illuminated by very strong noise sources. If these strong sources illuminate the AUT in a direction with a high sidelobe, it can cause significant noise and the system performance will degrade. Thus, the sidelobe performance can be a very serious matter and require measurements that are accurate even for huge dynamic ranges. That being the case, one has to be very concerned about stray signals in a chamber at wide angles.

50.10 CHAMBER EVALUATION

A major problem with antenna/radar test ranges today is the lack of knowledge of their test zone fields. Ideally, the test zone fields should be a uniform wavefront that represents the desired illumination of the AUT. In practice, depending on the range configuration, the test zone fields will show variations in magnitude as well as phase. Some of these variations are associated with the range geometry (spherical wavefront, taper in compact ranges, and so on), whereas some variations are caused by undesired (stray) signals present in the range. The sources of these stray signals tend to be localized, for example, a bad piece of absorber, feed spill over in compact ranges, and so on. The stray signals affect the quality of the measured data very differently than the variations in the test zone fields due to the range geometry. Let's say, a given measurement facility has a dB taper in the test zone fields due to the range geometry. This taper variation will lead to some drop in the measured sidelobe levels as well as some small reduction in the measured gain. On the other hand, if the test zone fields have a ripple due to the presence of stray signals, it can lead to large errors in the measured sidelobe levels. For example, suppose that the stray signal appears at 20 degrees with respect to the desired plane wave term and is 30 dB below the desired illumination. Furthermore, the AUT has a sidelobe level of -40 dB at 20 degrees. As the AUT is rotated toward the 20 degree direction, the desired signal level should be -40 dB; however, the main beam now points directly at the -30 dB stray signal and the received signal is -30 dB. Thus, this stray signal can cause a 10 dB measurement error. To reduce the measurement errors, stray signals must be found in a test zone and removed if at all possible. If the stray signals cannot be removed, they should be avoided during the measurement. Finally, if avoiding or controlling the stray signals is impossible, then their impact on a given measurement must be understood. This understanding will be explained at the end of this chapter. It is a new concept that can be used to answer the age old question: "Can your facility be used to accurately measure my antenna?"

A further advantage to chamber evaluation is an understanding of those factors that limit the facility performance. Generally, several factors contribute to different degrees to the measurement uncertainty and reducing each of the individual factors that limit performance is accompanied by different economic impacts. By using the chamber evaluation to determine the limiting factors and addressing the scope of ways to deal with the individual factors, the cost/benefit analysis for facility upgrades can be understood.

The first step in the range evaluation process is the determination of the stray signals in the chamber. This is best done in an antenna measurement facility through field probing. A *prober* should be installed in the center of the test zone. It can be an x/y or ρ/ϕ *prober system* that is oriented to scan across the full width and height of the test zone. The probe data is collected by moving the probe antenna in steps that satisfy the sampling criteria. At each step position, the probe data is collected over as wide a bandwidth as possible. This measured probe data contains the desired signal plus any undesired stray signals that are seen by the probe antenna. Note that the probe antenna should have as wide a pattern as possible so that the full half space forward of the prober is properly evaluated. Since one only wants to collect stray signal data in the front of the chamber, the probe antenna should be mounted on an absorber panel so that it does not see stray signals behind the probe antenna, including the scattering from the probe structure itself. Also, since most chambers have very broadband frequency capability, the probing should be done to cover the full operational bandwidth.

Once the test zone of a measurement facility has been probed, the probe data can be displayed in various formats. The most common format is a plot of the amplitude and phase as a function of probe position at a fixed frequency. Almost everyone has seen the probe data in this form. Typically as one looks at this type of data, it's possible to notice that it is

made up of small complex amplitude and phase variations added to the desired illumination term. These variations are not simple because they represent many small stray signals that emanate from various places within the chamber.

In order to make sense out of these complex responses, one must resort to some post-processing to resolve the various signals seen in the test zone. Many techniques for post-processing of the probe data have been reported in the literature. Gupta³¹ provides a summary of some simple yet very useful techniques for post-processing of the probe data such that the sources of the various stray signals in the antenna/RCS measurement facility can be properly located. These techniques include near field focusing, direction of arrival (DOA) estimation, time of arrival (TOA) estimation, time and direction of arrival estimation (TADOA), and so on.

TADOA estimation³² is a very useful approach for locating the sources of stray signals in an antenna/RCS test facility. In this approach, the probe data at each frequency is first transformed to the angle domain and then the frequency domain data is transformed to the time domain. Thus, each stray signal in a TADOA plot is isolated in terms of its specific time delay and angle-of-arrival. For example, Figure 50-7 shows the TADOA spectra of a test range that was evaluated from 250 MHz to 750 MHz. The main lobe in the middle of the plot corresponds to the desired illumination, whereas the other peaks correspond to stray signals. One can clearly see a strong stray signal at -50 degrees. This stray signal arrives 24 nanoseconds before the direct illumination. With this information, one can determine the true stray signal path within the chamber by tracing back from the center of the test zone along the angle-of-arrival direction. Once the true path is found, it should have the correct relative time of arrival versus the desired term as well as the proper direction-of-arrival angle. If one thinks about this approach in some detail, it becomes clear that each undesired stray signal path can be identified. Once the true stray signal sources are determined, one should immediately attempt to correct these undesired error terms. Note that the probe data must be re-collected after the chamber modifications to insure that the error term or terms have indeed been corrected. The beauty of this approach is that one can clearly isolate each stray signal and be assured that it has been removed even though the chamber may have many other small stray signal terms. Recall that if one corrects one small stray

FIGURE 50-7 TADOA spectra of a test range from 250 to 750 MHz

signal out of many, very little difference in the raw probe data will be seen, but the chamber improvements will be very clearly visible in the plots of TADOA spectra.

Now let's suppose that everything has been done to minimize the stray signal error terms in a given chamber. This means that one must live with what remains. That being the case, how can it be determined whether the chamber can be used to measure a given antenna? To answer this question, let's suppose that the chamber has been fully probed at the desired measurement frequencies. That means that the field incident on the AUT is known through the probe data. This measured probe data could then be used to create a plane wave spectrum that will ultimately illuminate the AUT at each desired frequency. Since the AUT was designed using some type of numerical simulation code, it has probably been fully characterized in terms of its amplitude and phase response versus various angles of incidence. In many cases, the full volumetric pattern has been computed. If the full pattern is not known, at least the dominant regions of the pattern are known. When this AUT is mounted in the test zone, it will be exposed to the same illumination as seen with the probe data. Thus, the plane wave spectrum of the measured probe data is a very good representation of the actual AUT illumination. That being the case, one can take this incident plane wave spectrum and illuminate the AUT in terms of a full simulation. Note that now the simulation is being used to determine what the measured pattern data should look like based on the measured incident fields in the test zone as opposed to the desired plane wave illumination. This will result in what one could call a "simulated measured pattern," or SMP for short. This SMP can then be compared with the predicted pattern using the desired illumination. This comparison can be done in many ways. But the bottom line is that one can use this technique to determine whether or not a given measurement facility can be used to measure a specific antenna. In fact, the expected error bounds could be known before any measurements are even taken. Thus, one can answer the age old question: "Yes, my chamber can be used to measure your antenna and here is the SMP data to prove it!"

One could become very uneasy about this chamber evaluation process because it could expose stray signals that cannot be corrected, which might result in the loss of potential chamber support. That is not necessarily the case, because the existence of a stray signal in a chamber is not really the problem. The problem is that the stray signal can impact an important measurement, which is the bottom line. To illustrate this point, let's again consider the feed spillover error term in a compact range. Since the feed antenna in a compact range is normally mounted near the floor, this feed spillover error term comes from a down look angle as seen from the center of the test zone. Let's suppose that the look angle for this error term is 20 degrees down and a large reflector antenna system is being measured in the test range. In this measurement, the full volumetric pattern data is needed. If one takes this pattern data by allowing the main beam to fully scan around the chamber, it will eventually scan down 20 degrees and measure the feed spillover error term through the main beam. The pattern measurement for this case is very likely to be in error. In fact, this measurement error could be tens of dBs, as described several times earlier. On the other hand, if the chamber operator is well aware of this error term and its impact on similar measurements, he or she would know to take the full volumetric pattern in such a way that the main beam never scans down. This way, the feed spillover is still present but it does not affect the measured results nearly as much as it would have otherwise. So, the value of this type of knowledge is priceless.

The previous example was very useful because it illustrates how one can avoid undesirable stray signals. This is well and good but how does one use this information for more complex measurements that have multiple beams or fan beams or shaped beams, and so on? Can one still find ways to avoid the stray signal errors for these very complex pattern measurements? Yes, this can be done through the simulation method described earlier.

Let's suppose that the SMP is computed and compared with the desired pattern. It is then noticed that the difference between the SMP and desired pattern is greater than what

is acceptable. This could very well be the case. But all is not lost at this point in that one now knows the error angles and some predicted error bounds for that specific measurement. Once this is known, one can take the pattern measurement in a different way and obtain data that is correct in the direction or directions that failed before; however, it fails in some other directions. That is not a problem, because one can anticipate these errors and their associated predicted error bounds. If the actual measurements follow these predicted findings, it is perfectly acceptable to use the correct data where it was predicted to be correct through simulation. However this will only work if the measurement and simulation experts work together to achieve their common goal of making accurate antenna pattern measurements.

The previous approach also solves another major issue with associated measurements in general. The antenna community has been divided into two groups: 1) the simulation group and 2) the measurement group. This has led to many confrontations between these two groups because the measured and calculated results oftentimes do not agree to the precision required in the evaluation of modern systems. That being the case, the two groups tend to defend their own turf and tend to point out the potential shortcomings of the other group. That is not right, in that both groups really have their own limitations. So they need to work together. This can be done using the approach presented here. In fact, the simulation group can determine the measurement error bounds before the measurements are even performed. Simulations can be used to determine if a given facility can be used to measure a given antenna with the desired accuracy. Unfortunately that is not happening today. Furthermore if the simulation group agrees that a given facility can do the measurement with certain restrictions, they cannot complain that the measurement is wrong in that their simulation fully justified the measurements. So, each group has a way to protect their own turf using this concept.

50.11 CLUTTERED ENVIRONMENT MEASUREMENTS

There are times that pattern measurements are taken and the results are not satisfactory. This can be the result of undesired stray signals that were never corrected. At this point, these error terms may not even be understood, yet accurate results are needed from this suspect facility. So, what can be done? This is the focus of this section.

To illustrate the value of this technique, let's suppose that the desired measurement is of a high gain antenna and the pattern is taken using a roll-over-azimuth rotational system so that the main beam is always scanned around the horizontal plane in the chamber. This being the case, the concern is associated with stray signals in the horizontal plane or nearly in the horizontal plane. To begin the process, the antenna is mounted in the center of the test zone and the first pattern is measured. Now let's examine a second pattern that can be taken to correct the errors in the first pattern. To grasp this concept, one needs to think about how a stray signal corrupts a given measurement. As stated earlier, it happens when the AUT main beam illuminates the stray signal direction and amplifies the stray signal level. Since a low sidelobe is being measured rather than the main beam, one needs a method that will naturally attenuate the main beam gain level without impacting the desired low sidelobe measurement. This can be done by taking a second pattern such that the two patterns add in-phase in the desired plane wave illumination direction and out-of-phase in the AUT main beam direction. It's possible to think of the summation of these two patterns as an array pattern that has a peak value in the plane wave illumination direction and null in the AUT main beam direction. This array pattern can be obtained if the second pattern is taken with the antenna positioned along a cross-range direction so that the plane wave illumination is always in-phase.

The position along the cross-range direction is selected so that the array pattern has a null in the AUT main beam direction for a particular azimuth pattern angle. Since this position changes with the pattern angle, the second pattern must be taken with the cross-range position changing with pattern angle. Yes, the motion control system has gotten more complex, but these two patterns can then be added together and the stray signal errors reduced by 20 dB or so. Furthermore, the actual measurement errors can be seen if these same two patterns are subtracted. If this subtracted pattern is negligible, the chamber measurements were correct because there were no undesired peaks in the subtracted pattern. If the subtracted pattern is relatively significant compared to the desired pattern, then the original measurement was in error and the actual error level can be clearly seen. This is a very powerful way to take measurements in a cluttered environment and still get valuable measured data that one can fully justify as being correct. This discussion has been greatly simplified in that it was simply used to highlight the method. For the full details, one should refer to Burnside and Gupta.³³

50.12 SUMMARY AND CONCLUSIONS

This chapter has attempted to examine indoor antenna measurements. It has been shown that modern measurement hardware has been so refined in recent years that it's now possible to have tremendous capability at your finger tips. Because of these awesome tools, S11 measurements can be taken with tremendous precision. For pattern, antenna temperature, and hardware-in-loop measurements, the major concern is stray signals that can contaminate the measured results. Therefore, one must be able to fully understand and control these undesired error terms as shown here.

Various indoor facilities have been examined in terms of their usefulness and limitations. The limitations can be specifically identified by taking probe measurements that characterize the test zone fields. By properly processing the probe data, the stray signal sources in any chamber can be isolated, identified, and potentially corrected. If they cannot be corrected, they should be understood so that any subsequent measurement can avoid these uncorrected stray signals.

In some cases, it is virtually impossible to know the impact of the residual stray signals on a complex antenna pattern measurement. That being the case, it has been proposed here that the antenna simulation team, which wishes to use a given chamber to measure their antenna, should take the measured probe data and create an incident plane wave spectrum. This plane wave spectrum can then be used through simulation to illuminate their antenna. The resulting pattern from these simulations can then be compared with the desired pattern. If they feel that the resulting simulated measured pattern is satisfactory, they will know that the given chamber will provide the desired results. This way, the simulation team will be able to justify using or not using a given facility for their measurements. In addition, the simulation team can propose back to the measurement team what could be done in terms of the measurement procedure within a given chamber to avoid certain errors that are critical to their specific antenna measurement. In any case, everyone knows what to expect so that the major conflicts that exist today between the simulation and measurement groups can be avoided to a large degree.

Finally, it has been shown that one can take measurements in a cluttered chamber provided that a second measurement can be obtained with the AUT moved in a cross-range direction while being rotated in angle. This second measurement is used to remove the stray signal errors. If these two patterns are added together, they form an array pattern that does not impact the desired plane wave illumination but places a null in the AUT main beam direction. Note that the null in the main beam direction will reduce the stray signal

error by about 20 dB. Since this is all based on measurements, it is a wonderful way to show the measurement performance of a given facility. On the down side, the motion control system becomes more complex because the AUT has to be moved in a cross-range direction as it rotates in angle. Even so, additional motion control systems can be an inexpensive fix as compared to modifying a very expensive measurement facility. In any event, it is important that one understands their facility and the impact that their facility has on any proposed measurement.

The bottom line here is that one can now use the tools presented in this chapter to answer the age-old question: "Yes, my facility can measure your antenna and here is the proof." Thus, it is hoped that the antenna community will eventually adapt these methods as standard practice.

51.1 GENERAL

In the applications of antennas, it is necessary to use some form of transmission line to connect the antenna to a transmitter or receiver. It is essential to know the propagation characteristics of the more common forms of line.

The transmission lines in Sections 51.2 to 51.6 are almost always used in the transverse electromagnetic (TEM) mode of propagation and therefore possess a unique characteristic impedance. In air, the guide wavelength λ_g is equal to the free-space wavelength λ . Propagation in this mode exists at any frequency, although above a certain frequency higher modes may also exist. It is assumed that the line loss is small and may be neglected in calculating the characteristic impedance.¹

The waveguides considered in Sections 51.7 and 51.8 use modes of propagation having a longitudinal component and do not possess a unique characteristic impedance.² Propagation may only take place above a certain unique cutoff frequency defined by the mechanical dimensions. The guide wavelength λ_g is related to the free-space wavelength λ by $1/\lambda_g^2 = 1/\lambda^2 - 1/\lambda_c^2$ where λ_c is the cutoff wavelength.

In all cases, it will be assumed that the skin depth is small compared with the dimensions of the conductors and that these conductors are nonmagnetic. The medium surrounding the conductors is often air, but for other dielectrics a loss will be introduced, and this is independent of the line dimensions. In the case of TEM modes this loss is

$$\alpha_D = \frac{\pi}{\lambda_D} \tan \delta \quad \text{Np/m}$$

where $\lambda_D (= \lambda / \sqrt{\epsilon_r})$ is the intrinsic wavelength in the medium and $\tan \delta$ is the loss tangent of the dielectric. ϵ_r is the relative dielectric constant. For waveguide modes, the wavelength in the guide must be considered, and the dielectric loss becomes

$$\alpha_D = \frac{\pi \lambda_g}{(\lambda_D)^2} \tan \delta \quad \text{Np/m}$$

In the circuits that have discontinuities, such as bends, the open types of lines will have additional loss because of radiation at these points, and therefore shielded types should generally be used for complex circuits.

The power-handling capacity of transmission lines in the following sections is given in terms of the maximum allowable field intensity E_a in the dielectric, whereas for waveguides the power is given directly for air dielectric. For such calculations, $E_a = 3 \times 10^6$ V/m is the theoretical maximum for air dielectric, at normal temperature and atmospheric pressure, but for proper derating a value of 2×10^6 V/m is more practical. Other dielectrics having a higher dielectric strength may be used to increase the power limit, but in the case of solid dielectrics, the increased field strength in air pockets (which are very likely to exist) imposes a serious limitation. A common method of increasing the power limit is to use pressurized air, the maximum power being proportional to the square of the absolute pressure.

The conditions discussed above apply to a matched line. The maximum power is inversely proportional to the standing-wave ratio.

Important transmission-line equations are shown in Table 51-1 for both TEM and non-TEM lines and waveguides.

*Case of low conductor loss

51.2 OPEN-WIRE TRANSMISSION LINES

Open-wire transmission lines are an arrangement of wires whose diameters generally are small compared with the spacings involved. This arrangement is sometimes used in conjunction with a ground plane to which the wires are parallel. Such transmission lines have the advantage of simplicity and economy. The spacing between the wires and between the wires and the ground plane is very much less than a wavelength.

The most common of the open-wire lines is the two-wire line. For two wires of diameter d , spaced at a center-to-center distance D , the characteristic impedance is

$$Z_0 = \frac{120}{\sqrt{\epsilon}} \cosh^{-1} \frac{D}{d} \quad \Omega$$

This relation is plotted in Figure 51-1. In the case of unequal wire diameters d_1 and d_2 , d is replaced by $\sqrt{d_1 d_2}$.

FIGURE 51-2 Open-wire lines (Note that d is small compared with other dimensions.)

The conductor loss is

$$\alpha_c = 2.29 \times 10^{-6} \sqrt{\frac{f\epsilon}{\sigma}} \frac{1}{d \log_{10}(2D/d)} \quad \text{Np/m}$$

The power-handling capacity is

$$P = \frac{E_a^2 d^2 \sqrt{\epsilon}}{240} \cosh^{-1} \frac{D}{d} \quad \text{W}$$

where E_a is the maximum allowable field intensity in the dielectric (Section 51.1).

Other configurations of open-wire lines are shown in Figure 51-2, together with formulas for the characteristic impedance. Lines near a ground plane are also included. Other types of open-wire lines can be found in the literature.

51.3 WIRES IN VARIOUS ENCLOSURES

It is often advantageous to tailor a transmission line to fit a specific application when one of the more common forms is not convenient. Furthermore, with many antenna configurations a nonstandard form of line has definite advantages.

Various forms of transmission line comprising wires in different-shaped enclosures are shown in Figure 51-3, together with formulas for characteristic impedance. These lines are shielded, with the exception of the corner enclosure, provided that those that are physically open have an opening less than one-half wavelength across, extend beyond the wire at least one-half wavelength, and have opposing surfaces that are maintained at the same potential.

FIGURE 51-3 Wires in various enclosures³ (Note that d is small compared with other dimensions except in case 1.)

51.4 PRINTED TRANSMISSION LINES

In printed transmission lines, the conductors are flat strips that most frequently are photoetched from a dielectric sheet which is copper-clad on one or both sides. Although not often used as uniform transmission lines, they are very useful for antenna feeds, networks, printed arrays, and slots. They are also useful for a number of microwave integrated circuits such as amplifiers, filters, and high-speed digital logic circuits.

A number of different types of these transmission lines have been suggested, but a good variety of useful characteristics are supplied by six basic types that complement each other well: microstrip, suspended microstrip, inverted microstrip, slotline, coplanar waveguide, and coplanar strip.⁴ Cross sections of these types are shown in Figure 51-4, and closed form equations for computing Z_0 and λ_g or effective dielectric constant are given in the subsections that follow.

Microstrip is made of a dielectric sheet with a narrow conducting pattern of copper on one side and a copper sheet serving as a ground plane on the other. Transmission is mostly of the TEM mode with a good part of the electric field between the broad face of the conductor and the large ground plane. Microstrip is similar to a wire above ground that has been flattened. The field pattern is more complex, as only a part of it is in the dielectric sheet and the rest is in the air above the dielectric sheet. The other three are also mostly TEM, but their electric field is between the edges of the conductor pattern.

Coplanar stripline is similar to a two-wire line with flattened wires. It too is complex, with the fields partly in the dielectric and partly in the air above and below the sheet. The impedance is high because the capacity per unit length is low owing to the edge-to-edge position of the conductors. Coplanar waveguide is really two coplanar striplines in parallel.

FIGURE 51-4 Printed transmission lines: (a) microstrip, (b) coplanar strips; (c) coplanar waveguide; (d) slotline; (e) suspended microstrip; (f) inverted microstrip

As might be expected, the impedance is lower for the same dimensions and dielectric. Slotline is similar to coplanar stripline, with very wide conductor patterns.

Microstrip Line

For a microstrip line of width W on a dielectric substrate of thickness h and relative dielectric constant ϵ_r , the characteristic impedance Z_0 in ohms is given by the expression⁵:

$$Z_0 = \frac{\eta_0}{2.0\sqrt{2.0} \pi \sqrt{\epsilon_r + 1.0}} \ln \left\{ 1.0 + \frac{4.0h}{w'} \left[\frac{14.0 + 8.0/\epsilon_r}{11.0} - \frac{4.0h}{w'} \right] + \sqrt{\left(\frac{14.0 + 8.0/\epsilon_r}{11.0} \right)^2 \left(\frac{4.0h}{w'} \right)^2 + \frac{1.0 + 1.0/\epsilon_r}{2.0} \pi^2} \right\}$$

where w' is an equivalent strip width that takes into account the thickness t of the strip and is given by

$$w' = W + \Delta w'$$

$$\Delta w' = \Delta w \left(\frac{1.0 + 1.0/\epsilon_r}{2.0} \right)$$

$$\frac{\Delta w}{t} = \frac{1.0}{\pi} \ln \left[\frac{4e}{\sqrt{\left(\frac{t}{h} \right)^2 + \left(\frac{1}{\frac{W}{t} + 1.1} \right)^2}} \right]$$

For $W/h \leq 1.0$, the effective dielectric constant ϵ_{eff} is given by the expression:

$$\epsilon_{eff} = \frac{\epsilon_r + 1}{2} + \frac{\epsilon_r - 1}{2} \left[\left(1 + \frac{12h}{W} \right)^{-0.5} + 0.04 \left(1.0 - \frac{W}{h} \right)^2 \right]$$

For $W/h \geq 1$:

$$\epsilon_{eff} = \frac{\epsilon_r + 1.0}{2.0} + \frac{\epsilon_r - 1.0}{2.0} \left(1 + \frac{12.0h}{W} \right)^{-0.5}$$

The previous equations are accurate to within 1% for

$$\epsilon_r \leq 16 \quad \text{and} \quad 0.05 \leq \frac{W}{h} \leq 20.0$$

and within 2% for

$$\epsilon_r > 16 \quad \text{and} \quad \frac{W}{h} < 0.05$$

The error in Z_0 is less than 2% for any ϵ_r and W .

Coplanar Stripline

For a symmetric coplanar stripline with strip width W and separation S on a dielectric substrate of thickness h and relative dielectric constant ϵ_r , the characteristic impedance Z_0 in ohms is given by the expression:⁵

$$Z_0 = \frac{\eta_0}{\sqrt{\epsilon_{eff}}} \frac{K(k)}{K(k')}$$

where the effective dielectric constant ϵ_{eff} is given by

$$\epsilon_{eff} = 1 + \frac{\epsilon_r - 1}{2} \frac{K(k')}{K(k)} \frac{K(k_1)}{K(k'_1)}$$

$$k = \frac{S}{S + 2W}$$

$$k' = \sqrt{1.0 - k^2}$$

$$k_1 = \frac{\sinh\left(\frac{\pi S}{4h}\right)}{\sinh\left(\frac{\pi(S + 2W)}{4h}\right)}$$

$$k'_1 = \sqrt{1.0 - k_1^2}$$

The ratio of the complete elliptic integrals of the first kind can be approximated by the following expressions, for $1.0 \leq K(k)/K(k') \leq \infty$ and $1.0/\sqrt{2} \leq k \leq 1.0$:

$$\frac{K(k)}{K(k')} = \frac{1.0}{2.0\pi} \ln \left[2.0 \frac{\sqrt{1.0+k} + \sqrt[4]{4.0k}}{\sqrt{1.0+k} - \sqrt[4]{4.0k}} \right]$$

For $0 \leq K(k)/K(k') \leq 1.0$ and $0 \leq k \leq 1.0/\sqrt{2}$:

$$\frac{K(k)}{K(k')} = \frac{2.0\pi}{\ln \left[2.0 \frac{\sqrt{1.0+k'} + \sqrt[4]{4.0k'}}{\sqrt{1.0+k'} - \sqrt[4]{4.0k'}} \right]}$$

In deriving the previous expressions the thickness t is assumed to be zero.

Coplanar Waveguide

For a symmetric coplanar waveguide with center strip conductor of width W and separated by slots of width S from adjacent ground planes, on a dielectric substrate of thickness h and relative dielectric constant ϵ_r , the characteristic impedance Z_0 in ohms is given by the expression:⁵

$$Z_0 = \frac{30.0\pi}{\sqrt{\epsilon_{eff,t}}} \frac{K(k'_t)}{K(k_t)}$$

where $\epsilon_{eff,t}$ is the conductor thickness t dependent effective dielectric constant and is given by

$$\epsilon_{eff,t} = \epsilon_{eff} - \frac{\epsilon_{eff} - 1.0}{\frac{(b-a)}{1.4t} \frac{K(k)}{K(k')} + 1.0}$$

$$\epsilon_{eff} = 1.0 + \frac{\epsilon_r - 1.0}{2.0} \frac{K(k')}{K(k)} \frac{K(k_1)}{K(k'_1)}$$

$$k = \frac{a}{b}, \quad k' = \sqrt{1.0 - k^2}, \quad a = W \quad \text{and} \quad b = W + 2.0S$$

$$k_1 = \frac{\sinh\left(\frac{\pi a_t}{4.0h}\right)}{\sinh\left(\frac{\pi b_t}{4.0h}\right)}, \quad k'_1 = \sqrt{1.0 - k_1^2}$$

$$k_t = \frac{a_t}{b_t}, \quad k'_t = \sqrt{1.0 - k_t^2}$$

$$a_t = a + \frac{1.25t}{\pi} \left[1.0 + \ln \left(\frac{4.0\pi a}{t} \right) \right]$$

$$b_t = b - \frac{1.25t}{\pi} \left[1.0 + \ln \left(\frac{4.0\pi a}{t} \right) \right]$$

The ratio $K(k)/K(k')$ can be determined using the expressions given in the previous section on coplanar striplines. Coplanar waveguide also has application in the design of

components such as directional couplers, filters, and baluns. More information on these components and systems can be found in the reference section.⁶

Slotline

In antenna applications, slotlines are fabricated either on low relative dielectric constant plastic substrates with $\epsilon_r \approx 2.2$ or on high relative dielectric constant ceramic substrates with $\epsilon_r \approx 9.8$. For a slotline with slot width W on a dielectric substrate of thickness h and relative dielectric constant ϵ_r , the characteristic impedance Z_0 in ohms at a free space wavelength λ_0 is given by the expression:⁷

For $0.0015 \leq W/\lambda_0 \leq 0.075$ and $2.2 \leq \epsilon_r \leq 3.8$

$$\begin{aligned} Z_0 = & 60.0 + 3.69 \sin \left[\frac{(\epsilon_r - 2.22)\pi}{2.36} \right] + 133.5 \ln(10.0 \epsilon_r) \sqrt{W/\lambda_0} \\ & + 2.81[1.0 - 0.011 \epsilon_r (4.48 + \ln \epsilon_r)](W/h) \ln(100.0 h/\lambda_0) \\ & + 131.1(1.028 - \ln \epsilon_r) \sqrt{h/\lambda_0} \\ & + 12.48(1.0 + 0.18 \ln \epsilon_r) \frac{W/h}{\sqrt{\epsilon_r - 2.06 + 0.85(W/h)^2}} \end{aligned}$$

The corresponding effective dielectric constant ϵ_{eff} at a free space wavelength λ_0 is given by

$$\epsilon_{eff} = \left\{ 1.045 - 0.365 \ln \epsilon_r + \frac{6.4(W/h) \epsilon_r^{0.945}}{238.64 + 100.0 W/h} - \left[0.148 - \frac{8.81(\epsilon_r + 0.95)}{100.0 \epsilon_r} \right] \ln \frac{h}{\lambda_0} \right\}^{-2}$$

The wavelength in the slotline or the guide wavelength λ_g can be calculated from ϵ_{eff} using the expression

$$\epsilon_{eff} = \left(\frac{\lambda_g}{\lambda_0} \right)^{-2}$$

Using the previous set of expressions, the computed Z_0 and λ_g/λ_0 for $0.006 \leq h/\lambda_0 \leq 0.060$ are accurate to better than 2.7% and 2.2%, respectively.

For $0.075 \leq W/\lambda_0 \leq 1.0$ and $2.2 \leq \epsilon_r \leq 3.8$

$$\begin{aligned} Z_0 = & 133.0 + 10.34(\epsilon_r - 1.0)^2 + 2.87[2.96 + (\epsilon_r - 1.582)^2] \\ & \left\{ (W/h + 2.32 \epsilon_r - 0.56) [(32.5 - 6.67 \epsilon_r)(100.0 h/\lambda_0)^2 - 1.0] \right\}^{0.5} \\ & - (684.45 h/\lambda_0)(\epsilon_r + 1.35)^2 + 13.23 [(\epsilon_r - 1.722)W/\lambda_0]^2 \end{aligned}$$

The corresponding effective dielectric constant ϵ_{eff} at a free space wavelength λ_0 is given by

$$\epsilon_{eff} = \left\{ 1.194 - 0.24 \ln \epsilon_r - \frac{0.621 \epsilon_r^{0.835} (W/\lambda_0)^{0.48}}{1.344 + W/h} - 0.0617 \left[1.91 - \frac{\epsilon_r + 2.0}{\epsilon_r} \right] \ln(h/\lambda_0) \right\}^{-2}$$

The computed Z_0 and λ_g/λ_0 for $0.006 \leq h/\lambda_0 \leq 0.060$ are accurate to better than 5.4% and 2.6%, respectively.

For $0.0015 \leq W/\lambda_0 \leq 0.075$ and $3.8 \leq \epsilon_r \leq 9.8$

$$Z_0 = 73.6 - 2.15 \epsilon_r + (638.9 - 31.37 \epsilon_r)(W/\lambda_0)^{0.6} \\ + \left(36.23\sqrt{\epsilon_r^2 + 41.0} - 225.0\right) \frac{W/h}{W/h + 0.876 \epsilon_r - 2.0} \\ + 0.51(\epsilon_r + 2.12)(W/h) \ln\left(\frac{100.0h}{\lambda_0}\right) - 0.753 \epsilon_r \frac{h/\lambda_0}{\sqrt{W/\lambda_0}} \\ \epsilon_{eff} = \left\{ 0.9217 - 0.277 \ln \epsilon_r + 0.0322 \left(\frac{W}{h} \right) \sqrt{\frac{\epsilon_r}{\frac{W}{h} + 0.435}} - 0.01 \ln \left(\frac{h}{\lambda_0} \right) \left[4.6 - \frac{3.65}{\epsilon_r^2 \sqrt{\frac{W}{\lambda_0} \left(9.06 - 100 \frac{W}{\lambda_0} \right)}} \right] \right\}^{-2}$$

The computed Z_0 and λ_g/λ_0 for $0.006 \leq h/\lambda_0 \leq 0.060$ are accurate to better than 5.4% and 3.0%, respectively.

For $0.075 \leq W/\lambda_0 \leq 1.0$ and $3.8 \leq \epsilon_r \leq 9.8$

$$Z_0 = 120.75 - 3.74 \epsilon_r + 50.0 \left[\tan^{-1}(2.0 \epsilon_r) - 0.8 \right] \\ \times \left(\frac{W}{h} \right)^{\left\{ 1.11 + \left[0.132(\epsilon_r - 27.7) / \left(100.0 \frac{h}{\lambda_0} + 5.0 \right) \right] \right\}} \\ \times \ln \left[100 \frac{h}{\lambda_0} + \sqrt{\left(100 \frac{h}{\lambda_0} \right)^2 + 1.0} \right] \\ + 14.21(1.0 - 0.458 \epsilon_r) \left(100.0 \frac{h}{\lambda_0} + 5.1 \ln \epsilon_r - 13.1 \right) \left(\frac{W}{\lambda_0} + 0.33 \right)^2 \\ \epsilon_{eff} = \left\{ 1.05 - 0.04 \epsilon_r + 1.411 \times 10^{-2} (\epsilon_r - 1.421) \right. \\ \times \ln \left[\frac{W}{h} - 2.012 (1.0 - 0.146 \epsilon_r) \right] \\ + 0.111 (1.0 - 0.366 \epsilon_r) \sqrt{\frac{W}{\lambda_0}} \\ \left. + 0.139 [1.0 + 0.52 \epsilon_r \ln(14.7 - \epsilon_r)] \left(\frac{h}{\lambda_0} \right) \ln \left(\frac{h}{\lambda_0} \right) \right\}^2$$

The computed Z_0 and λ_g/λ_0 for $0.006 \leq h/\lambda_0 \leq 0.060$ are accurate to better than 5.8% and 3.2%, respectively.

A low loss transition between a slotline and a fin line is very simple and easy to design and therefore used extensively to excite a tapered slot antenna (TSA) at millimeter wave frequencies.⁸

The ranges of Z_0 available and the losses with the different types of strip transmission lines are compared in Table 51-2. These show that the microstrip and the coplanar waveguide

TABLE 51-2 Comparison of Z_0 Limits and Loss for the Various Lines ($\epsilon_r = 10.0$, $h = 25$ mil, or 0.635 mm, and frequency = 10 GHz)

Transmission line	Z_0 range		Loss, dB/cm	
	Minimum	Maximum	50	100
Microstrip	20 (m)	110 (d)	0.04	0.14
Coplanar waveguide	25 (m, d)	155 (m, d)	0.08*	0.28*
Slotline	55 (d)	300 (m)	0.15†	
Coplanar strips	45 (m, d)	280 (m, d)	0.83*	0.13*

NOTE: (m) = Z_0 limited by mode; (d) = Z_0 limited by small dimensions

* $h/W = 2$

† $\epsilon_r = 16$, $Z_0 = 75 \Omega$

are most useful for low-impedance circuits and that the slotline and coplanar strips are more appropriate for high-impedance circuits.⁹

The characteristics of microstrip are shown in Figure 51-5. The dotted curve is the plot of Z_{0m}^a for airline, while the solid curves are for finding the square root of the effective dielectric constant. The Z_{0m} for other dielectrics is $Z_{0m}^a / \sqrt{\epsilon_{re}}$. Figure 51-6 shows the losses in microstrip on different substrates. Line wavelengths and characteristic impedance of coplanar strips and of coplanar waveguide are shown in Figures 51-7 and 51-8. These same characteristics for slotline are shown in Figure 51-9.

**FIGURE 51-5** Characteristic impedance and effective dielectric constant of microstrip lines

FIGURE 51-6 The conductor and dielectric losses when microstrip is constructed on different substrates

FIGURE 51-7 Line wavelength and characteristic impedance of coplanar strips

FIGURE 51-8 Line wavelength and characteristic impedance of coplanar waveguide

FIGURE 51-9 Line wavelength and characteristic impedance of slotline

Suspended Microstrip

The suspended and inverted microstrip lines have lower dispersion than conventional microstrip lines. Hence, simple quasi-TEM mode analysis yields quite satisfactory results for components such as couplers and filters at higher microwave frequencies. In addition, for the same characteristic impedance, substrate thickness, and a comparable air gap, the strip width when compared to conventional microstrip line is larger—which lowers the attenuation due to conductor losses by a factor of 2 to 3 and also eases fabrication tolerances.

The effective dielectric constant ϵ_{eff} for a suspended microstrip line with strip width W , air gap height h_1 , substrate thickness $h - h_1$, and relative dielectric constant ϵ_{r2} is given by¹⁰

$$\epsilon_{eff} = 1 - q_1 - q_2 + \epsilon_{r1}\epsilon_{r2}(q_1 + q_2)^2/(\epsilon_{r1}q_2 + \epsilon_{r2}q_1)$$

For wide lines with $W/h > 1$, the filling factors are given by

$$q_1 = f_1 \{1 - 0.6523 / u_1 \ln[1.801 u_1 \sin(\phi)/x + f_2 \cos(\phi)]\}$$

$$q_2 = 1 - q_1 - q_w$$

In the previous expression q_w is the Wheeler's filling factor for wide lines and is given by

$$q_w = 0.6523/u_1 \ln(1.801 u_1)$$

In addition, u_1 is the normalized effective line width given by

$$u_1 = w_{eff}/h = u + 2/\pi \ln[17.08(u/2 + 0.92)]$$

$$u = W/h$$

$$x = h_1/h$$

$$\phi = \frac{\pi}{2} x$$

$$f_1 = x^{(0.8605+0.3491/E)}$$

$$E = \epsilon_{r2}/\epsilon_{r1}$$

$$f_2 = (1.929 + 5.908/E)u_1^\alpha$$

$$\alpha = (1.208 + 0.1077E) \times (u/4)^{(0.3048(0.5-x))}$$

For narrow lines with $W/h \leq 1$, the filling factors are

$$q_1 = q_n \left\{ 1 - \left[2/\pi \cos^{-1}(x f_1) \right]^{f_2} \right\}$$

$$q_2 = q_n - q_1$$

where q_n is the Wheeler's filling factor for narrow lines given by

$q_n = 1/2 + 0.26144 / \ln(8/u) \times (1 + 0.2855E_{12}^{-0.7517})$ and x , u , and E are as defined previously

$$E_{12} = x(\epsilon_{r1} - \epsilon_{r2}) + \epsilon_{r2}$$

$$f_1 = [u_1/2(1+x)/(1-x+u_1)]^{0.3915}$$

$$u_1 = (0.13955 + 0.8095/E)(0.0538 + 0.597u + 0.5624u^2)$$

$$f_2 = [1.677 + 0.7848/E - (1.4021 + 0.06055E) \times x + (0.7954 + 0.04382E) \times x^2] \times (u/0.4)^{[0.07(x-0.5)]}$$

Having determined the ϵ_{eff} , the characteristic impedance Z_0 in ohms is calculated as follows

$$Z_0 = \frac{Z}{(\epsilon_{eff})^{0.5}}$$

where Z is the characteristic impedance of an identical air-filled microstrip line and is given by

$$Z = \frac{\eta_0}{2\pi} \ln \left[\frac{f(u)}{u} + \sqrt{1 + \left(\frac{2}{u}\right)^2} \right]$$

where

$$f(u) = 6 + (2\pi - 6) \exp \left[- \left(\frac{30.666}{u} \right)^{0.7528} \right]$$

and $\eta_0 = 376.73 \Omega$ and $u = W/h$.

Inverted Microstrip

The effective dielectric constant ϵ_{eff} for an inverted microstrip line with strip width W , air gap height h , substrate thickness $h_2 - h$, and relative dielectric constant ϵ_{r2} is given by¹⁰

$$\epsilon_{eff} = \epsilon_{r1} q_1 + \epsilon_{r2} (1 - q_1)^2 / (\epsilon_{r2} q_3 + q_2)$$

For wide lines with $W/h > 1$, the filling factors are given by

$$q_1 = 1 - q_w f_1$$

$$q_2 = 1 - q_1 - q_3$$

$$q_3 = 0.6523(1 - f_2) u_1 \ln[u_1 \cos(\phi) / (0.5552 + f_2 \times f_3) + \sin(\phi)]$$

where u_1 and q_w are the normalized effective line width and Wheeler's filling factor for wide lines, respectively. The expressions for u_1 and q_w are identical to those given previously for the suspended microstrip line.

$$u = W/h$$

$$f_1 = 1 - 0.06078[1 - \cos(\pi x^{0.5})] \times [1 - 0.3206/u_1 - 2.3188/u_1^3] \times E^{0.4356}$$

$$x = 1 - h/h_2$$

$$E = \frac{\epsilon_{r2}}{\epsilon_{r1}}$$

$$f_2 = x^\alpha$$

$$\alpha = 0.4746 + 1.3778/E - (0.1376 + 0.00945E)x + 0.6153x^3$$

$$\phi = \frac{\pi}{2} f_2$$

$$f_3 = (3.9717 + 8.0922/E) u_1^{-(0.1321 + 1.3907/E)}$$

For $W/h \leq 1$, the filling factors are given by

$$q_1 = 0.5 + (q_n - 0.5) f_1$$

$$q_2 = 1 - q_1 - q_3$$

$$q_3 = (f_2 - f_3) / [\pi \ln(8/u)]$$

where q_n is the Wheeler's filling factor for narrow lines given by

$$q_n = 0.5 + 0.26144 / \ln(8/u) \times (1 + 0.2855 \epsilon_{r1}^{-0.7517})$$

and

$$f_1 = 1 + 0.1431[1 - \cos(\pi x)] \times [1 - 1.652 / \ln(12.532/u)] \times E^{0.641}$$

$$f_2 = \ln(A) \cos^{-1}[(x A^{0.5})^\alpha]$$

$$A = (2 - x) / [x + u/4(1 - x)]$$

$$\alpha = [0.14695 + 1.657/E + (0.6386 + 0.7881/E) \times x] \times (2x_1)^{[0.3075(u-0.4)]}$$

$$x_1 = 1 - x$$

$$f_3 = 1.0558 x_1^{1.928} (u/0.4042)^{[x(0.30035 + 0.2096/E)]}$$

Having determined the ϵ_{eff} , the Z_0 is determined in an analogous manner, using the expression given previously for suspended microstrip line.

51.5 COAXIAL LINES: SOLID CONDUCTOR

Coaxial transmission lines using a cylindrical center conductor within a cylindrical tubular outer conductor are widely employed for the propagation of microwave power. Although more costly than open-wire transmission lines, they completely enclose the electromagnetic fields, preventing radiation losses and providing shielding from nearby circuits.

Coaxial-Line Parameters

For a coaxial line with inner-conductor diameter $2a$ and outer conductor diameter $2b$, the characteristic impedance is

$$Z_0 = \frac{138}{\sqrt{\epsilon}} \log_{10} \frac{b}{a} \quad \Omega$$

which is plotted in Figure 51-1.

The cutoff wavelength of the first higher mode is²

$$\lambda_c = F\pi\sqrt{\epsilon} (a + b) \quad F \cong 1$$

The conductor loss for the dominant mode is

$$\alpha_c = 1.14 \times 10^{-6} \sqrt{\frac{f\epsilon}{\sigma}} \left(\frac{1}{a} + \frac{1}{b} \right) \frac{1}{\log_{10} \frac{b}{a}} \quad \text{Np/m}$$

The minimum conductor loss occurs at the limiting size for the first higher mode, in which case $\sqrt{\epsilon} Z_0 = 92.6 \Omega$ and

$$\alpha_c = 0.637 \frac{\epsilon}{(\lambda_c)^{3/2} \sqrt{\sigma}} \quad \text{Np/m}$$

For a fixed outer-conductor size, the minimum conductor loss occurs for $\sqrt{\epsilon} Z_0 = 77 \Omega$ and is

$$\alpha_c = 0.164 \frac{1}{b} \sqrt{\frac{\epsilon}{\sigma \lambda}} \quad \text{Np/m}$$

The power transmitted by the line is

$$P = \frac{E_a^2 a^2 \sqrt{\epsilon}}{52.2} \log_{10} \frac{b}{a} \quad \text{W}$$

where E_a is the electric field intensity at the center conductor (Section 51.1). The maximum power-handling capacity occurs for a 44.4Ω line operating at the limit of the first higher mode and is

$$P_{\max} = 6.53 \times 10^{-5} \frac{E_a^2 \lambda_c^2}{\sqrt{\epsilon}} \quad \text{W}$$

For a fixed outer-conductor size, the maximum power-handling capacity occurs for $\sqrt{\epsilon_r} Z_0 = 30 \Omega$ and is

$$P'_{\max} = 1.53 \times 10^{-3} E_a^2 b^2 \sqrt{\epsilon} \quad \text{W}$$

The effect of dimensional tolerances on the characteristic impedance may be found from

$$\frac{\Delta Z_0}{Z_0} = \frac{60}{Z_0 \sqrt{\epsilon}} \left(\frac{\Delta b}{b} - \frac{\Delta a}{a} \right)$$

while the effect of eccentricity is to change the characteristic impedance to

$$Z_0 = \frac{138}{\sqrt{\epsilon}} \log_{10} \left[\frac{b}{a} \left(1 - \frac{e^2}{b^2} \right) \right] \quad \Omega, \quad \frac{e}{b} < \log_{10} \frac{b}{a} < 0.7$$

where e is the off-center distance.

For a balanced coaxial line (sheathed two-wire line) having two center conductors spaced at a distance s within a single outer conductor, the characteristic impedance is given by

$$Z_0 = \frac{276}{\sqrt{\epsilon}} \log_{10} \left(\frac{s}{a} \frac{4b^2 - s^2}{4b^2 + s^2} \right) \quad \Omega$$

Coaxial Line with Helical Center Conductor

Coaxial lines with a helical inner conductor are sometimes useful to obtain a high characteristic impedance or slow propagation velocity. Design relations for this are given in the reference section.¹¹

Coaxial Line, Bead-Supported

In order to support the center conductor of an air-dielectric coaxial line, insulating beads are often used. These beads will introduce discontinuities and, if not properly designed, will all produce large reflection losses. The design procedure for these support beads depends upon the frequency range of application, a broad range requiring a more complex design. The more common procedures are summarized in Figure 51-10, and others can be found in the references.¹²

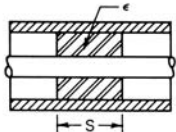

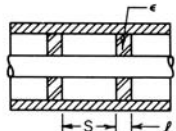

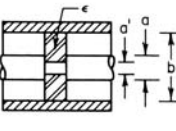

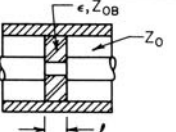

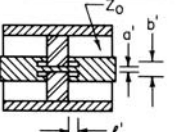

TYPE	CONFIGURATION	DESIGN FORMULAS	REMARKS
1. HALF WAVE		$S = \frac{\lambda}{2\sqrt{\epsilon}}$	FREQUENCY-SENSITIVE
2. SPACED PAIR		$S = \frac{1}{\beta} \arctan \left[\frac{2\sqrt{\epsilon}}{1+\epsilon} \cot \beta l \sqrt{\epsilon} \right]$ $\beta = \frac{2\pi}{\lambda}$	FREQUENCY-SENSITIVE
3. SIMPLE UNDERCUT		$a' = b \left(\frac{b}{a} \right)^{-\sqrt{\epsilon}}$	GOOD AT LOW FREQUENCY. NEGLECTS FRINGING CAPACITANCE AT UNDERCUT.
4. COMPENSATED UNDERCUT		$l = \frac{1}{\beta} \arctan \left[\frac{2\omega C Z_{0B}}{(\omega C Z_{0B})^2 + \left(\frac{Z_{0B}}{Z_0} \right)^2} \right]$ $\beta = \frac{2\pi\sqrt{\epsilon}}{\lambda}$	COMPENSATES FRINGING CAPACITANCE AT UNDERCUT. MATCH AT $f = \omega/2\pi$, LOW REFLECTION AT LOWER FREQUENCIES.
5. COMPOUND UNDERCUT (REF. 4)		$\sqrt{L/C} = Z_0$ $L = \frac{138 l'}{v} \log_{10} \frac{b'}{a'}$ FIND a' AS IN 3) ABOVE $v = 3 \times 10^8 \text{ m/s}$	VERY LOW REFLECTION IF DISCONTINUITIES ARE OF INFINITESIMAL EXTENT ($l' < \lambda/20$). GOOD WHERE MANY BEADS MUST BE USED.

FIGURE 51-10 Coaxial-line beads. Capacitive discontinuities at an abrupt change in diameter (as in items 4 and 5) can be found from this curve if the discontinuities are separated by at least the space between the inner and outer conductors in the intervening line. If the ratio of the inner and outer conductors is less than 5 before and after the discontinuity, the curves are accurate to better than 20%.

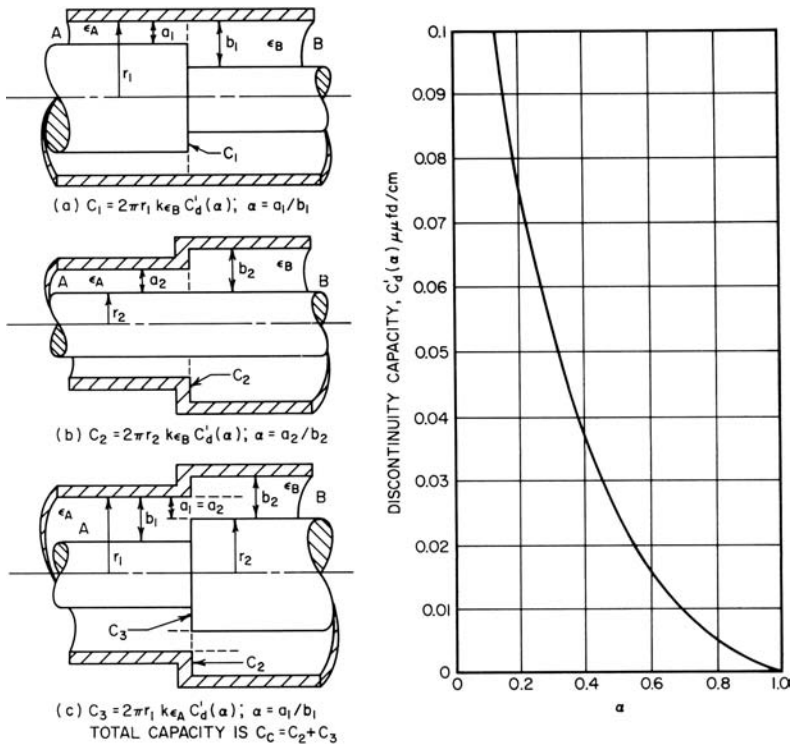

FIGURE 51-10 (Continued)

In the bead-supported line, the cutoff wavelength in the bead section should be kept below the operating wavelength. The power-handling capacity is about 0.033 times that of the theoretical maximum for the unsupported line.

Coaxial Line, Stub-Supported

In many applications, particularly when high power is to be transmitted, it is desirable to support the center conductor of an air-dielectric coaxial line by means of stubs. The power-handling capacity of a stub-supported line is about 0.15 times that of the theoretical maximum for the unsupported line. Such stubs take the form of a short length of short-circuited transmission line in shunt with the main transmission line. For frequencies at which the stub is an odd number of quarter wavelengths long, it presents zero admittance and therefore does not affect the main line. Obviously, it is often necessary to maintain a low stub admittance over a broad range of frequencies, and this may be affected by using an impedance transformer on the main line at the junction with the stub. The design of stubs and transformers can be found in the literature.¹²

Semiflexible Coaxial Lines

There are several commercially available coaxial lines having a limited permissible bending radius but exhibiting a loss only slightly greater than that of rigid coaxial lines. They are

characterized by a helical-, ribbed-, or foamed-dielectric support for a copper center conductor and a solid copper or aluminum tube for the outer conductor.¹³ A number of these have been qualified as MIL spec. components and are becoming more widely used. They are useful where their greater mechanical stability permits good phase matching and control in critical RF circuits.

51.6 FLEXIBLE COAXIAL LINES

Flexible coaxial line using a solid or stranded inner conductor, a plastic-dielectric support, and a braided outer conductor is probably the most common means of connecting together many separated components of a radio-frequency system. Although the transmission loss is relatively high because of the dielectric loss, the convenience often outweighs this factor in applications for which some loss is tolerable. Such lines are commercially available in a wide variety of size and impedance.

Table 51-3 summarizes the characteristics of the more common lines. The attenuation is shown in Figure 51-11, and the power-handling capacity in Figure 51-12.

Leakage of electrical energy through the braided outer conductor is sometimes a problem. The amount of leakage has been evaluated in two ways. One is to measure the equivalent coupling impedance to the outside environment, often another cable.^{14,15} Typical coupling impedance for a M17/74 cable has been reported as $150\ \mu\text{h}/\text{ft}$ from 100 to 5500 MHz. The other is to measure the shielding factor of the cable as the decibel loss through the cable-shielded braid.^{16,17} The coupling loss increases linearly with length (and the shielding decreases with length) and increases slightly at higher frequencies, where the openings between wires in the shield braid become a bigger part of a wavelength. Single-braid cable typically provides 30- to 40-dB shielding from 1 ft of cable. For longer lengths, shielding in decibels is reduced by $20\ \log$ (length in feet). Double-braid cable provides 60 to 80 dB. Special braid of flat metal strip provides 80 to 90 dB. Semirigid lines, which have a solid sheath, provide from 300 to several thousand decibels at the higher frequencies, where the skin depth becomes very small and the field inside penetrates to only a small part of the solid metal sheath.

Frequently used cable connectors are listed in Table 51-4.

51.7 HOLLOW-TUBE WAVEGUIDES

Electromagnetic energy can be propagated down hollow metal tubes, if the tubes are of sufficient size and are properly excited. The size of the tubes required usually limits their use to the very-high frequency (VHF) region or higher.

The energy can be propagated in a number of different types of waves as described next. In the usual case, waveguide devices are designed for transmission of a single wave type (most often the dominant wave or that having the lowest cutoff frequency) because the design problems are very greatly simplified.

Propagation Parameters

TE_{mn} waves: In the transverse electric waves, sometimes called H_{mn} waves, the electric vector is always perpendicular to the direction of propagation.

TM_{mn} waves: In the transverse magnetic waves, sometimes called the E_{mn} waves, the magnetic vector is always perpendicular to the direction of propagation.

SIL/DAC-VI = dacron braid over silicon rubber, Type VI, per MIL-C-17E Rubber per MIL-C-17E

XLPE = cross-linked polyolefin

Comments

SW indicates spec. requirement for swept frequency attenuation and SWR testing.

NS/ indicates the M17 number for the unswept version of the same cable (recommended only to 400 MHz).

Armored/indicates the M17 number for the same cable with armor.

NHLs/indicates similar cable for nonhalogen, low-smoke environments (uses cross-linked polyolefin jacket).

FIGURE 51-11 Approximate attenuation of flexible coaxial lines (M17 numbers are indicated on each curve.)

FIGURE 51-12 Approximate power-handling capacity of flexible coaxial lines. (M17 numbers are indicated for each curve.) Conditions are the following: ambient temperature 40°C , sea level, center conductor is 80°C for polyethylene and 200°C for PTFE.

*Fits Types C and SC only.

† Fits Type N only.

The propagation constant γ_{mn} determines the amplitude and phase of each component of a wave as it is propagated along the waveguide. Each component may be represented by $A \exp(j\omega t - \gamma_{mn}z)$, where A is a constant, z is the distance along the direction of propagation, and $\omega = 2\pi f$. When γ_{mn} is real, there is no phase shift along the waveguide, but there is high attenuation. In fact, no propagation takes place, and the waveguide is considered below cutoff. The reactive attenuation L along the waveguide under these conditions is given by

$$L = \frac{54.58}{\lambda_c} \left[1 - \left(\frac{\lambda_c}{\lambda} \right)^2 \right]^{1/2} \text{ dB/unit length}$$

where λ is the wavelength in the unbounded medium and λ_c is the cutoff wavelength of that wave (a function of waveguide dimensions only). Waveguides are often used at frequencies far below cutoff as calibrated attenuators, since the rate of attenuation is determined by cross-section dimensions of the waveguide and the total attenuation in decibels is a linear function of the displacement of the output from the input.¹⁸

When γ_{mn} is imaginary, the amplitude of the wave remains constant but the phase changes with z and propagation takes place. γ_{mn} is a pure imaginary quantity only for lossless waveguide. In a practical case, γ_{mn} has both a real part α_{mn} , which is the attenuation constant, and an imaginary part β_{mn} , which is the phase constant; that is $\gamma_{mn} = \alpha_{mn} + j\beta_{mn}$.

The wavelength in a uniform waveguide is always greater than the wavelength in the unbounded medium and is given by

$$\lambda_g = \frac{\lambda}{[1 - (\lambda / \lambda_c)^2]^{1/2}}$$

The phase velocity is the apparent velocity, judging by the phase shift along the guide. Phase velocity, $v = c (\lambda_g / \lambda)$, is always greater than that in an unbounded medium.

The group velocity is the velocity of energy propagation down the guide. Group velocity, $u = c (\lambda / \lambda_g)$, is always less than that in an unbounded medium.

For air-filled guide and guides filled with dielectric having very low loss, the attenuation is mainly due to conductor losses in the walls. For any particular type of wave, the loss

FIGURE 51-13 Field configurations for rectangular waveguide

is high near cutoff and decreases as the frequency is increased. For all excepting the TE_{0n} waves in circular waveguide, the attenuation reaches a minimum value for that wave and that waveguide, and then increases with frequency. For most waves, this minimum is slightly above $2f_c$. To avoid high loss near cutoff and the complexity of multiwave transmission, the useful band is usually considered to lie between $1.3f_c$ of the desired mode and $0.9f_c$ of the next higher mode. For rectangular waveguides having a width equal to twice the height, the useful range is about 1.5:1.

Rectangular Waveguides

For TE_{mn} waves in rectangular waveguides, m and n may take any integer value from 0 to infinity, except for the case $m = n = 0$. For the TM_{mn} waves, m and n may take any value from 1 to infinity. The m and n denote the number of the half-period variations of the electric field for TE waves or magnetic field for TM waves in the direction of the small and large dimensions respectively of the waveguide. Field patterns for some of the simpler waves are shown in Figure 51-13.

The propagation constant for rectangular guides is given by

$$\gamma_{mn} = \sqrt{\left(\frac{m\pi}{a}\right)^2 + \left(\frac{n\pi}{b}\right)^2 - \omega^2\mu\epsilon} = \frac{2\pi}{\lambda_g}$$

where a is the wide dimension, b is the narrow dimension, ϵ is the dielectric constant, and μ is the permeability of the dielectric in the waveguide. Since propagation takes place only when the propagation constant is imaginary, the cutoff frequency for rectangular waveguide is

$$f_c = \frac{c}{2\sqrt{\mu\epsilon}} \sqrt{\left(\frac{m}{a}\right)^2 + \left(\frac{n}{b}\right)^2}$$

and

$$\lambda_c = \frac{2\sqrt{\mu\epsilon}}{\sqrt{(m/a)^2 + (n/b)^2}}$$

Most frequently, operation is limited to the TE_{10} or dominant wave in rectangular waveguide. For this simplified case, the important formulas reduce to

$$\begin{aligned}\lambda_c &= 2a\sqrt{\mu\epsilon} \\ \gamma &= 2\pi\sqrt{(1/4a)^2 - f^2\mu\epsilon}\end{aligned}$$

In order to relate the waveguide properties to similar properties of low-frequency circuits, the impedance concept has been developed. Three characteristic impedances can be defined, differing from each other by a constant:¹⁹

$$Z_{VI} = \frac{V}{I} = 377 \frac{\pi}{2} \frac{b}{a} \frac{\lambda_g}{\lambda} = 592 \frac{b}{a} \frac{\lambda_g}{\lambda}$$

$$Z_{PV} = \frac{V^2}{2P} = 754 \frac{b}{a} \frac{\lambda_g}{\lambda} = 754 \frac{b}{a} \frac{\lambda_g}{\lambda}$$

$$Z_{PI} = \frac{2P}{I^2} = 377 \frac{\pi^2}{8} \frac{b}{a} \frac{\lambda_g}{\lambda} = 465 \frac{b}{a} \frac{\lambda_g}{\lambda}$$

Any one of the three is reasonably satisfactory if used consistently throughout, since the most frequent use is in determining mismatch at waveguide junctions and it is the ratio of impedance that matters. Ratios involving only different values of b give accurate indication of impedance mismatch. Differences in a give ratios nearly correct for small changes in a from the usual cross-section dimensions of rectangular waveguide, but errors are appreciable for large differences in a . Z_{PV} is most widely used, but Z_{VI} is found to be more nearly correct in matching coaxial line to waveguide.

Circular Waveguides

The usual coordinate system is ρ , θ , z , where ρ is the radial direction, θ is the angle, and z is the longitudinal direction.

For TE_{mn} waves in circular waveguides, m denotes the number of axial planes along which the normal component of electric field vanishes and n the number of cylinders including the boundary of the guide along which the tangential component of electric field vanishes. The number m may take any integral value from 0 to infinity, and n may take any integral value from 1 to infinity. The dominant wave in circular waveguide is the TE_{11} . For TM_{mn} waves, m denotes the number of axial planes along which the magnetic field vanishes and n the number of cylinders to which the electric field is normal. The number m may take any integral value from 0 to ∞ , and n may take any integral value from 1 to ∞ . Of the circularly symmetrical waves, the TM_{01} has the lowest cutoff frequency.

Field patterns for some of the simpler waves in circular guides are shown in Figure 51-14. The cutoff wavelength in lossless circular guide is given by

$$\lambda_c = \sqrt{\mu\epsilon} D_{mn} a$$

FIGURE 51-14 Field configurations for circular waveguide

where a is the radius, ϵ the dielectric constant, μ the permeability of the dielectric, and the constant D_{mn} is as shown in Table 51-5.

A summary of the cutoff and attenuation constant formulas for circular and rectangular waveguides is given in Table 51-6, where

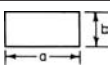

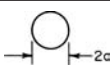

$$A = \frac{\sqrt{c/\lambda}}{\sqrt{1 - (\lambda/\lambda_c)^2}}$$

c = velocity of light in free space $\approx 3 \times 10^8$ m/s

Lastly, a transition between a rectangular waveguide to a circular waveguide is a very useful component in antenna feed systems and one such device is described in the reference section.²⁰

For copper and air, $\alpha_0 = 3.5 \times 10^{-8}$ Np/m. To convert nepers per meter to decibels per 100 ft, multiply by 264.

Standard Waveguide Sizes

The waveguide sizes, which have become standardized, are listed in Table 51-7, together with the flanges used in connecting them together.

Flexible Waveguides

Flexible rectangular waveguides are made to match most of the standard waveguides. These differ primarily in mechanical construction. Waveguides using seamless corrugations, spiral-wound strip with adjacent edges crimped and soft-soldered, and spiral-wound strip with heavier crimping to provide sliding contact, as well as vertebra type (consisting of cover-choke wafers held in place by a rubber jacket), are available. The first two will bend in either plane, stretch, or compress but will not twist. The other two twist as well as bend and stretch. When the guide is flexed during operation or pressurized, it is nearly always covered with a molded-rubber jacket. When unjacketed, all are subject to a minimum bending radius (of the guide centerline) of 2 to 3 times the outer guide dimension in the plane of the bend, and when jacketed, to about 4 to 6 times the outer dimensions. The mismatch between rigid and flexible guide is small when straight and designed for lower frequencies. Mismatch increases as the waveguide size decreases, since the depth of convolutions cannot be decreased as fast as the waveguide dimensions (mismatch also increases as the bending radius is decreased). Similarly, attenuation which is only slightly greater than that in rigid guide for low frequencies becomes about twice as great at 40 GHz. Power capacity is nearly equal to that of rigid guide.

Hollow-Tube Waveguides with Other Cross Sections

One of the most useful of the many cross sections that might be used is the ridged waveguide as shown in Figure 51-15, which is useful in wide-band transmission. For ridged waveguide²¹⁻²³ (and waveguide of arbitrary cross section), the best method for obtaining cutoff wavelength is by resonance in the cross section. First, a convenient longitudinal plane is chosen. At cutoff, the susceptance looking into the shorted parallel-plate guide to the right of this plane is equal in amplitude and opposite in phase to that looking to the left. If the guide is symmetrical, only half of the guide need be used since Y at the center is zero. For the ridged guide this gives

$$\cot \frac{2\pi l}{\lambda_c} - \frac{B}{Y_{01}} = \frac{b}{a} \tan \frac{2\pi S}{\lambda_c 2}$$

where B is the capacitive discontinuity at the height change.

*These flanges mate with themselves.

The loading in the center of the guide lowers the cutoff frequency of the dominant mode, so that a useful bandwidth of over 4:1 may be obtained with single-mode transmission. The impedance is reduced by the loading and can be adjusted by proportioning the ridges for impedance matching of the waveguides to coaxial lines, for example.

The ridged guide for a given frequency band is smaller than the regular guide, but the losses are higher.

Design exists, and there are government standards for both single- and double-ridge guide with bandwidth ratios of 2:4 and 3:6. The loss of the 3:6-bandwidth guide approaches that of some of the low-loss coaxial lines and has not had wide acceptance. The 2:4-bandwidth double ridge is being used above 3.5 GHz, and the characteristics of the more popular sizes are listed in Table 51-8.

FIGURE 51-16 Fin-line guide

Fin-Line Guide Shown in Figure 51-16, fin-line guide uses central loading as in ridge guide, but the central-loading fin is an etched pattern on a suitable plastic or ceramic and may be insulated from the rest of the structure. It has the same wide bandwidth and concentration of the electric field at the guide center as the ridge guide, providing excellent excitation of the etched circuit patterns and any lumped circuit elements mounted on the center fin. Although not widely used as a uniform transmission line, fin-line guide is very useful when it is necessary to build filters, mixers, and other circuit elements right into the antenna feed.²⁴⁻²⁵ There are several different types of fin-lines, and design data for these fin-lines can be found in the references.²⁶⁻²⁷

51.8 MISCELLANEOUS TYPES OF WAVEGUIDES

In this section, the propagation parameters of the trough waveguide, radial line and biconical guide, dielectric waveguide, multimode waveguide, beam waveguide, optical-fiber waveguide, and elliptical waveguide are presented.

Trough Waveguide²⁸

Trough waveguide having the cross section shown in Figure 51-17 is derived from the lowest TE mode on symmetrical stripline by inserting a longitudinal electric wall at the center of the strip. Energy is transmitted in the TE modes in which the electric fields are symmetrical about the center vane. The cross section is such that probes, tuning, or attenuating devices may easily be inserted and moved from the open side with a minimum of electrical disturbance. Trough waveguide is a broadband transmission device since the cutoff of the second propagating mode is three times that of the dominant mode instead of twice, as in rectangular waveguide. It is easily fed from an end-on transition from coaxial or symmetrical stripline. The outer conductor of the TEM line is connected to the outer walls of the trough guide.

Note: Attenuation is computed at $f = 3f_{c10}$. Actual attenuation may be considerably higher, depending on operating frequency and temperature. Actual power handling may be considerably less, depending on temperature, altitude, operating frequency, and so on. See further information on both attenuation and power-handling capacity and on other design characteristics.²³

FIGURE 51-17 Cutoff wavelength of trough waveguide

The inner conductor of the line is connected at a point on the center vane of the trough guide at a distance S up from the bottom of the center vane, as determined from the relation for the power-voltage characteristic impedance at that point;

$$Z_{pV}(S) = 754 \frac{D}{\lambda_c} \frac{\lambda_g}{\lambda} \sin^2 \left(\frac{2\pi S}{\lambda_c} \right)$$

Alternatively, a coaxial connector can feed it from the rear wall of the trough.²⁹ This approach effectively shortens the length of the antenna structure and shields the coaxial transition from the radiation. Similarly, a crystal may be attached at an appropriate point to provide a crystal mount. The cutoff wavelength of the dominant mode in trough waveguide may be determined from the graph in Figure 51-17.

Radial Line and Biconical Guide

Two circular parallel conducting plates, separated by a dielectric and fed at the center or outer edge, form a line in which the transmission is radial. This type of line is frequently used in choke junctions and resonant cavities, such as microwave oscillator tubes. The simplest wave transmitted by this type of line is a TEM wave. The phase front of this wave is a circle of ever increasing or decreasing radius. The radial current in one plate returns radially through the other plate. With radial lines it is very useful to know the input impedance with (1) known termination, (2) output shorted, and (3) output open. Input impedance is

$$Z_i = Z_{oi} \left[\frac{Z_L \cos(\theta_i - \psi_L) + jZ_{0L} \sin(\theta_i - \theta_L)}{Z_{0L} \cos(\psi_i - \theta_L) + jZ_L \sin(\psi_i - \psi_L)} \right]$$

FIGURE 51-18 Radial transmission-line quantities

where

Z_i = input impedance, Ω

Z_{0i} = characteristic impedance, Ω , at input (Z_0 of Figure 51-18 at $r = r_i$)

Z_{0L} = characteristic impedance at output (Z_0 of Figure 51-18 at $r = r_L$)

Z_L = terminating impedance, Ω

θ_i , θ_L , ψ_i , ψ_L = angles as plotted in Figure 51-18

In one special case of this, $Z_L = 0$; then

$$Z_i = jZ_{0i} \frac{\sin(\theta_i - \theta_L)}{\cos(\psi_i - \theta_L)}$$

In another $Z_L = \infty$; then

$$Z_i = jZ_{0i} \frac{\cos(\theta_i - \psi_L)}{\sin(\psi_i - \psi_L)}$$

Many higher-order modes are possible. Those with variations in ϕ will only propagate with any spacing of plates. Those having variations in z propagate only if the plate separation is greater than a half wavelength.^{1-2,30}

Two cones with their apices facing and fed by a balanced input at the center, as shown in Figure 51-19, form a biconical waveguide. This structure also simulates a dipole antenna and certain classes of cavity resonators.

One important wave transmitted by this type of guide has no radial components and propagates with the velocity of light along the cones. It is analogous to the TEM wave in cylindrical systems. The ratio of voltage to current or characteristic impedance is

$$Z_0 = 120 \log_e \cot \frac{\theta}{2} \quad \Omega$$

where θ is the conical angle. From this it is seen that the characteristic impedance is independent of radius and not variable as in the radial line.

FIGURE 51-19 Biconical waveguide

Many higher modes can propagate on this system. These will all propagate at a velocity different from that of light. Transmission of higher modes is also possible.¹⁻²

Dielectric Waveguide

Electromagnetic waves will propagate along a dielectric rod,³¹ if the rod is of sufficient size. At low frequencies, there is little advantage to dielectric wave-

guides since low loss in metal waveguide makes them a convenient shielded carrier of microwave energy. At frequencies above 20 GHz, the lower loss possible with dielectric waveguides makes their use attractive. For lossless dielectric waveguides, the propagation constant can never be real, so there is no cutoff frequency as with metal waveguides. For a given waveguide, VHF energy is confined entirely within the dielectric. The velocity of propagation and the loss correspond to that in the waveguide dielectric. As the frequency is reduced, more of the field is outside the waveguide, and the velocity and loss approach that of the surrounding air, but the dielectric ceases to guide the wave. The only TE and TM modes possible in a circular rod are those having axial symmetry. One hybrid mode, the HE_{11} (hybrid because it has both E_z and H_z components), is particularly well adapted for microwave transmission. It can be small (it is the only mode which can be propagated when the ratio of diameter to wavelength is low; less than 0.6 for polystyrene). It can be launched from the dominant TE metallic waveguide mode, and it has low loss. The approximate field configuration of this mode is shown in Figure 51-20.

Figures 51-21 to 51-23 show variation of guide wavelength with diameter, loss as a function of diameter, and a waveguide launcher for the HE_{11} hybrid mode. The polarization of the hybrid mode in circular rod is subject to rotation because of internal stresses, dimensional nonuniformity, and bends. A rectangular or oval cross section prevents this depolarization. Measurements of loss and radius of field extent (radius at which field decreases to $1/e$ times that at surface) for cross sections of the oval type are shown in Table 51-9 for 24 and 48 GHz.

FIGURE 51-20 Approximate E -field configuration of HE_{11} mode on a dielectric rod waveguide

**FIGURE 51-22** Waveguide launcher for HE_{11} mode**FIGURE 51-23** Attenuation of dielectric tube wave-length with a dielectric of 1.5 for the HE_{11} mode

Transmission with dielectric tubes as well as rods is possible. Tubes can have lower loss than rods, and theoretical calculations indicate³² that with a polystyrene tube attenuation at 30 GHz compares with TE_{01} guide.

Other calculations shown in Figure 51-23 indicate that losses of a few decibels per kilometer can be attained up to the infrared region by choice of the proper diameter.³³⁻³⁴

The image line³⁵⁻³⁷ is a variation of the dielectric guide which simplifies the support problem. The HE_{11} mode, being symmetrical, can be split longitudinally and one-half replaced by a metal plate, as shown in Figure 51-24. Losses at bends are lower for concave bends than for convex ones. Losses in the image plane are lower than those in the dielectric for all commonly used materials.

A variation of the image line has been suggested for use in integrated circuits. In this version,³⁸ a rectangular dielectric strip is laid on top of an integrated circuit board, which is copper-clad on the lower surface. An overview on dielectric waveguide microwave integrated circuits technology and system applications can be found in the reference section.³⁹ Tapering the dielectric strip and inserting it into a rectangular waveguide normally excite the dominant mode in a dielectric waveguide. However, a microstrip line can also excite dielectric waveguides and one such transition was developed at about 15 GHz.⁴⁰

A disadvantage of an open dielectric waveguide is its high radiation loss, which occurs at bends and other discontinuities. This spurious radiation not only increases the attenuation but also causes interference with other parts of the circuit. To overcome this problem, a non-radiative dielectric (NRD) waveguide has been proposed.⁴¹ In this structure, the dielectric waveguide is sandwiched between two metal plates separated by a distance smaller than half wavelength.

FIGURE 51-24 Image line using HE_{11} mode

Multimode Waveguide

Normally, waveguides are used in the lowest mode, and the higher modes are avoided. At millimeter-wave frequencies, losses in the lowest-mode-only waveguide become very high because of conductor losses. By using low-loss modes in the circular waveguide far above cutoff, most of the energy is carried in the fields in the air inside and losses are reduced. Operating far from cutoff also reduces the dispersion and increases the signal bandwidth. Special efforts must be taken to prevent excitation of unwanted modes. Multimode circular guide has demonstrated a signal bandwidth of 40 to 117 GHz and transmission losses of less than 1 dB/km.⁴²

Beam Waveguide

Another method of avoiding conductor loss is to use lenses to focus the energy into a converging beam or at least a nondiverging beam, refocusing periodically along the transmission path.⁴³

Optical-Fiber Waveguide

Optical fiber is usually a single strand of glass designed to hold an electromagnetic wave closely bound to the glass signal path. Since it is not a carrier of the fundamental signal frequency (a microwave signal would ordinarily be modulated on a light beam), it is not covered in detail here. It has many of the advantages of the multimode waveguide, the beam waveguide, and the

dielectric waveguide, principally low loss and large bandwidth. A small amount of dispersion limits the distance that a wideband signal can go before some frequencies overtake others and cause information degradation. However, operational use has demonstrated losses well under 1 dB/km and bandwidths of over 1 GHz divided by the distance in kilometers.⁴⁴ It will undoubtedly become a major transmission medium for wideband signals.

Semiconductor laser diodes and photo detectors with gigahertz bandwidth have been recently demonstrated. These devices allow the optical carrier to be directly modulated at gigahertz frequencies⁴⁵ and hence have given rise to a new field of optically controlled microwave devices.⁴⁶ This new field has enabled optically controlled beam scanning of active phased arrays and true time delays phase shifters for phased arrays.⁴⁷

Elliptical Waveguide

Waveguide with an elliptical cross section is very useful for antenna feeds. It has many of the same characteristics as rectangular waveguide, including a similar waveguide mode (so it mates easily with rectangular guide), and about the same loss and guide wavelength. It does have a narrower bandwidth, and it is formed with corrugations along its length, which gives it high transverse stability and crust strength yet allows bending in both planes and a small amount of twist. This makes installation easier than with rectangular guide. It is usually covered with tough black polyethylene to protect it during the hanging, installation, and use. Elliptical waveguide is made in long lengths or is assembled in desired sections with an adapting flange to rectangular guide. Although not yet standardized, it is made by several manufacturers. Most give it a prefix indicating elliptical waveguide such as EW or WE, followed by the lowest frequency or a midfrequency in tenths of a gigahertz. Characteristics of typical sizes are shown in Table 51-10.

51.9 LIST OF SYMBOLS

The symbols used in this chapter are listed here:

- f = frequency, Hz
- $\omega = 2\pi f$
- c = velocity of light $\approx 3 \times 10^8$ m/s
- λ = wavelength
- ϵ = relative dielectric constant
- ϵ_0 = permittivity of free space, 8.854×10^{-12} F/m
- μ = relative permeability
- μ_0 = permeability of free space, $4\pi \times 10^{-7}$ H/m
- σ = conductivity, S/m
- α = attenuation constant, Np/m (Np = 8.686 dB)
- E_a = breakdown of air, V/m
- P = power, W
- $\tan \delta$ = loss tangent or dissipation factor

The properties of some commonly used metals will be found in Chapter 55. The conductivity σ can be found from the resistivity values by the relationship

$$\sigma(\text{S/m}) = \frac{10^8}{\text{resistivity } (\mu\Omega \cdot \text{cm})}$$

Values for ϵ and $\tan \delta$ of some commonly used dielectrics will be found in Chapter 55.

52.7 BALUNS	52-26

52.1 GENERAL¹

Impedance matching is the control of impedance for the purpose of obtaining maximum power transfer or minimum reflection. This chapter describes circuits and techniques used for impedance matching, with emphasis on those most suitable for broadband operation. The impedance-matching methods of this chapter are limited to the use of linear, passive, and reciprocal elements.

Impedance Matching for Maximum Power Transfer

A load impedance connected to a source will receive the maximum possible power (the *available power* P_0) from the source when its value is adjusted to equal the complex conjugate of the impedance of the source (Figure 52-1a). The load impedance and source impedance are then matched on a conjugate-impedance basis (or simply *conjugate-matched*).

A mismatched load impedance $Z_L \neq Z_G^*$ will receive a reduced power $P = P_0 (1 - |m|^2)$, where m is the conjugate mismatch reflection coefficient

$$m = \frac{Z_L - Z_G^*}{Z_L + Z_G}$$

The mismatch may be eliminated by a properly designed network (Figure 52-1b) interposed between them. This “matching” network transforms the source impedance to the

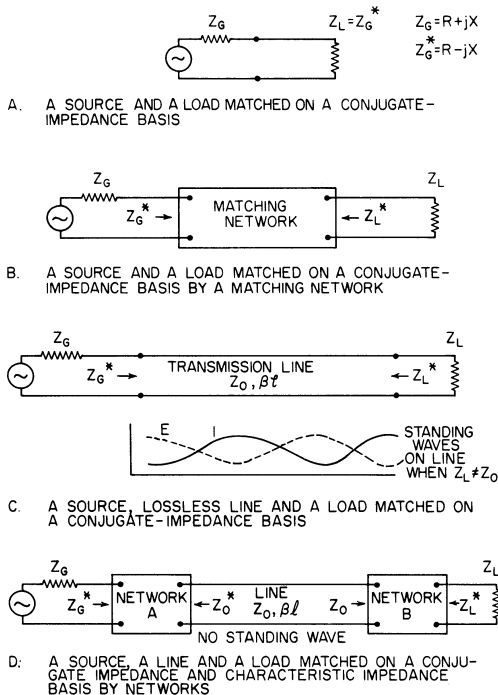

FIGURE 52-1 Impedance matching of transmission circuits

conjugate of the load impedance, and vice versa. Thus a conjugate-impedance match occurs at the input to the network and at the output of the network. Since maximum power transfer is the goal, it is usually the case that the matching network is lossless. It is true of any lossless transmission circuit that if a conjugate-impedance match is obtained at any point along the transmission path, then a conjugate-impedance match is obtained at all other points along the path.

Impedance Matching for Minimum Reflection

A length of transmission line may form one link in a transmission circuit. The line in general supports two waves (direct and reflected), propagating in opposite directions. In passing from one end of a length ℓ of line to the other, each wave is phase-delayed by an amount $\beta\ell$ (called the electrical length of the line) in its direction of propagation, where β is the phase constant or propagation constant of the line measured in units of rad/m. The interference between these waves creates standing-wave patterns of voltage and current and time-delayed “ghosts” of the direct signal. Sometimes these effects are tolerable, but usually they are undesirable. The voltage reflection coefficient at a load junction is the ratio of phasor voltage in the reflected wave to that in the direct or incident wave, and is given by

$$\rho = |\rho| \exp(j\phi) = \frac{Z_L - Z_0}{Z_L + Z_0}$$

Here Z_L is the load impedance and Z_0 is the characteristic impedance of the transmission line. The line is said to be matched on a reflection basis (or more simply, *reflection-matched*) if $\rho = 0$ (i.e., if $Z_L = Z_0$).

In the most general situation, reflection matching does not ensure maximum power transfer to the load.^{2,3} However, the lines commonly used in antenna systems have very low loss and characteristic impedances that are purely or nearly real. Characteristic impedances designated by Z_0 in this chapter will be assumed to be real unless otherwise noted. In this case, maximum power transfer will occur when the circuit is adjusted for a conjugate-impedance match (Figure 52-1c).

Losses in a transmission line will cause attenuation in the form of reduction in amplitude by a factor $e^{-\alpha\ell}$ for each voltage wave after traveling a length ℓ along a section of line (α is called the attenuation constant of the line, measured in units of Np/m). Reduction in power is thus $e^{-2\alpha\ell}$, which is often expressed in terms of the normal line attenuation $A = 8.686\alpha\ell$ (dB). If the line has nonzero attenuation, maximum power transfer from the source to the load is obtained only when the following conditions are met:

- The generator is loaded by the conjugate of its internal impedance.
- The line is terminated in its characteristic impedance.

The first condition provides maximum power delivery from the source. The second condition provides minimum power dissipation in the line by eliminating the reflected wave on the line. Figure 52-1d shows a “matched” system, that is, a system matched both on a conjugate-impedance basis and on a characteristic-impedance basis. This represents an ideal condition.

The importance of matching can be seen by an examination of the detrimental effects of a mismatch. The power in the load is reduced from the maximum available power by the factor $(1 - |\rho|^2)$. This reduction in transmission is called *reflection loss* [in dB, $-10 \log_{10}(1 - |\rho|^2)$]. Sometimes this effect is expressed in terms of the *return loss* $|\rho|$ (in dB, $-20 \log_{10} |\rho|$). The reflected wave combines with the incident wave on the line to form a

FIGURE 52-2 Reflection loss

standing wave having a standing-wave ratio (SWR) S defined as the ratio of maximum voltage to minimum voltage:^{*}

$$S = \frac{1 + |\rho|}{1 - |\rho|}$$

The presence of the standing wave decreases the breakdown-limited power deliverable to the load by the factor $(S + 1)^2 / (2S)^2$. Transmission loss in dB is shown as a function of the SWR in Figure 52-2.

The efficiency η of the line is the ratio of power delivered to the load to power input to the loaded section of the transmission line. It is given in terms of the SWR and normal line attenuation as

$$\eta = \frac{P_L}{P_{in}} = \frac{4S}{10^{0.1A}(S+1)^2 - 10^{-0.1A}(S-1)^2}$$

where A is the normal line attenuation in decibels.

The Smith Chart

The reflection coefficient is a complex quantity, related directly to impedance ratio and mismatch. Its magnitude does not exceed unity on a lossless line, so a plot of all possible reflection ratios for passive impedances may be charted within a circle of unit radius (see Figure 52-3a). Furthermore, the loci of a mismatch at different distances along the length of a line lie on a constant radius from the center of the chart, at angles proportional to the distances. Coordinate systems of immittance normalized to the characteristic or reference immittance are superimposed to give the useful Smith chart,⁴ shown in skeleton form in Figures 52-3b and c (the characteristic admittance $Y_0 = 1/Z_0$). Additional scales are frequently provided. Interpretation is aided by labels for open- and short-circuit points, and for inductive and capacitive sides.

^{*}The notation S for standing-wave ratio should not be confused with that of a scattering parameter.

FIGURE 52-3 Reflection coefficient charts in skeleton form, positive real axis to the right: (a) reflection coefficient in polar coordinates $|\rho|$ and ϕ , (b) the Smith chart, with impedance coordinates $r = R/Z_0$ and $x = X/Z_0$, and (c) admittance version of the Smith chart, with coordinates $g = G/Y_0$ and $b = B/Y_0$

Bandwidth Limitations

In principle, frequency-independent resistances can be matched over an arbitrarily wide frequency band. In general, narrowband networks designed to match greatly differing resistances can be replaced by cascades of similar networks, each of which transforms the impedance by a small fraction of the total resistance ratio. Although in practice losses and space considerations will limit how far this approach can be taken, simple networks like the L-sections or quarter-wave transformers, discussed in the following sections, can often be broadbanded in this way.

It is not possible to match a frequency-dependent impedance at all frequencies.⁵ The smaller the desired reflection coefficient, the smaller the bandwidth over which this condition can be realized. While specific matching network topologies are presented in this chapter, it is possible to obtain in a more systematic way networks that have optimum matching behavior over a given range of frequencies. Modern computer-aided design techniques can be employed to advantage in such cases, and the reader is referred to the literature for details.⁶⁻¹⁴

52.2 IMPEDANCE MATCHING WITH LUMPED ELEMENTS

Throughout the lower range of radio frequencies it is convenient to use lumped reactance elements, such as coils and capacitors, in impedance-matching networks. In higher frequency ranges, pure inductance or capacitance may not always be obtained from practical elements, but it is convenient to analyze circuits in terms of their equivalent lumped reactance (and resistance) elements.

Any two complex impedances may be matched by a simple L section of two reactance elements. If, in addition to matching, it is necessary to maintain given phase relationships between the source and load voltages and currents, a third element must be used to form a T or π section. A lattice section using four elements is more convenient for some applications.

The primary use of the simple sections is for matching at a single frequency, although it is possible to obtain matching at two or more separate frequencies by replacing each reactance element of the basic network with a more complex combination, giving the required reactance at each specified frequency. Harmonic reduction can be achieved in a similar manner by introducing high series reactances or low shunt reactances at the harmonic frequencies.

The frequency performance of a matching network is characterized by the fractional bandwidth

$$w = \frac{f_+ - f_-}{f_0}$$

where f_0 is the design frequency, while $f_- < f_0$ and $f_+ > f_0$ are the lowest and highest frequencies at which some specified performance criterion is satisfied.

L Section

The expressions for the required reactance values for an L section providing a match between pure resistances are shown in Figure 52-4a. (Here and in the remainder of this chapter, X and B will designate reactance and susceptance values respectively.) If X_s is positive, the network will delay the phase of the wave by an angle θ . If X_s is negative, it will advance the phase by that angle. The reflection coefficient of R_1 with respect to R_2 is reduced by a factor of at least 10 over a fractional bandwidth of at least 10% by introducing the proper L section of one capacitor and one inductor, provided that $R_2/R_1 < 2.0$.

If two complex terminations are to be matched, the series reactance X_s' is made to include a compensation for the series reactance of the left-hand termination and the shunt susceptance B_p' is made to include the susceptance of the right-hand termination, as shown in Figure 52-4b. For this case θ represents the phase between the current in the left-hand termination and the voltage on the right-hand termination.

FIGURE 52-4 Impedance matching with reactive L sections

T and π Sections

Design expressions are given in Figure 52-5 for T and π sections matching between resistive terminations with a desired phase shift of θ . If the terminations contain reactive or susceptive components, it is necessary to include appropriate compensating components in the end elements, as in the case of the L section.

L, T, and π sections may be used in unbalanced circuits as shown, or in balanced circuits by moving one-half of each series element to the opposite conductor of the line. The lattice section described next is inherently balanced.

Lattice Section

The elements of a lattice section as well as of T and π sections are given in Figure 52-6 in terms of an equivalent transmission line having the same characteristic impedance and phase shift. The required equivalent line parameters Z_0 and $\theta = \beta l$ may be determined as described in Section 52.3.

Inductive Coupling

A pair of inductively coupled coils is useful in a wide variety of impedance-matching circuits. Figure 52-7 shows two possible equivalent circuits of lossless coupled coils. The first is expressed in terms of reactance elements, including the mutual reactance X_m . The second is in terms of susceptance elements including the transfer susceptance B_T . (The transfer susceptance is the susceptance component of the transfer admittance, which is the ratio of the current induced in the short-circuited secondary to the voltage applied to the primary.) If capacitive tuning reactances are added, the equivalent circuits can be designed in accordance with the T and π matching sections described previously.

FIGURE 52-5 Impedance matching with reactive T and π sections

FIGURE 52-6 T, π , and lattice equivalents of a transmission-line section of characteristic impedance Z_0 and electrical length $\theta = \beta \ell$

The capacitive reactances required for (1) series tuning and (2) parallel tuning are given in Figure 52-8 for matching from R_1 to R_2 .

The series and parallel capacitors may also be used for tuning out the series reactance or shunt susceptance, respectively, of a complex termination.

Lumped Matching Reactance

The standing wave on a transmission line may be eliminated on the source side of the load using a matching reactance that is properly chosen and positioned, as shown in Figure 52-9.

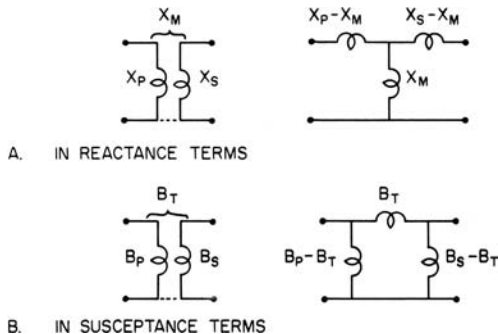

FIGURE 52-7 Inductively coupled circuits and equivalent T and π sections

FIGURE 52-8 Tuned inductively coupled circuits for matching between resistances

The choice of series or parallel connections, or inductive or capacitive elements, may be determined by the position of the standing-wave pattern and other practical considerations. A short-circuited or open-circuited transmission-line stub may be used in place of the lumped reactance as described in the next section, resulting in the so-called single-stub matching circuit.

FIGURE 52-9 Determination of lumped reactance to match a transmission line

52.3 IMPEDANCE MATCHING WITH DISTRIBUTED ELEMENTS

In many frequency ranges, it is desirable to use sections of transmission line having distributed reactances rather than lumped reactances in the form of coils and capacitors. The lines usually have negligible loss so that the following expressions for impedance relationships in lossless lines apply:

$$Z_{in} = Z_0 \frac{Z_L \cos \beta \ell + jZ_0 \sin \beta \ell}{Z_0 \cos \beta \ell + jZ_L \sin \beta \ell} \quad (52-1)$$

= input impedance of line ($Z_0, \beta \ell$) terminated in Z_L

For a short-circuited line, $Z_L = 0$, so that

$$Z_{in} = Z_{sc} = jZ_0 \tan \beta \ell \quad (52-2)$$

For an open-circuited line, $Z_L = \infty$, so that

$$Z_{in} = Z_{oc} = -jZ_0 \cot \beta \ell \quad (52-3)$$

It should be kept in mind that when an actual transmission line is connected to a load or to another transmission line, field fringing near the junction point results in excess or *parasitic* inductances and capacitances,¹⁵ whose effects must be compensated for when designing a matching network. Such parasitics will not be explicitly accounted for here, but are readily accounted for in RF circuit modeling software.

Transmission-Line Stubs

Lengths of transmission line short-circuited or open-circuited at one end are often used as reactances in impedance-matching circuits. Inspection of Eqs. 52-2 and 52-3 shows that the choice of characteristic impedance and line length gives the designer control over the reactance value and slope (with respect to frequency) at any given frequency. Alternatively, the designer may control the values of reactance at any two frequencies. If $\beta \ell < \pi/2$, the available slope of reactance is always greater than that obtainable from a single lumped reactance element. Unfortunately, the available slope of reactance is always positive, although a negative slope would be ideal in many applications. However, an effect similar to that of a series-connected or parallel-connected reactance having the unattainable negative slope may often be obtained over a limited frequency range by the use respectively of a parallel-connected or series-connected reactance.

The use of stubs in place of lumped reactances in the matching scheme of Figure 52-9 results in the so-called single-stub matching circuit. Two or three stubs connected at appropriate locations provide additional design flexibility that can be used to increase the bandwidth of the match.¹⁶

Kuroda Identities

In certain cases, the use of either series or shunt-connected stubs may be impractical. In such cases, the Kuroda identity^{17,18} may be employed to replace a shunt-connected open-circuit stub with a series-connected short-circuit stub, at a different location on the line, as shown in Figure 52-10.

FIGURE 52-10 Kuroda identity

The stubs have the same electrical length, but the characteristic impedances are in general different, as shown.

General Line Transformer

The expression for Z_{in} given in Eq. 52-1 may be recast to relate generator and load impedances ($Z_G = R_G + jX_G$, $Z_L = R_L + jX_L$) to the characteristic impedance and electrical length of a line section, providing a perfect match between them. The new expressions are

$$Z_0 = \sqrt{\frac{R_L |Z_G|^2 - R_G |Z_L|^2}{R_G - R_L}}$$

$$= \sqrt{|Z_G G_L| \frac{\frac{R_L}{R_G} \left| \frac{Z_G}{Z_L} \right| - \left| \frac{Z_L}{Z_G} \right|}{1 - \frac{R_L}{R_G}}}$$
(52-4)

$$\tan \beta \ell = \frac{Z_0 (R_L - R_G)}{R_L X_G - R_G X_L}$$

$$= \frac{Z_0 (X_G - X_L)}{R_L R_G + X_L X_G - Z_0^2}$$
(52-5)

For Z_0 to be a positive finite real number, it is necessary that

$$\frac{1}{2} < \frac{\log \left| \frac{Z_L}{Z_G} \right|}{\log \left(\frac{R_L}{R_G} \right)} < \infty$$

Instead of using the previous expression for $\tan \beta \ell$, one may determine $\beta \ell$ from a plot of Z_L/Z_0 and Z_G^*/Z_0 on a Smith chart once Z_0 has been determined. The two points will be at the same radius. The electrical angle measured clockwise from Z_L/Z_0 to Z_G^*/Z_0 is $\beta \ell$. (Note that $Z_G^* = R_G - jX_G$.) The values of Z_0 and $\beta \ell$ for the required line section may be used to compute T , π , or lattice sections of lumped reactances to perform the same function by using the expressions given in Figure 52-6.

FIGURE 52-11 Line transformer to match to a resistance

Line Transformer for Matching to Resistance

For the frequently encountered case in which either the load impedance or the source impedance is a pure resistance, it may be possible to obtain a solution for the required matching line from Figure 52-11. The complex impedance $R + jX$ is located on the Smith chart in terms of its normalized components R/Z_0 and X/Z_0 , where Z_0 is the resistance to which a match is desired. A second set of coordinates Z_T/Z_0 and ℓ/λ is then overlaid on the Smith chart, corresponding to the characteristic impedance and length of the required matching section of line. If the impedance $R + jX$ is located within the area covered by these new coordinates, a solution is possible. Note that any impedance may be converted to a pure resistance at a single frequency by connecting it to an appropriate length of transmission line. However, if the line length is significant, undesirable frequency dependence may be incurred when using this method.

Quarter-Wave Transformer

The useful quarter-wave transformer results from the general line transformer when $\beta\ell = \pi/2$. It has an impedance-inverting property, as seen from an inspection of

$$Z_{\text{in}} = \frac{Z_0^2}{Z_L}$$

The input impedance is thus proportional to the reciprocal of the load impedance. The phase angle of the input impedance is the negative of that of the load impedance. The quarter-wave line can be used, for example, to transform an inductive low impedance to a capacitive high impedance.

The quarter-wave transformer is often used to match between different resistance levels. In this case,

$$Z_0 = \sqrt{R_1 R_2}$$

In a mismatched coaxial line, a quarter-wave transformer formed by a simple external conducting sleeve can be used to tune out the reflection. The sleeve forms an enlargement of the inner conductor or a constriction of the outer conductor, which may be stationed where required. The characteristic impedance of the line is reduced over the quarter-wave length by the sleeve to a value of

$$\frac{Z_0}{\sqrt{S}}$$

where S is the initial SWR of the line. The load end of the sleeve is positioned at a voltage minimum on the standing-wave pattern. The impedance, here looking toward the load, is Z_0/S . The transformer transforms this to Z_0 so that the line on the source side is perfectly matched.

Z_0 Trimmer

The transformation ratio of a quarter-wave section can be adjusted by a reactive trimming immittance, as shown in Figure 52-12, in order to obtain a match when other adjustment of circuit parameters values is not convenient. The immittance required is given by

$$\frac{X}{Z_0} = \frac{R_1 + R_2}{\sqrt{R_1 R_2}} \left(\frac{R_1 R_2}{Z_0^2} - 1 \right) \quad \text{or} \quad \frac{B}{Y_0} = \frac{R_1 + R_2}{\sqrt{R_1 R_2}} \left(\frac{Z_0^2}{R_1 R_2} - 1 \right) \quad (52-6)$$

and the positioning parameter Δ is given by

$$\Delta = \frac{A\lambda}{4\pi} \quad \text{where} \quad A = \cos^{-1} \left(\frac{R_2 - R_1}{R_2 + R_1} \right) \quad (52-7)$$

The resulting network is nearly equivalent to a line for which $Z_0^2 = R_1 R_2$.

Frequency Sensitivity of Line Transformer

The mismatching effect of a departure from the design frequency for the general line transformer (and hence the quarter-wave transformer) can be estimated from Figure 52-13.

FIGURE 52-12 Shunt and series reactive transformation trimmers for a quarter-wave transformer

FIGURE 52-13 Frequency sensitivity of a transmission-line transformer

Cascaded Quarter-Wave Transformers^{16,19-21}

A number of quarter-wave transmission-line sections may be arrayed in cascade, in order to realize great improvement in wideband performance over a single-section transformer, as shown in Figure 52-14. The characteristic impedances of the successive sections are proportioned to divide the overall transformation systematically.

In the discussion that follows, $R_1 < R_2$ are the terminating resistances, $R_0 = \sqrt{R_1 R_2}$ is the mean impedance, $f_0 = (f_+ + f_-)/2$ is the design frequency, f_+ is the upper frequency limit, f_- is the lower frequency limit, the frequency ratio is $f_+ / f_- = (2 + w) / (2 - w)$, and w is the bandwidth. Each section is a quarter wavelength long at f_0 .

$$\text{Ratios} = \frac{\log(Z_n/R_1)}{\log(R_2/R_1)} = 1 - \frac{\log(R_2/Z_n)}{\log(R_2/R_1)}$$

Binomial Transformer

The binomial (or binomial-coefficient) distribution gives almost maximally-flat performance. In this distribution the logarithms of the impedance ratios of the steps between sections are made to be in the ratio of the binomial coefficients. Table 52-1 may be used to determine the characteristic impedance Z_n of the n th section in an N -section binomial transformer as a function of R_2/R_1 for values of N up to 7.

The input SWR of an N -section binomial transformer is given by

$$S = 1 + (\cos \theta)^N \ln \frac{R_2}{R_1}$$

where θ is the electrical length of each section at the operating frequency. This expression is subject to the assumptions of small impedance steps, no parasitics at the steps, and equal lengths of the sections.

The two-section transformer has a maximally-flat bandwidth curve for all transformation ratios. For other values of N the performance approximates the maximally flat curve for transformation ratios near unity.

Chebyshev Transformer

If a certain maximum reflection coefficient ρ_m may be tolerated within the operating band, an optimum design in which the reflection coefficient oscillates between 0 and ρ_m within the band and increases sharply outside the band is possible. This is called the Chebyshev transformer, since Chebyshev polynomials are used in its design.

The input SWR of the Chebyshev transformer is given by

$$S = 1 + \ln \left(\frac{R_2}{R_1} \right) \frac{T_N \left(\frac{\cos \theta}{\cos \theta_-} \right)}{T_N \left(\frac{1}{\cos \theta_-} \right)}$$

where $T_m(x)$ is the Chebyshev polynomial of m th degree defined by

$$T_0(x) = 1$$

$$T_1(x) = x$$

$$T_2(x) = 2x^2 - 1$$

$$T_{m+1}(x) = 2xT_m(x) - T_{m-1}(x)$$

and where θ is the electrical length of each section and θ_- is the electrical length at f_- . The expression is subject to the same assumptions that were made in the binomial case.

Another expression of Chebyshev transformer performance, which does not require the assumption of small steps, is

$$P_L = 1 + \frac{\left(\frac{R_2}{R_1} - 1\right)^2}{\frac{4R_2}{R_1}} \frac{T_N^2\left(\frac{\cos \theta}{\cos \theta_-}\right)}{T_N^2\left(\frac{1}{\cos \theta_-}\right)}$$

where P_L is the power-loss ratio defined by $1/(1 - |\rho|^2)$.

The previous equation may be converted to an implicit relationship among four principal quantities, namely:

R_2/R_1 the transformation ratio,

ρ_m , the maximum tolerable reflection coefficient within the band,

N , the number of sections, and

$F = w/2$, the half-bandwidth or frequency coefficient.

Any one of these may be determined by reference to Figure 52-15, if the other three are known. The design constant C of Figure 52-15 can be used as a measure of the difficulty of transformation. It may be expressed as a function of R_2/R_1 and ρ_m or as a function of N and F :

$$C(R_2/R_1, \rho_m) = (R_2/R_1 - 1) \sqrt{(1/\rho_m^2 - 1) R_1/4R_2}$$

$$C(N, F) = T_N(1/\cos(\pi/2(1 - F))) \geq C(R_2/R_1, \rho_m)$$

The characteristic impedances may be calculated from functions given in Table 52-2. The impedance of the center section when N is odd is simply $\sqrt{R_1 R_2}$ and is independent of F .

Dual-Band Transformers²²

Multisection transformers can be synthesized for dual or multiple passbands by the systematic distribution of the available reflection-coefficient zeros over the passbands. The sequence of impedance levels used in each section becomes nonmonotonic for a large frequency ratio between the two passbands. A nonmonotonic design for one operating band can be made with an arbitrarily short length by placing a second dummy passband at an arbitrarily high frequency.

FIGURE 52-15 Performance of a Chebyshev transformer

Short-Step Transformer

A two-section transformer, as shown for $N = 2$ in Figure 52-14, but with a much shorter overall length at midband, is useful for narrow bandwidth or for transformation ratios near unity. $Z_1 Z_2$ is set equal to $R_1 R_2$. The electrical length of each section at the exact-match or design frequency f_0 is set to

$$\beta \ell = \tan^{-1} \sqrt{\frac{R_2/R_1 - 1}{(Z_1/R_1)^2 - Z_2 - Z_1}} \quad (52-8)$$

TABLE 52-2 Design Ratios for a Chebyshev Transformer

N	$\frac{\log (R_2/R_1)}{\log (Z_1/R_1)}$	$\frac{\log (Z_2/R_1)}{\log (Z_1/R_1)}$	$\frac{\log (Z_3/R_1)}{\log (Z_2/R_1)}$
2	$4 - 2C_1^2$		
3	$8 - 6C_1^2$		
4	$16 - 16C_1^2 + 2C_1^4$	$5 - 4C_1^2$	
5	$32 - 40C_1^2 + 10C_1^4$	$6 - 5C_1^2$	
6	$64 - 96C_1^2 + 36C_1^4 - 2C_1^6$	$7 - 6C_1^2$	$32 - 30C_1^2 + 9C_1^4$

NOTE: $C_1 = \cos \theta = \cos [(1 - F) \pi/2]$

The length can be made as short as desired by selecting Z_1/Z_2 sufficiently high within limits imposed by increasing effects of parasitics. Within the ranges $R_2/R_1 < 2$ and $Z_1/Z_2 < 2$, the total bandwidth $2\Delta f$ is equal to $k f_0 \rho_m / \rho_0$, where ρ_m / ρ_0 is the ratio of maximum inband reflection coefficient to the reflection coefficient without the transformer, and k is a coefficient greater than unity. The coefficient becomes much greater than unity for $\beta \ell = \pi/8$ or more. The special case with $Z_1 = R_2$ and $Z_2 = R_1$ is a handy design for matching two dissimilar transmission lines simply by the use of sections of those lines.^{23,24} For this special case, $\beta \ell \leq \pi/6$ and $k \geq 1.1$.

Much advanced theory has been developed for lumped-constant circuits. Useful adaptation to distributed-constant circuits is often possible by transformation of the frequency variable.²⁵

52.4 COMBINATIONS OF TRANSFORMERS AND STUBS

The simple quarter-wave transformer has rather poor performance over a wide band, especially if a large impedance ratio must be matched. It is possible to enhance its performance by combining it with suitably connected stubs as detailed in this section.

Transformer with Two Compensating Stubs

The wideband performance of a quarter-wave transformer may be improved greatly by the addition of a compensating stub at each end, as shown in Figure 52-16. The reactance introduced by each stub counteracts the variation with a frequency of one-half of the transformer length at and near the design frequency. For the impedance proportions shown, the performance is maximally flat and comparable with that of a three-section binomial transformer.

Equiripple performance within the band, for a maximum reflection coefficient of ρ_m , is obtained with modified stub impedances. Table 52-3 lists some examples of equiripple performance, showing an improvement in bandwidth by a factor of about 1.2 over the maximally flat case for $\rho_m = 0.1 \rho_0$.

Transformer with Single Compensating Stub

If it is convenient to use only one compensating stub with the transformer, one of the circuits shown in Figure 52-17 may be used. In this equiripple design, the allowable maximum standing-wave ratio S_m affects the choice of Z_1 and Z_2 .

TABLE 52-3 Transformer with Two Compensating Stubs, Equiripple Case, $\rho_m = 0.1 \rho_0$

FIGURE 52-16 Transformer with two compensating stubs; maximally flat case

FIGURE 52-17 Transformer with single compensating stub

FIGURE 52-18 Tapped-stub transformer

Tapped-Stub Transformer

The tapped-stub transformer, shown in Figure 52-18, is a useful circuit for matching between two widely different resistive terminations. The design chart shows the relationship existing between R_2/R_1 , Z_0^2/R_1R_2 , and the two line lengths ℓ_1 and ℓ_2 for the matched condition. The total stub length is a minimum of one-quarter wavelength and increases with increasing Z_0 . The chart is based on a lossless transmission line. For very high transformation ratios, the effect of even small loss is appreciable and must be accounted for separately. For moderate transformation ratios, a 5 or 10 percent bandwidth over which the maximum reflection coefficient is no more than 0.1 ($R_2 - R_1)/(R_2 + R_1)$) usually can be obtained.

52.5 TAPERED LINES

If the characteristic impedance of a long section of transmission line varies gradually enough with distance along the line, a nearly perfect match between resistive terminations may be obtained. Since a line of such length and such small taper can seldom be afforded, much attention has been directed toward the design of tapered lines giving acceptable transforming performance over short lengths and broad bandwidths.^{16,26-41}

A nonuniform line does not, in general, support the independent propagation of direct and reflected waves as on the uniform line. However, the law of impedance transformation by such a line can be obtained approximately if the taper is gradual enough. For example, if the characteristic impedance $Z_0(x)$ and propagation constant $\beta(x)$ are slowly-varying functions of the position coordinate x along the line ($0 < x < l$), which

is connected between a resistive load $R_L = R_2 = Z_0(\ell)$ and a uniform line in $x < 0$ with characteristic impedance $R_1 = Z_0(0)$, then the reflection coefficient at $x = 0$ is given approximately by:

$$\rho(0^-) = \int_0^\ell e^{-2j\varphi(x)} \frac{Z_0'(x)}{2Z_0(x)} dx \quad (52-9)$$

where $\varphi(x) = \int_0^x \beta(x') dx'$ is the so-called *phase-integral function*. Exact evaluation of the impedance transformation of a tapered line is possible only in a few special cases.

Exponential Line

The exponential line is commonly employed to transform between two resistance levels equal to the values of characteristic impedance at the ends. Sections of exponential line are useful both as simple impedance transformers and as cascaded elements in a more complexly tapered line. The name comes from the function describing the magnitude of the characteristic impedance:

$$Z_0(x) = Z_0(0) \exp(\delta x)$$

where δ is the taper constant and x is the length coordinate that is positive in the direction of increasing impedance. We will assume that the propagation constant β does not vary with x , but this will not be true, for example, in structures such as microstrip. Although exact solutions for the impedance transformation properties of this line (and a few others) are known,³³ it is sufficient for most practical purposes to use the approximation of Eq. 52-9:

$$\rho = 0.5 \ln(R_2/R_1) \frac{\sin(\beta\ell)}{\beta\ell} e^{-j\beta\ell}$$

where $\ln(R_2/R_1) = \delta\ell$. Reflection zeros exist for section lengths of $n\pi$ radians, where n is an integer, and successive maxima of $|\rho|$ between these zeroes decrease in magnitude as $\beta\ell$ increases. The accuracy is acceptable if $\beta\ell > \pi/2$, with the error in phase generally greater than the error in magnitude.

Other Tapered Lines

Several tapered lines^{33,38} are attractive for special simplicity in analysis. Optimum high-pass tapers have also been described.^{16,27} The taper of Klopfenstein^{27,37} is optimum in the sense that for a given taper length the input reflection coefficient, as approximated by Eq. 52-9, has the minimum peak magnitude, or that for a specified peak magnitude the taper has the minimum length. The design is based on the multisection Chebyshev transformer, in which the number of sections is increased without limit so as to raise the upper cutoff frequency indefinitely high. The maxima of $|\rho|$ after the first zero have the same magnitude (equal ripple), and the resulting reflection coefficient in the passband is

$$\rho = \frac{0.5 \ln(R_2/R_1) \cos[(\beta\ell)^2 - A^2] e^{-j\beta\ell}}{\cosh A}$$

where $\beta\ell$ is the electrical length and A is a parameter related to the maximum in-band reflection coefficient by

$$\rho_m = 0.5 \ln (R_2/R_1) / \cosh A$$

At the low-frequency cutoff $\beta\ell = A$, the length of the tapered section is $A/2\pi$ wavelengths. The characteristic impedance taper over the section length ℓ as a function of x , measured from the midpoint of ℓ toward the high-impedance (or R_2) end, is

$$Z_0(x, A) = (R_1/R_2)^{1/2} (R_2/R_1)^{1/M(x)}$$

where

$$M(x) = -M(-x) = A^2 \phi(2x/\ell, A) / \cosh A$$

$$\phi(2x/\ell, A) = -\phi(-2x/\ell, A) = \int_0^{2x/\ell} \frac{I_1(A\sqrt{1-y^2})}{A\sqrt{1-y^2}} dy; \quad (2x/\ell \leq 1.0)$$

and I_1 is the modified Bessel function of the first kind and first order. Values of the function ϕ can be computed for different values of $z = 2x/\ell$ and A using the simple routine of Grossberg:³⁶

$$\phi(z, A) = \sum_{k=0}^{\infty} a_k b_k$$

where

$$a_0 = 1; \quad a_k = \frac{A^2}{k(k+1)} a_{k-1}; \quad b_0 = \frac{z}{2}; \quad b_k = \frac{\frac{z}{2}(1-z^2)^k + 2kb_{k-1}}{2k+1}$$

and the coefficients a_k and b_k are computed iteratively, the series being truncated when the desired numerical convergence is reached.

Other criteria for choosing an optimal taper are possible as well.^{29-32,34-41} For example, it is possible to minimize reflection only over a certain band of frequencies, at the expense of higher mismatch outside this band.

52.6 BROADBANDING⁴²

The most general problem in broadbanding is that of synthesizing a circuit to match one arbitrary impedance to another arbitrary impedance over a prescribed frequency range to within a prescribed tolerance. It has already been remarked that in general this is a very difficult design problem. Fortunately, the broadbanding problems found in practice involve impedances that are not completely arbitrary, inasmuch as they are composed of a combination of physically realizable inductances, capacitances, resistances, and transmission line sections. A further simplification of the broadbanding problem often occurs because at least one of the impedances to be matched is usually the characteristic impedance of a transmission line and thus is either constant and resistive or nearly so.

Nevertheless, the impedances to be matched are functions of frequency that usually are too complex for simple analysis. An iterative approach is often taken. The subject impedance,

prescribed by theoretical or experimental data, is examined to perceive a suitable step toward optimum broadbanding. Graphical representations of the function are usually helpful for this. The matching network or a portion of it is added to the circuit. The resulting impedance is found by calculation or experiment. The steps are repeated until the required broadband match is obtained. Modern computational tools and measuring instruments minimize the tedious detail and impart the needed accuracy and so make the iterative approach rapid and efficient.

The problem of matching two resistive impedances has been treated in Sections 52.2 to 52.5. The problem of matching a load of frequency-varying impedance to a constant resistance is so common that the following discussion will be limited to this case.

Several broad rules that apply to broadbanding practice are given, as follows:

1. The difficulty of obtaining a prescribed tolerance of match increases with the required bandwidth. Refer to performance charts of a Chebyshev transformer for an example of this (and of the following rule).
2. The difficulty increases with impedance transformation ratio (expressed as a quantity greater than 1).
3. The difficulty increases with the electrical length of the transmission circuit between the load and the first point of control.
4. Improvement of match throughout one sector of the frequency range will generally be accompanied by an increase in mismatch in other sectors of the frequency range.
5. Any physically realizable passive impedance plotted on the reflection-coefficient plane, using the conventions of Figure 52-3, displays a circular or spiral motion having a clockwise sense of rotation with frequency.

The effect of a length of mismatched transmission line between the load terminals and the first impedance-matching control is to introduce an additional variation with frequency that is seldom favorable over an appreciable bandwidth (see rule 3). For this reason it is advantageous to conduct impedance-matching control at a position close to the load terminals. In fact, if control of the load impedance is available from within the load itself, advantage should be taken of this circumstance to select the most suitable shape and position of the impedance locus on the reflection-coefficient plane.

Two things are required in order to perform a transformation of the given impedance locus on the chart to one that is compactly situated about the *desired* impedance point. First, a method of moving the impedance locus, and second, a method of compensating for both the variation with frequency inherent in the original impedance locus and that introduced by the moving process must be found. Means for moving the impedance locus may include lumped or distributed constant elements forming shunt or series reactances, cascade transformers, or a combination of these. The selection is made so as to introduce as little adverse variation of impedance with frequency as possible.

Compensation of variation of impedance with frequency is usually limited to a band including less than one complete convolution of the original impedance locus if a high degree of compensation is required. Typically, a sector of the original impedance locus, which may be made to appear similar to those shown in Figure 52-19, is selected. Then a matching circuit having a variation of reactance of opposite sense (and of the proper magnitude) is added to yield the tightly knotted transformed locus as shown. Essentially all the reactance variation may be eliminated; however, a small reactance variation and a larger resistance variation remain. In certain instances it may be advantageous to utilize two stages of compensation, as illustrated in Figure 52-20, in order to accomplish a doubly knotted transformed locus.

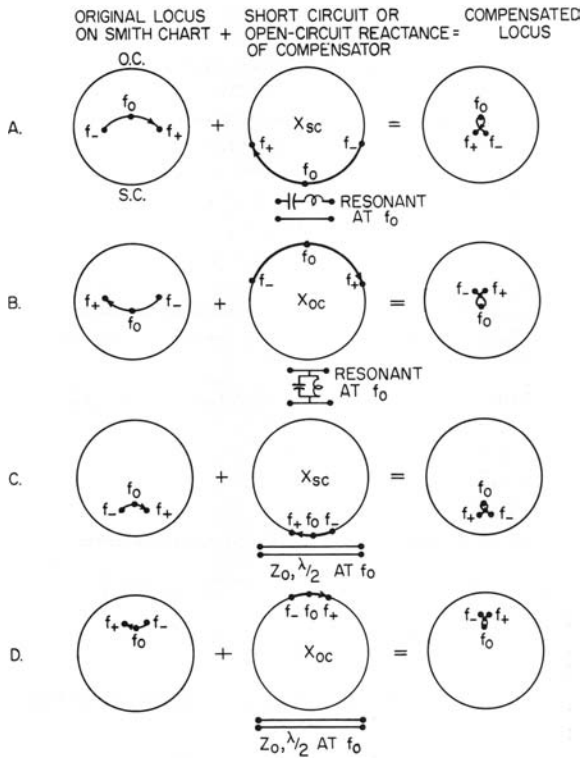

FIGURE 52-19 Broadband compensation methods

FIGURE 52-20 A two-stage compensation method

FIGURE 52-21 Possible physical embodiments of Figure 52-19

There are many ways of forming these matching circuits into physical structures. A few simple examples are shown in Figure 52-21. A more complex structure, utilizing a transformer with two compensating stubs in a circuit described earlier in this chapter, is shown in Figure 52-22.

Resonant lengths of the transmission line may be used in place of the lumped-constant resonant circuits. The LC product or the length of the line is selected for resonance at f_0 , the midfrequency of the sector. The L/C ratio or the characteristic impedance of the line section is selected to give the proper amount of compensating reactance at f_+ and f_- , the edge-band frequencies.

FIGURE 52-22 Structure to match barretter to 50-Ω impedance

52.7 BALUNS

Antennas, if not driven properly, may interact in undesirable and unpredictable ways with their environment. Frequently, this interaction can be minimized by enforcing balanced operation: the currents in the two arms of a symmetric dipole should be equal, for example. A *balun* is a three-port network designed to couple an unbalanced transmission circuit at one port to a balanced transmission circuit at the other two ports. A balun may be a current balun, which forces the currents at the balanced ports to be equal and opposite, or a voltage balun, which does the same thing for the voltages at the balanced ports. Though many types of balun also possess impedance transformation properties, this is not the distinguishing feature of balun operation. Any desired impedance transformation can usually be accomplished using established methods.^{43,44} Conversion between a balanced mode and an unbalanced mode requires special techniques. Many balun designs have been developed, some of the basic types of which are shown in Figure 52-23. Further information on balun design can be found in the references.⁴⁵⁻⁴⁸

A balanced circuit is obtained in type 1 by introducing a high impedance of a resonant coaxial-choke structure between the outer conductor of the unbalanced coaxial circuit and ground. There is no counterpart of the choke impedance in the other side of the balanced circuit. Hence the balun does not present a well-balanced impedance at any frequency for which the choke impedance is not high. This shortcoming of type 1 is overcome in types 2 and 3. Symmetry of the balanced circuit is maintained independently of frequency by a two-conductor choke (type 3) or by two identical, opposed, coaxial-choke cavities (type 2). The first three types have been widely used because of their simplicity and mechanical adaptability. The impedance bandwidth is limited by the shunting effect of the choke. Thus it is advantageous to keep the characteristic impedance of the choke lines as high as possible for a wideband operation.

Type 4 represents an improvement for many applications, particularly those involving impedance-level transformation. Unlike types 2 and 3, type 4 has the balanced circuit in the innermost line. Coupling is attained through a gap between line sections, as before. The necessary choke cavity, however, is around this gap in the unbalanced side of the structure. An unbalanced or single-ended cavity can be used without disturbing the perfect balance. The connections at the gap may be either of the series type, as in types 4a and 4c, or of a parallel type, as in types 4b and 4d. The parallel connection results in a balanced-to-unbalanced impedance ratio of 4.

An additional impedance control is available in any of the type 4 baluns at some expense of bandwidth by application of the principle of the tapped-stub transformer. This is illustrated by the alternative position of the unbalanced line in the drawing of type 4a. The desired impedance transformation ratio determines the length of coaxial-choke line on each side of the unbalanced-line tap position in accordance with Figure 52-18. Broadband compensation techniques⁴³ may be applied to types 2, 3, and 4.

The type 5 balun employs a half-wave delay line. It is connected between the two balanced-line terminals as shown, forcing the potentials to ground to be equal and opposite at the design frequency. A balanced-to-unbalanced impedance ratio of 4 is obtained. Bandwidth can be increased by adding multiple sections.⁴⁹

Type 6 employs helically wound transmission lines. At the unbalanced end, they are connected in parallel. Enough line length is used to develop high impedances to ground at the opposite ends. There the lines are connected in series to form the balanced terminals. A balanced-to-unbalanced impedance ratio of 4 is obtained.

Type 7a is a conventional $6\lambda/4$ hybrid ring which operates similarly to type 5. The path length from A to C is one-half wave longer than the path from A to B. Each path is an odd number of quarter waves long so that impedance transformation may be incorporated by

FIGURE 52-23 Types of baluns

proper selection of wave impedances. Furthermore, a load resistor at D is connected to terminals B and C by quarter-wave lines. This arrangement tends to dissipate the energy of an unbalanced wave without affecting the balanced wave. Type 7b is a $4\lambda/4$ hybrid ring that operates similarly, except that the impedance-matching function is performed by the separate quarter-wave line AC .

Type 8 is a familiar lattice circuit, wherein the incoming unbalanced wave energy is divided equally between two channels, one providing a 90° lead, the other a 90° lag. The output voltage is balanced with respect to ground and is in quadrature with the input voltage. The lattice may be proportioned to match any two resistance values. The lumped-element reactances may be replaced with transmission-line stubs, which is particularly suitable for printed-circuit applications.⁵⁰⁻⁵¹ The lattice balun may be generalized to a higher-order circuit to improve its bandwidth.⁵²

Type 9 is similar in principle to type 6. It is most suitable for operation at the longer wavelengths where the size of a type 4 tends to become excessive. It may be connected for an impedance ratio of 1 or of 4.

Type 10a is a convenient balun type for feeding balanced dipoles. The slotted portion of transmission line supports two modes of transmission simultaneously. Energy in a coaxial mode from the unbalanced input is substantially unchanged by the presence of the slots. The field of this mode is almost completely confined within the outer conductor. There is also a balanced mode in which the halves of the slotted cylinder are at opposite potentials and the center conductor is at zero potential. The field is not confined to the space within the slotted cylinder. (If leakage and radiation are to be minimized, another cylinder may be added overall for shielding.) The connection strap between the inner conductor and one-half of the slotted cylinder requires that the coaxial-mode voltage be equal and opposite to that half of the balanced-mode voltage. Thus a balanced-to-unbalanced impedance ratio of 4 is obtained.

Type 10a will give almost perfect balance over a wide frequency range if the slot width is kept small and symmetry is maintained at the strap end. A variation of this basic type of balun is the three-wire balun shown in type 10b. It is sufficiently well balanced for use in noncritical applications.

Type 11 illustrates another method by which an impedance transformation may be obtained by a connection independently of frequency. Two coaxial lines are connected in parallel at the unbalanced terminal and in series at the balanced terminal. A third cylinder is added to preserve symmetry. The impedance transformation ratio for this structure having two lines is 2^2 , or 4. More coaxial lines could be added to give impedance transformation ratios of 9, 16, etc., but practical limits are soon reached in this direction. Bifilar coils can also be used in a balun operating on this principle.

Baluns of types 1-4, 10a,b, and 11 are based on various multiconductor transmission lines. Many variants on this idea have been studied in detail.⁵³⁻⁵⁵ Some types of balun, for example 1 through 4, 6, 9, and 11, can be improved for very wideband operation by the inclusion of such high-permeability materials as ferrite or powdered iron. The material in the form of toroidal cores, cylindrical cores, pot cores, or beads, placed in the magnetic field of a low-frequency-limiting shunt element, increases the length of that element, raises its impedance, and improves the low-frequency match. The influence of the material is much less at the high-frequency end, which can be 1 GHz or higher, because of a reduced effective permeability. Compact baluns and transmission-line transformers of the bifilar-coil and coiled-cable types, having ferrite cores, typically operate over bandwidths of two to three decades.⁵⁶⁻⁵⁷ Core loss is low because the core does not interact strongly with the transmission-line mode.

The wideband balun of type 12 is a half wave or more of tapered transmission line that converts gradually, in cross-sectional characteristics, from an unbalanced line (coaxial line or stripline) at a first impedance at one end to a balanced two-conductor line at a second impedance at the other end, using a Chebyshev taper.⁵⁸⁻⁵⁹

53.1 GENERAL DISCUSSION

This section introduces the need for radomes and their purpose in antenna systems. Design considerations for electrical, mechanical, and environmental performance are then discussed.

Purpose of Radomes

A *radome* is a protective enclosure for an antenna.¹ The word radome was coined as a contraction of “radar dome,” however many radomes do not cover radar antennas and are not shaped like domes. The primary function of a radome is to protect an antenna system from the environments encountered in ground-based, shipboard, airborne, and aerospace applications. It is also important that a radome be designed to have minimum impact on the electrical performance of enclosed antennas.

Radomes are generally composed of low-loss dielectrics shells, with thickness comparable to the wavelength of operation. They are shaped to cover the antenna and provide the internal volume necessary for mechanical antenna scanning. If needed for the application, they provide aerodynamic streamlining. Radomes are used with virtually all aperture-type airborne antennas and with many ground-based and shipboard aperture antennas, which must be protected from severe weather conditions. See Figure 53-1.

The importance of protecting antennas in their operational environment was recognized from the early days of radar. Many significant interactions with scanning antennas were then identified.² Stationary and conformal antennas on vehicles also frequently require protection by flat or slightly curved windows. Applications include communication and radar altimeter antennas for reentry spacecraft, where extreme temperatures are encountered and ceramic materials must be used.³ A *radant* is a radome that includes an antenna as an integral part. Today, the term *electromagnetic window* is used for all types of radomes, windows, and radants, as well as for the transparent protective covers for optical and infrared sensors.

Electrical Considerations

The electrical performance of an enclosed antenna is always altered by a radome. This is due to distortion of the fields near the antenna caused by interactions at the material interfaces, and amplitude, phase, and polarization changes in the radome material. Radome-induced pattern distortion (Figure 53-2) includes changes in gain, sidelobe levels, beamwidth, null depth, and polarization characteristics. Streamlined radomes cause pointing or *boresight error* in angle-tracking systems. For proportional navigation systems, the rate of change of boresight error with antenna scan (*boresight-error slope* or rate) will affect guidance accuracy. Reflected power from the radome may cause magnetron pulling.² For high-power applications, excessive losses in the radome material can raise the temperature to a point where both structural properties and electrical performance are degraded.⁴ Radome losses also raise the system noise temperature.⁵

First-order radome effects are often explained in terms of transverse electromagnetic (TEM) wave transmission and reflection from planar dielectric panels. Waves transmitted by large aperture antennas can be approximated as a plane wave near the antenna and a curved radome wall can be considered as locally planar at each point of incidence. Reflected and transmitted waves are then approximated from planar slab theory and the

FIGURE 53-1 Radomes for airborne and surface based applications (*Courtesy Raytheon Company*)

FIGURE 53-2 Radiation patterns showing radome effects on element and sum beams

resultant effects on overall antenna performance calculated. By reciprocity, the effect of the radome on a receiving antenna is the same as for transmitting.

Mechanical Considerations

Radome design is based on the materials and construction needed to provide adequate safety margins and acceptable weight. The materials must provide necessary strength over the service temperature and not have fatigue problems from vibration or impacts.

Mechanical stresses are produced in radomes by aerodynamic loading due to air-flow, acceleration forces, and sudden thermal expansion due to aerodynamic heating (thermal shock).⁶ In high-speed radomes, thermal shock often causes the highest mechanical stresses. These stresses are greatest in the nose region, which often contains a metal tip that must be integrated with the mechanical design.

The radome attachment to the airframe is also a critical design problem in high-temperature applications, because high aerodynamic loads produce large bending moments, which often occur near the end of missile flight and after exposure to significant heating. Bonding, fasteners, and clamps have been used for attachments.

Environmental Considerations

The radome environment is a primary factor in determining material type, wall design, and shape. All radome designs must consider operating temperature, structural loads, vibration, wind, sand, hail, and rain.

For ground-based radomes, wind loading is the most important factor in the selection of a radome design. Other factors to be considered are humidity, blowing dust or sand, rain, ice, snow, and moisture buildup on the outer wall.⁷ The radome configuration and

mounting scheme will evolve from these environmental considerations and the electrical requirements. Typical surface-based structures include the metal space-frame,⁸ sandwich, monolithic-wall, and air-supported (inflatable) radomes.

Missile and aircraft radome designs are driven primarily by aerodynamic loads and the thermal environment. The selected configuration must be a trade between materials and shapes based on vehicle speed, trajectory, and electrical performance over the elevated temperatures produced by aerodynamic heating. Dielectric constant and loss tangent of radome materials can vary significantly with temperature. Non-uniform heating of the radome wall also produces changes in boresight-error performance.

Rain erosion is a severe problem in missile-radome operation and can be a limitation for aircraft radomes. The radome shape, material type, and velocity influence rain erosion. A sharp-nose radome is less susceptible to damage than a blunted-nose radome because less impact energy is transferred to the structure. Rain erosion manifests itself as pitting of the radome surface and, in severe cases, leads to catastrophic failure. Degraded RF performance can also result from the change in wall thickness. Special rain-erosion coatings and metal tips are used to provide resistance to rain erosion.

Water absorbed by a radome increases the dielectric constant and loss tangent of the wall. Preferred radome materials do not readily absorb water or must be treated with protective coatings. Water absorption also reduces the strength of most composite materials.

Static electricity caused by air friction can present a serious shock hazard. Thin antistatic coatings are used to neutralize static charge by providing a conducting path to attached structures. Lightning strikes to aircraft are common, so metallic lightning-diverter strips are used to minimize structural damage to the radome. Diverter cause some increase in sidelobe levels.

53.2 RADOME WALL DESIGN

This section discusses the configuration of radome walls and plane-wave analysis methods for predicting transmission and reflection properties. The importance of radome shape is also introduced.

Electrical Analysis

The most basic problem in radome electrical design is development of a wall configuration that supports the antenna system requirements and is also compatible with the overall mechanical and environmental requirements. This requires a model for the RF transmission and reflection properties of the wall. From the beginnings of radome use, it was recognized that tractable models can be based on some treatment of the incident field as a plane wave and the radome wall as an infinite planar slab. Solutions for this configuration are straightforward and have long been applied in radome design and analysis.¹⁻²

The conditions for a plane wave incident on a uniform, isotropic dielectric slab are shown in Figure 53-3. The *incidence angle* (θ_i) is the angle between the vector pointing to the source ($-\hat{k}$) and the surface normal (\hat{n}). The plane containing \hat{k} and \hat{n} is the *plane of incidence*. Polarization is referenced to the plane of incidence with components in this plane, called *parallel polarized*, and perpendicular to the plane, called *perpendicular polarized*. These references are significant because, for isotropic materials, parallel polarized incidence results in completely parallel-polarized reflection and transmission, and likewise for perpendicular polarization. Therefore, these polarizations are *eigen-polarizations* of an isotropic slab.

FIGURE 53-3 Conventions used for plane-wave propagation through a flat dielectric panel

The fields internal to the slab are a combination of forward- and backward-traveling waves produced by reflections between the interfaces. Boundary conditions require continuity of the tangential electric and magnetic at all material interfaces. Therefore, analysis can be based on the transverse field components and their relationship between adjacent boundaries. These fields and dielectric slabs are analogous to cascaded TEM transmission lines and the *ABCD transmission matrix* used for microwave circuits⁹ can also be used to describe the wall transmission and reflection properties. The transverse components of the total fields at the input side are made up of the incident and reflected fields, $E_i^i(1 + \Gamma)$ and $H_i^i(1 - \Gamma)$, and are related to the transverse components on the output side, E_t^i and H_t^i , by

$$\begin{bmatrix} E_i^i(1 + \Gamma) \\ H_i^i(1 - \Gamma) \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} E_t^i \\ H_t^i \end{bmatrix} \quad (53-1)$$

Since wall interactions only depend on relative dielectric properties, all material parameters can be normalized to free space. For a slab with constitutive parameters, $\epsilon_r = \epsilon_r' - j\epsilon_r'' = \epsilon_r'(1 - j\tan\delta_e)$ and $\mu_r = \mu_r' - j\mu_r'' = \mu_r'(1 - j\tan\delta_m)$, the ABCD matrix is given by

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \begin{bmatrix} \cosh(jk_x t) & Z_r \sinh(jk_x t) \\ Z_r^{-1} \sinh(jk_x t) & \cosh(jk_x t) \end{bmatrix} \quad (53-2)$$

where t is the slab thickness, λ_0 is the free space wavelength, and

$$Z_r = \mu_r / \sqrt{\mu_r \epsilon_r - \sin^2 \theta_i} \quad (\text{for perpendicular polarization})$$

$$Z_r = \sqrt{\mu_r \epsilon_r - \sin^2 \theta_i} / \epsilon_r \quad (\text{for parallel polarization})$$

$$k_x = \frac{2\pi}{\lambda_0} \sqrt{\mu_r \epsilon_r - \sin^2 \theta_i} \quad (\text{the propagation constant in the x-direction})$$

The slab transmission coefficient, $T = E^t / E^i$, and reflection coefficient, $\Gamma = E^r / E^i$, are given by

$$T = \frac{2}{A + B/Z_0 + CZ_0 + D} \quad (53-3a)$$

$$\Gamma = \frac{A + B/Z_0 - CZ_0 - D}{A + B/Z_0 + CZ_0 + D} \quad (53-3b)$$

where $Z_0 = 1/\cos\theta_i$ for perpendicular polarization and $Z_0 = \cos\theta_i$ for parallel polarization are the normalized transverse impedances for the incident and transmitted waves.

The phase of T is referenced to the output side of the slab. An important parameter for radome performance is the phase shift introduced by insertion of the slab into the propagation path. This is obtained by removing the free space phase shift from input to output to form the *insertion phase*, IP, given by

$$IP = \angle T + \frac{2\pi}{\lambda_0} t \cos\theta_i \quad (53-4)$$

For radome analysis, the phase of T is adjusted by the IP obtain the *insertion transmission coefficient*. Insertion phase can be a strong function of polarization and incidence angle, which for appreciably-curved radomes, leads to distortion of the transmitted wave-front and causes radome boresight errors and cross-polarization antenna responses.

The ABCD formulation is useful in analysis of multilayered structures because the output of one layer becomes the input to the adjacent layer. Therefore, the ABCD matrices of individual layers can be cascaded in a matrix product to obtain the overall transmission and reflection coefficients of all layers.

Wall Configurations

Radome wall structures are configured to address design requirements using available materials and construction techniques. This section describes the electrical characteristics of some basic configurations including homogeneous single-layer (monolithic), multilayer, space-frame, and grooved walls. Figure 53-4 shows the common wall types.

A *monolithic-wall* consists of a single constant-thickness slab of homogeneous dielectric material. The thickness of a monolithic wall radome may be selected to be electrically thin (less than approximately one-tenth wavelength) or an integer multiple of one-half wavelength in the dielectric. *Thin-wall* designs are applicable at lower frequencies where the permissible electrical thickness also provides adequate strength and rigidity, while multiple half-wave designs are used at higher frequencies where structural considerations prohibit the wall from being electrically thin and the operating bandwidth is sufficiently narrow (usually not more than 6–10%).

FIGURE 53-4 Radome wall-construction nomenclature

FIGURE 53-5 Transmission magnitude (dB) for a half-wave design at 9.0 GHz and $\theta_d = 60^\circ$ ($d = 8.6$ mm, $\epsilon_r = 4.5$, and $\tan \delta = 0.01$)

To illustrate characteristics of a monolithic wall, Figure 53-5 shows the transmission of a panel designed for 9 GHz and 60° incidence angle. Three polarization states are shown for performance over a 0–20 GHz frequency range and for 0– 90° incidence angles. High transmission is seen at very low frequencies, the design frequency, and twice the design frequency. Transmission for circular polarization is the complex average of parallel and perpendicular, $T_{CP} = (T_\perp + T_\parallel) / 2$, and is equal for right- and left-hand senses.

The low-frequency properties seen in Figure 53-5 apply to any electrically thin wall. These properties vary with wall thickness and dielectric, polarization, and incidence angle. Since there is low wall-absorption loss in low loss-tangent materials, the loss mechanism is mainly reflection. Thin-wall design curves for the maximum thickness required for a specified transmission level are presented by Kay.¹⁰

Transmission resonances occur in a monolithic wall at frequencies that produce integer multiples of a half wavelength thickness in the dielectric. The design thickness for these resonances, d , is given by

$$d = \frac{n\lambda_0}{2\sqrt{\epsilon_r - \sin^2 \theta_d}}, \quad n = 1, 2, 3, \dots \quad (53-5)$$

The integer n is the *order of the radome wall* with $n = 1$ being a *half-wave wall*. The incidence angle, θ_d , is the *design angle*. For lossless materials, reflection will be zero at this angle of incidence, transmission will be unity, and equal insertion phase will occur for perpendicular and parallel polarization. Thus, at the design angle and frequency, Figure 53-5 shows high transmission for all polarizations.

Transmission for parallel polarization is always greater or equal to that for perpendicular polarization. In addition, at the *Brewster angle*, θ_B , defined by

$$\theta_B = \tan^{-1} \sqrt{\epsilon_r} \quad (53-6)$$

lossless materials will have zero reflection and unity transmission for parallel polarization, independent of panel thickness and frequency. No similar condition exists for perpendicular polarization.

Monolithic radome walls are used in many ground-based and shipboard applications where weight is not a problem and simplicity of design and construction is desired. Half-wave and full-wave walls are also common in high-speed airborne radomes, however lighter sandwich structures are often used for lower-speed aircraft and missile applications. Complete transmission curves for monolithic wall designs can be found in the reference section.^{1,11}

Multilayer structures are used when a monolithic wall is unacceptable or does not provide adequate performance, especially in areas such as bandwidth, weight, or strength. Common multilayer configurations include the A sandwich, B sandwich, and C sandwich (Figure 53-4).

The *A sandwich* consists of three layers: two dense high-strength skins separated by a lower-density, lower-dielectric core material such as foam or honeycomb. This configuration can provide much higher strength for a given weight than a monolithic wall.

The design of an A sandwich usually begins by selection of the skin thicknesses and then the core thickness is chosen so that the reflected wave from the second skin cancels the reflected wave from the first skin at the desired frequency and incidence angle. Other than at normal incidence, the core thickness required for matching will be different for parallel and perpendicular polarization. Usually perpendicular matching is selected because good transmission for parallel is provided by the Brewster angle phenomena. Figure 53-6 illustrates transmission properties for an A sandwich designed for 9 GHz, 50° incidence, and perpendicular polarization.

Design formulas and graphical data for A-sandwich walls are presented in the reference section.^{1,11} For the symmetric A sandwich, the inner and outer skins are identical and are usually thin with respect to wavelength. For higher frequencies of operation where a half-wave wall would be structurally unacceptable, an A sandwich can be constructed

FIGURE 53-6 Transmission magnitude (dB) for a symmetric A sandwich designed for perpendicular polarization at an incidence angle of 50° and 9 GHz (skins: $t = 1.27$ mm, $\epsilon_r = 4.0$, $\tan \delta = 0.02$; core: $t = 7.75$ mm, $\epsilon_r = 1.2$, $\tan \delta = 0.005$)

using two half-wave tuned skins separated by an arbitrary-thickness of low-dielectric core, since matching will not require reflection from one skin to be cancelled by reflection from the other. A sandwich designs are used in many narrowband, blunt-nose radomes because the low incidence angles provide nearly uniform transmission properties. A-sandwich walls are also used in some streamlined missile radomes to obtain wideband performance.

The *B sandwich* has three layers, reversed to the A sandwich: a dense core material and two lower-density outer materials, which can serve as quarter-wave matching layers. A B sandwich can provide very wide bandwidth at high incident angles. But, because the low-density outer layers usually have poor structural or environmental properties, it is only used in applications where this is acceptable. When the outer layers are selected for quarter-wave matching, both the thickness and dielectric constant must be specified and these will be different for the parallel and perpendicular polarization.

The *C sandwich* consists of five layers, like two A sandwiches joined together. These additional layers may be used to provide greater strength and rigidity in the mechanical design and also give more degrees of freedom for the electrical design. For example, a good transmission match can be obtained independent of the insertion phase. This enables the design of a highly curved radome using varying layer thicknesses to obtain uniform amplitude and phase transmission characteristics and thereby create minimal impact on low sidelobe antenna performance.¹²

Multilayer structures may contain any number of dielectric layers needed to achieve desired properties such as high transmission over a broad frequency band or multiple bands, or to incorporate desired environmental and structural features. Initial design of multilayer radomes should always be based on consideration of the fundamental properties of the low-order structures. Optimization of the final design parameters can then be achieved using numerical techniques based on analysis of the cascaded wall layers.

Metal-loaded radomes consist of a combination of dielectric and conducting materials. The inclusion of conducting material in a radome wall provides an additional design component to achieve RF properties that cannot be obtained with all-dielectric structures. Conducting material may consist of thin metal films with a periodic pattern of features arranged in a lattice or an electrically-thick metal with apertures. A thin patterned-metal acts as a shunt admittance on the equivalent transmission-line model of the wall, whereas the thick wall with apertures acts as a waveguide transmission line and has waveguide properties such as low-frequency cutoff.¹³ An infinite planar array of such elements is commonly called a *frequency selective surface (FSS)* due to the frequency dependent properties not found in purely dielectric walls.

Metallic radomes offer the potential for higher operating temperatures, better rain-erosion resistance, high strength-to-weight ratio, decreased static-charge buildup, ease of handling, and reduced interference from out-of-band signals. Good transmission properties have been demonstrated on a metallic radome¹⁴ that uses slots in a thin metal outer skin.

Design and analysis of FSS structures can be based on an infinite planar periodic array (or grid) with plane-wave incidence, representation of the fields by a harmonic series (*Floquet modes*), and expansion of the induced currents or aperture fields using selected modal sets.¹⁵⁻¹⁸ Analysis can also be performed using the FDTD method.¹⁹ All FSSs exhibit resonant frequency behavior (band pass and band stop.) Operation of a radome with a FSS may be near a resonant frequency or well below resonance. Common elements used in the sub-resonance region include wire grids and capacitive platelets. Wire grids are useful because they act as shunt inductive circuit elements,¹³ which can be used to tune a thin-wall radome or the skins of an A sandwich.²⁰ Wire grids can also be used to increase the bandwidth of a half-wave design.¹¹ Arrays of electrically-small metal platelets act as shunt capacitive elements that can be embedded in a dielectric skin to increase its effective thickness.²⁰ Many types of metal-grid patterns have been described.^{11,15-16} FSS layers are also used in designs similar to radomes such as transmission and reflection polarizers, and dual-band subreflectors.¹⁵

A *space-frame radome* consists of a network of structural beams covered with a electrically thin dielectric material.^{8,11} It is often in the shape of a truncated sphere and is used in ground-based applications. The dielectric or metallic structural beams form triangular sections networked together to support the loads applied to the dielectric material. Although some antenna gain reduction is caused by the beams, their size and random orientation minimize undesired pattern distortion and boresight errors.

The *grooved radome* is a non-resonant structure consisting of a thick dielectric into which V-shaped grooves have been cut on both sides.²¹ The grooves on one side can be oriented 90° , with respect to those on the other side, to help cancel the anisotropic effects and equalize the transmission properties for orthogonal polarizations. Grooves provide a gradual transition from air to dielectric and back again, thus giving a continuous match to the incident wave analogous to pyramidal absorber materials. The groove depth determines the lowest frequency of operation, and the spacing the upper frequency limit.

Radome Shape

Radome shape and wall construction together comprise the radome configuration. Blunt radome shapes include the cylinder, the sphere, and combinations thereof. Since the incidence angles encountered in these shapes are generally less than 30° , such radomes have been called *normal-incidence radomes*² because they can be successfully designed by consideration of only the normal-incidence wall transmission properties, which are independent of polarization. Reflections can be a problem in blunt radomes since the reflected energy can be returned directly to the antenna and increase the VSWR in the feed system.²²

Streamlined shapes are used to reduce drag in nose radomes for airborne applications. Common streamlined shapes are the *ogive* (Figure 53-7), von Kármán, Sears-Haack, conical,

FIGURE 53-7 Antenna-radome geometry for a tangent ogive radome

ellipsoidal, power-series, and log-spiral.⁶ Incidence angles can range from 0 to 80° and higher, depending on the degree of streamlining which is often described by the radome length-to-diameter ratio called *fineness ratio*. Radome back reflection (VSWR) is not significant in streamlined radomes, but focusing effects, Lloyd's mirror effect, and trapped waves may have significant impact to electrical performance.¹

The superspheroid was developed as a parametric representation which can be used for a wide variety of radome shapes: both blunt and streamlined.²³

Radome shape affects both aerodynamic and electrical performance. In general, the more streamlined airborne shapes have less drag and are more resistance to rain damage; however, electrical performance is usually better for less streamlined shapes due to the lower incidence angles encountered. Sound design practice dictates that radome shape be optimized by considering both aerodynamic and electrical requirements.

53.3 ELECTRICAL ANALYSIS AND MODELING APPROACHES

This section describes methods that have been used to predict electrical performance of radomes and therefore can be used as design tools.

Antenna/Radome Interaction Phenomenology

The basic question in radome electrical design and analysis is how an antenna and radome will perform together as a system. This is a very difficult problem for most radomes because they are electrically large structures with complex geometry. Various quasi-optical techniques have historically been used for analysis. Recent advances in computational resources are now permitting more rigorous solutions as a boundary value problem. This section discusses the theoretical foundation for analysis and some techniques that have been applied.

Common to all radome analysis and modeling techniques are two primary issues:

1. How is RF transmission/reflection modeled at the radome wall?
2. How is near-field propagation modeled within the antenna/radome cavity?

One modeling technique is based on the equivalence principle.²⁴ In this approach, a transmitting antenna is considered and the fields transmitted to the radome interior are computed. Transmission through the wall is then calculated by a technique such as the plane wave/planar slab approximation to obtain the fields over the radome outer surface. Radiation to the far field is then determined from equivalent currents obtained from the tangential field components over the external surface. See Figure 53-8.

Another approach is based on the Lorentz reciprocity theorem.²⁴ In this method the received voltage is found by an integration that is performed over a closed surface, S_1 , surrounding the antenna. The integral requires the fields over S_1 that are produced by a source in the far field (with desired direction, frequency and polarization) and the fields produced by the antenna when transmitting. The voltage V_R received in each channel of a monopulse antenna is given by

$$V_R = c \oint\limits_{S_1} (\mathbf{E}_T \times \mathbf{H}_R - \mathbf{E}_R \times \mathbf{H}_T) \cdot \hat{\mathbf{n}} \, da \quad (53-7)$$

FIGURE 53-8 Use of equivalence and Lorentz reciprocity theorems to find antenna patterns in the presence of a radome

where

- $\mathbf{E}_T, \mathbf{H}_T$ = antenna near fields when transmitting (sum or difference beams),
- $\mathbf{E}_R, \mathbf{H}_R$ = fields from the far-field source and incident on the closed surface S_1 ,
- \hat{n} = outward unit normal to surface S_1 , and
- C = a complex scale factor.

The integration surface may be chosen to coincide with the antenna aperture, the radome internal or external surface, or an arbitrary surface inside or outside the radome. It is the choice of the surface S_1 and the approximations used to find the fields over it which distinguishes the various methods of radome analysis.²⁵ Some techniques that have been used in modeling near-field propagation and wall transmission/reflection are summarized in Table 53-1 and are discussed next.

Radome analysis methods have paralleled the development of airborne radar systems. Silver² describes the geometrical-optics approaches taken up to 1949. By the mid 1960s radome design issues were well understood,¹ even though computational electromagnetics was still in its infancy. Principles identified by early researchers show great insight into antenna/radome interactions. Their work is well worth reading.

Perhaps the oldest analysis technique is referred to as ray tracing. It is usually described for a receiving antenna with the incident wave modeled by ray bundles. The radome wall is treated as being locally planar and modeled with the polarization-dependent, complex transmission coefficients for an infinite planar slab, lying in the tangent plane at the points

Table 53-1 Analysis Techniques for Modeling Transmission/Reflection at the Radome Wall and Propagation Within the Radome Cavity

Wall Transmission/Reflection	Propagation Within Radome Cavity
<ul style="list-style-type: none"> • Tangent Plane Approximation • Finite Element Method (FEM) • Finite-Difference Time-Domain (FDTD) • Integral Equation • Complex Ray 	<ul style="list-style-type: none"> • Ray-Tracing (diffraction ignored) • Near-Field Source Integration • Finite-Difference Time-Domain (FDTD) • Plane Wave Spectrum (PWS) • Finite Element Method (FEM)

of incidence of the impinging rays. The incidence angle and local polarization are determined by the surface normal and propagation vector. After applying transmission coefficients, the wave travels to the receiving aperture in the same direction as the incident field, thus ray tracing. Because diffraction effects due to changes in amplitude or phase are ignored, this is a geometric-optics approach. For electrically large systems, ray tracing is reasonably accurate in determining first order effects since only weak diffraction occurs between the radome and high-gain antenna. Ray tracing analysis is fast because extensive operations, such as matrix inversion, are not required.⁵

The limitations of ray tracing in modeling antenna near fields lead to techniques based on summation of distributed sources for predicting diffraction effects. Tricoles²⁶ formulated a three-dimensional method of radome analysis based on Shelkunoff's induction and equivalence theorems. Paris²⁷ applied these principles by integrating equivalent currents over the radome external surface in order to find the pattern of a horn antenna covered by a radome. Incident near-fields at the radome were found by a near-field summation and the tangent-plane approximation used for wall transmission. Tavis²⁸ describes a three-dimensional ray-tracing technique to find the fields on an equivalent aperture external to an axially symmetric radome.

Wu and Rudduck²⁹ developed a surface-integration method that uses an analytical plane-wave spectrum (PWS) representation to characterize the antenna near fields. This can be generalized for arbitrary apertures by use of the fast Fourier transform (FFT), which can also speed up the computer calculations.³⁰ Huddleston et al²⁵ have compared three-dimensional radome-analysis methods, which use a general formulation based on the Lorentz reciprocity theorem.

Siwiak et al³¹ applied the reaction theorem to the analysis of a tangent-ogive missile radome to determine boresight error. Their approach is based on surface integration of the antenna near fields and received fields carried out over the radome interior surface. The tangent plane approach was used to find the received fields at the radome interior and a model for one-bounce reflection from the radome far wall was based on ray tracing. A similar approach, but for the transmit case, has been developed for arbitrary shaped radomes.³²

Hayward et al³³ compared the accuracies of two methods of analysis in the cases of large and small radomes to show that ray tracing does not accurately predict wavefront distortion in small radomes. Burks et al³⁴ developed a ray-tracing analysis for large radomes which includes first-order reflections from the radome wall, and they demonstrated the correlation between wavefront distortion and boresight error including effects of polarization.

Gao and Felsen³⁵ presented a method of tracing complex rays through a tapered dielectric radome to find the near and far fields of the antenna. Orta et al³⁶ developed a Green's function technique to describe wall transmission characteristics independent of the excitation fields.

For most radomes, which are many wavelengths in size, integral-equation and finite-element methods (FEM) have been impractical due to the enormous computing resources required. However, the assumption of an axisymmetric shape greatly reduces the computational burden and forms the basis for a FEM method described by Gordon and Mittra³⁷ and the unimoment analysis of Kvam and Mei.³⁸ A volume integral approach for solution of two-dimensional radome problems has also been described by Sukharevsky et al.³⁹

A hybrid technique for electrically large axisymmetric radomes can be based on method-of-moments analysis of the wall in the nose region, tangent-plane approximations for the remaining wall, and analytical surface integration of equivalent currents to calculate antenna patterns.⁴⁰

A purely numerical approach for radome analysis can be implemented using the finite-difference time-domain (FDTD) technique, a method for solving the differential form of Maxwell's equations.⁴¹ FDTD uses the same model to account for both wall transmission/reflection and propagation. No added complexity is needed to account for tip and

bulkhead scattering. This technique is limited only by numerical accuracy and approximations needed to grid the radome and space, and the appropriate boundary conditions at the edges of the solution volume.

Effects on Antenna System Performance

Radomes will have some effect on every aspect of antenna performance and therefore affect all system parameters that rely on antenna characteristics. This includes changes in gain, sidelobe levels, beamwidth, null depth, and polarization. *Radome loss* is the difference in antenna gain with and without the radome present. Loss reduces system sensitivity, ERP, and link margin. Losses occur due to both impedance mismatch at the radome wall and dissipation within the wall. Loss can also be caused by increased antenna beamwidth due to amplitude and phase errors introduced by transmission through a curved wall and depolarization of the main beam.

Radome-induced changes in the amplitude and phase of antenna near fields usually increase far field sidelobe levels. Collimated reflection off the wall can also create a large *reflection sidelobe*, especially in highly streamlined radomes. Polarization of sidelobes will be changed by the radome and for some directions cross-polarized sidelobes will be higher than co-pol. Cross polarization is especially significant for the difference patterns used in monopulse tracking systems. Within the sum main-lobe, missile radomes can produce cross-polarized responses in the difference pattern that are as high as -20 dB with respect to sum. Furthermore, the slope of this cross-pol difference response is often opposite to that for co-pol, which will cause positive feedback in a tracking system and thus create a vulnerability to cross-pol jamming.

Boresight errors are caused by the asymmetric wavefront distortion of signals that pass through a radome and are received by angle-tracking antennas. This is an especially significant problem for homing missiles that use guidance based on estimates of target direction. Depending on the guidance system employed, boresight errors and boresight-error slopes affect missile performance in different ways. Consequently, radome specifications should be developed using consideration of overall tracking-system performance. Since it is impossible to obtain zero BSE at all scan angles (except for hemispherical radomes), angle-error compensation may be implemented in processing software based on measurements and lookup tables. If the table data is taken at ambient temperatures, there will be some uncertainty about its accuracy at elevated operating temperatures. Also, there may be some residual errors when receiving wave polarizations other than those used for making the compensation table.

Design Techniques

Radome design represents an enormous challenge due to the competing requirements from many disciplines. Material selection must be based on structural and thermal considerations. Shape is based on aerodynamic requirements and accommodation of antenna mounting and scanning. The wall configuration must support both electrical and structural goals. Radome design is always an iterative process based on understanding of the performance trades and component interactions.

The wall configuration is selected based on materials suitable for the thermal environment and a cross-section design that will support both the mechanical loads and the system center frequency and bandwidth. After selection of a baseline, one-dimensional thermal analysis can be performed to compute safety factors based on material strength and stress analysis of expected loads. Preliminary assessment of electrical performance can be based on flat panel analysis using incidence angles estimated by ray tracing.

Refinement of the design will occur as a result of these analyses. Optimization of the wall for minimum boresight error and gain loss over scan angle and frequency can be achieved by creating histograms of the incident angles and then tapering the wall thickness for best transmission and uniform insertion phase at the most likely incidence angles. Computer-aided analysis based on one of the techniques discussed previously will speed this process and provide performance predictions that can be used in system analysis. Two and three dimensional analysis of thermal and structural performance should be done in parallel with electrical optimization. Final design for a prototype will be based on engineering judgment with consideration of all analysis and verification then provided by testing.

53.4 RADOME MATERIALS

Electrical, structural, and thermal performance are primary factors in the selection of radome materials. Reliability, length of service, and cost can also be important considerations.

Ceramics

Ceramic materials that have been considered for radomes include aluminum oxide, beryllium oxide, boron nitride (pyrolytic and hot-pressed), magnesium aluminate (spinel), magnesium aluminum silicate (cordierite), magnesium oxide, silicon dioxide, sintered silica, and silicon nitride. The electrical properties of some ceramic radome materials are tabulated in Table 53-2. These electrical properties will vary depending on fabrication method, material density, and temperature.

Table 53-2 Ceramic Radome Materials (8.5×10^9 Hz, Ambient Temperature)

Material	Density, g/cm ³	Dielectric Constant	Loss Tangent
ALON, 9Al ₂ O ₃ -5AlN	3.69	9.28	0.0003
Aluminum oxide	3.32	7.85	0.0005
Alumina, hot-pressed	3.84	10.0	0.0005
Beryllium oxide	2.875	6.62	0.001
Boron nitride, hot-pressed	2.13	4.87	0.0005
Boron nitride, pyrolytic	2.14	5.12	0.0005
IRBAS	3.25	7.75	0.0012
Magnesium aluminate (spinel)	3.57	8.26	0.0005
Magnesium aluminum silicate (cordierite)	2.44	4.75	0.002
Magnesium oxide	3.30	9.72	0.0005
Pyroceram 9606	2.60	5.58	0.0008
Silicon dioxide	2.20	3.82	0.0005
Silica-fiber composite (AS-3DX)	1.63	2.90	0.004
Slip-cast fused silica	1.93	3.33	0.001
Silicon nitride	2.45	5.50	0.003

For high-speed homing missiles, currently used radome materials include Pyroceram 9606, slip-cast fused silica, and IRBAS (in-situ reinforced barium aluminosilicate). Silicon nitride also holds promise for radome applications due to its strength and hardness.

Radome materials for multimode missile seekers must have low transmission losses at some combination of microwave, millimeter-wave, optical, and infrared (IR) wavelengths. Materials that can be considered for this application include zinc sulfide, zinc selenide, magnesium fluoride, ALON, spinel, sapphire, yttria, diamond, and gallium arsenide.⁴²

Organic and Composites

Many thermoplastic and thermoset materials are suitable for radome use. Structural properties of resin systems can be enhanced by combination with a reinforcement material to create a composite. The electrical and structural properties of composite materials will depend on the matrix/reinforcement ratio, material purity, porosity, moisture content, temperature, fabrication process, and changes that occur during aging or environmental exposure. All these factors should be thoroughly investigated for any radome design. Some commonly used materials are listed in Table 53-3, and more comprehensive lists are found in the reference section.⁵⁻⁶

Thermoplastic materials are limited to applications involving modest temperatures, whereas laminates using polyimide or polybenzimidazole resins can withstand temperatures near 750°F. For higher temperatures, either ceramic materials or ablative coatings are usually required. Fiber-loaded Teflon (Duroid®) materials can be used at very high temperatures for a short period of time due to the temperature limiting properties of ablation. Duroid 5650 has been chosen as the best performer in a high-supersonic-rain environment.

Table 53-3 Organic Radome Materials (8.5×10^9 Hz, Ambient Temperature)

Material	Dielectric Constant	Loss Tangent
Thermoplastics		
Lexan	2.86	0.006
Teflon	2.10	0.0005
Noryl	2.58	0.005
Kydex	3.44	0.008
Composites		
Epoxy-E glass cloth	4.40	0.016
Polyester-E glass cloth	4.10	0.015
Polyester-quartz cloth	3.70	0.007
Polybutadiene	3.83	0.015
Fiberglass-polybenzimidazole	4.9	0.008
Quartz-reinforced bismaleimide	3.3	0.004
Quartz-reinforced cyanate-ester	3.3	0.005
Quartz-reinforced polyimide	3.2	0.008
Duroid 5650 (loaded Teflon)	2.65	0.003

Polyurethane and fluoroelastomer coatings are used for rain-erosion protection and, when slightly loaded with conductive fillers, also provide an antistatic coating. For adequate protection, the coating thickness is typically 0.01-0.02 inch (0.25-0.50 mm). For higher-speed missiles, rain-erosion coatings of polyurethane or neoprene are not used because of the higher temperatures involved. However ablative coatings such as Duroid and Avcoat offer a method to reduce rain erosion. Ablative coatings will change the wall thickness during flight and this must be considered in the radome electrical design. Protective coatings that cause beading of water have lower effects on electrical performance than those which produce continuous films.⁴³

53.5 FABRICATION AND TESTING

After design, a radome must be built and tested. This section summarizes common fabrication and testing techniques.

Fabrication Methods

Radome fabrication methods depend on the selected radome materials, and the final selection of materials is often based on the availability of a reliable and affordable manufacturing method. Construction methods for organic radomes include wet lay up, vacuum bag, autoclave, pressure bag, matched die, filament winding, resin transfer, foam in place, and injection molding.

Ceramic radomes have been constructed using slip casting, cold pressing, injection molding, hot pressing, glass forming, and flame spraying.⁶ Machining is often required for both organic and inorganic radomes to provide the necessary tolerances on wall thickness and interface dimensions.

Mechanical and electrical tests are performed throughout production. Before fabrication, tests are performed on specimens of the candidate radome structures to ensure that the required mechanical and electrical properties are reproducible within the required tolerances. During fabrication, quality-control tests are carried out to ensure correct shape, size, dielectric constant, loss tangent, and wall thickness. After fabrication, laboratory and operational tests are performed to validate radome performance in the field.

Electrical Test

Electrical testing of radomes includes measurements of complex permittivity of radome materials and electrical characteristics of the complete antenna-radome combination. Dielectric constant and loss tangent of material samples can be determined at microwave frequencies and high temperatures by using free-space transmission,⁴⁴ Fabry-Perot resonator,⁴⁵ and waveguide transmission or reflection techniques.⁴⁶ Accuracy is enhanced by use of modern network analyzers.⁴⁷

Radome electrical testing includes measurement of transmission efficiency, boresight error, boresight-error slope, beam deflection, radome reflection, antenna-pattern distortion, and depolarization as functions of antenna-radome orientation (scan) and frequency. Standard antenna range equipment, with the addition of a radome-test fixture,⁴⁸ can be used to measure pattern distortion, transmission efficiency, reflection (VSWR), and depolarization. Boresight-error measurements are more demanding because the indicated source direction must be accurately measured for varying antenna/radome geometry. Ways for

doing this include moving the source antenna on a xy-positioner in an automated closed-loop and using the indicated-angle error voltages in an open loop.⁴⁸

Mechanical and Aero/Thermal Test

Mechanical testing includes measurements of physical dimensions and testing of the structural, thermal, and rain-erosion properties of the complete radome. Ultrasonic and microwave-interferometer techniques can be used to measure wall thickness. Structural testing involves static loading of the radome, using mechanical, pressure, or vacuum methods in a manner simulating operational conditions. This must often be done at design temperatures. High-temperature and thermal-shock testing can be carried out by using oxyacetylene torches, quartz lamps, rocket motors, ramjet engines, solar furnaces,⁴⁹ and supersonic wind tunnels.⁵⁰⁻⁵¹ Rain-erosion testing has been carried out by using rocket sleds,⁵² rotating arms, shotgun lead pellets, and single and multiple impact waterjet apparatus.^{6,42} While highly desirable, it is extremely difficult to combine electrical and thermal tests, due to problems such as the reverberant RF environment in a wind tunnel, dynamics of a rocket sled test, and non-uniform heating of a solar furnace.

During radome development, computer-aided analyses should be used to predict the temperatures and mechanical stresses produced by aerodynamic loading and heating as functions of trajectory, altitude profile, velocity, and maneuvers of the vehicle. Parameters to be calculated include thermal-induced stresses, melting, dielectric changes, and maneuver loads versus trajectory time. Of particular interest is stress concentration in the tip region due to dissimilar materials and thermal expansion, and also bending stresses at the base of the radome due to aerodynamic pressure and maneuver. All radome test programs should be guided by the likely failure modes predicted by analysis.

54.1 INTRODUCTION AND OVERVIEW OF PROPAGATION EFFECTS

An antenna is a component in an electromagnetic system that provides an interface between the transmitter or receiver and the external environment. The effect of the external environment on electromagnetic propagation also is an important component of the electromagnetic system, and often plays a strong role in the design of the overall system as well as the antenna components. Because there are numerous environments in which antennas are employed (for example, underground, inside buildings or tunnels, inside the human body, and so on), a complete discussion of propagation effects would include a wide variety of such environments and the propagation behaviors unique to each. In addition, the physical means by which electromagnetic waves are transmitted from one location to another (called propagation “mechanisms”) are highly dependent on the electromagnetic wave frequency. Again a complete discussion would consider frequencies ranging from as low as the sub-kHz range up to optical frequencies or even beyond. These facts make clear that EM wave propagation in general is an immense subject, within which numerous topics and subdisciplines are contained. However, given the focus of the current volume on antenna design primarily at microwave frequencies (for example, around 300 MHz to 100 GHz), the discussion in this chapter is focused on microwave propagation effects in the Earth’s troposphere, as this is the environment in which many antenna applications occur. Some discussion of propagation effects at frequencies as low as 1 MHz in the Earth environment is also provided. While “reflections” by the Earth’s ionosphere are not a useful propagation mechanism at frequencies greater than around 50 MHz, ionospheric effects remain important in some applications up to frequencies as high as 6 GHz, as will be discussed in Section 54.7.

If sufficient antenna gain exists so that illumination of any obstacles (including the Earth’s surface) is avoided, the propagation environment becomes the Earth’s atmosphere and any weather-related features contained within. While this environment is reasonably approximated as free space in many situations, propagation effects including gaseous and rain attenuation, refraction, multipath fading, and atmospheric scintillations are present and can be determining factors in system design in some cases. If obstacles are illuminated, multipath fading becomes more prominent, and the diffraction mechanism becomes important if the line-of-sight path is obstructed. This chapter discusses propagation in free space, effects related to atmospheric refraction, gas and rain attenuation, empirical models for path loss on terrestrial links, basic multipath fading models, and ionospheric effects. References to more detailed information on these and other subjects are provided throughout.

It is important at this point to clarify the possible interaction of the propagation environment with an antenna’s properties. By coupling an electronic system to the outside world, the antenna becomes sensitive to its environment; therefore, properties such as its radiation pattern, impedance, and efficiency are strongly influenced by the location and surroundings of the antenna. It is important that the antenna designer consider these effects when developing a design in order to ensure that the desired antenna functionality is achieved when the antenna is placed in its operating location. For mobile systems, the antenna’s environment will change frequently, so that consideration of antenna functionality in a range of possible surroundings is desirable. While the distinction between propagation contributions and environmental effects on antenna properties in a given measurement can sometimes be difficult to make, most practicing engineers would describe the influence of structures (obstacles, water, and so on) located very close to the antenna as influencing the antenna rather than the propagation environment. This chapter excludes discussion of such environmental influences on antenna properties and focuses

instead on the typical meaning of propagation effects, which involve the contributions of the environment outside the very near region of the transmit or receive antennas. One related antenna parameter discussed elsewhere in this volume is the antenna noise temperature, which is also influenced by the external environment. See Chapter 50 (by Burnside et al) for further discussion.

While references for specific topics will be provided, a general resource for information on radio wave propagation is the Radio Communication Sector of the International Telecommunication Union (ITU-R).¹ The Recommendations series of the ITU-R describes methods for predicting electromagnetic wave propagation in a variety of situations; the methods presented have been agreed upon internationally following a detailed evaluation process, and continue to be revised as improved models are developed. The reader is recommended to examine the ITU-R web site to determine if further improvements to the Recommendations cited (current as of 2007) are available.

54.2 FREE SPACE PROPAGATION

If it is assumed that both transmit and receive antennas operate in a medium composed entirely of vacuum, the Friis formula (named for Harald Friis of Bell Laboratories who first proposed it in 1946) describes the power received (P_R , Watts) at a receiving antenna at a distance R in the far-field of a transmitting antenna to which P_T Watts of power are input:

$$P_R = P_T G_T(\theta_T, \phi_T) G_R(\theta_R, \phi_R) \left(\frac{\lambda}{4\pi R} \right)^2 |\hat{a}_E \cdot \hat{a}_R|^2 \quad (54-1)$$

where λ is the electromagnetic wavelength utilized and $G_T(\theta_T, \phi_T)$ and $G_R(\theta_R, \phi_R)$ represent the transmit and receive antenna gain patterns, respectively, evaluated at the angles at which the other antenna is viewed. The polarization factor $|\hat{a}_E \cdot \hat{a}_R|$ accounts for any mismatch between the polarization of the electric field impinging upon the antenna (\hat{a}_E) and the polarization properties of the receive antenna pattern (described by \hat{a}_R). It is important to recognize in non free-space environments that \hat{a}_E may not be precisely the polarization produced by the transmitting antenna, due to potential depolarization effects (caused for example by Faraday rotation in the ionosphere, by rain, by multipath effects, or by other mechanisms) in the propagation environment. Losses due to impedance mismatch effects, at either the transmit or receive sides, are neglected in Eq. 54-1.

It is often convenient to recast Eq. 54-1 in terms of decibel notation. If the powers are represented in terms of decibels above one Watt (dB,w), and if units of km and MHz are used for distance and frequency, respectively, Eq. 54-1 becomes

$$P_{R,\text{dBw}} = P_{T,\text{dBw}} + G_{T,\text{dB}}(\theta_T, \phi_T) + G_{R,\text{dB}}(\theta_R, \phi_R) - 20 \log_{10} R_{\text{km}} - 20 \log_{10} f_{\text{MHz}} \\ + 20 \log_{10} |\hat{a}_E \cdot \hat{a}_R| - 32.44 \quad (54-2)$$

This form of the Friis equation can be useful for simple system calculations. Note that the Friis equation states that received power is inversely proportional to the square of both the distance between the transmitter and receiver and the frequency utilized, although any frequency dependence of the antenna gains and the polarization mismatch must also be included.

54.3 ATMOSPHERIC REFRACTION

For systems operating in the Earth's environment, an apparently unimpeded path between transmitter and receiver does not consist of free space, but rather contains the Earth's atmosphere and any weather related features therein. This environment can have several influences on propagation, including refraction, attenuation, polarization modification, and so on. Here the refraction mechanism is discussed.

First, because the index of refraction of Earth's atmosphere n , in the absence of rain, snow, or other precipitation, is usually very close to unity, it is commonplace to discuss instead the "refractivity," N , defined through

$$n = 1 + N \times 10^{-6} \quad (54-3)$$

The term "N-units" is assigned to denote refractivity values. An expression for N valid over most frequencies of interest² is

$$N = 77.6 \frac{P}{T} + 3.732 \times 10^5 \frac{e}{T^2} \quad (54-4)$$

where P is the atmospheric pressure in mbar (or hPa), T is the temperature in Kelvin, and e is the water vapor pressure in mbar. The two terms of Eq. 54-4 are called the dry and wet refractivities, respectively. The water vapor pressure included in the wet term may be expressed in terms of the relative humidity H (specified in percent) as

$$e = \frac{6.1121H}{100} \exp \left[\frac{17.502(T - 273.15)}{T - 32.18} \right] \quad (54-5)$$

or in terms of the water vapor density ρ (in grams of water per cubic meter of atmosphere) through

$$e = \frac{\rho T}{216.7} \quad (54-6)$$

Because the total pressure, temperature, and water vapor pressure can all vary significantly depending on atmospheric conditions, the atmosphere's index of refraction is not spatially uniform, and refraction occurs. The dependence of the associated propagation effects on meteorology, which remains difficult to forecast precisely, motivates a statistical treatment of atmospheric refraction as well as many other propagation phenomena. It is commonplace to encounter probability distribution functions of many propagation parameters; these functions specify the percent of time that a particular parameter is likely to either exceed or fall below a given value, and therefore can be used in planning, for example, the number of hours per year that a given system problem is expected to be encountered. Most distribution functions are obtained empirically through averages over an entire year, although results are sometimes presented for the "worst month" as well in order to highlight behaviors over shorter time periods.³ Such information for the refractivity of the atmosphere can be found in the references;² further discussion of statistical effects will be provided in Section 54.6.

Despite the dependence on meteorology, it is often reasonable to assume that the atmosphere's properties are uniform horizontally over a propagation path (for example, distances up to tens of km), but vertical variations in atmospheric properties are pronounced

and cannot be neglected. A global mean description of the index of refraction as a function of height h is recommended as²

$$n(h) = 1 + (N_0 \times 10^{-6}) \exp \left[-\frac{h}{h_0} \right] \approx 1 + (N_0 \times 10^{-6}) - (N_0 \times 10^{-6}) \frac{h}{h_0} = n(0) + \left. \frac{dn}{dh} \right|_{h=0} h \quad (54-7)$$

where the final two forms apply for $h \ll h_0$, and with global mean values of 315 for N_0 at sea level and 7.35 km for h_0 . There is also additional information on expected properties of these parameters in specific global regions.² Note that weather phenomena can cause significant deviations from the typical values, and even the form of equation (54-7) can be invalid in some situations (for example, in ducting environments as will be discussed).

The assumption of horizontal homogeneity results in a locally spherically symmetric environment, and the associated form of Snell's law of refraction is

$$n(0) \cos[\psi(0)] = n(h) \left(1 + \frac{h}{a_E} \right) \cos[\psi(h)] \quad (54-8)$$

where a_E is the radius of the Earth (≈ 6370 km), and $\psi(h)$ is the angle at height h made by the ray path with respect to the local horizontal. If it is assumed that these angles are always small (as for terrestrial paths) and the linear approximation of $n(h)$ is used, Snell's law can be approximated as

$$\psi^2(h) = \psi^2(0) + \frac{2h}{a_E} \left[1 + \frac{a_E}{n(0)} \frac{dn}{dh} \right] \approx \psi^2(0) + 3.14 \times 10^{-4} h_{\text{km}} \left(1 + \frac{dN}{dh} \left[\frac{1}{157} \right] \right) \quad (54-9)$$

with the refractivity gradient $\frac{dN}{dh}$ in N-units/km and $\psi(h)$ in radians. This equation makes the two standard refraction phenomena apparent. First, if the refractivity gradient vanishes (i.e., $\frac{dN}{dh} = 0$), the ray angle nevertheless increases with altitude due to the changing horizontal direction associated with the curvature of the Earth.

The presence of a negative refractivity gradient (as is typical) decreases the rate at which the ray angle increases, with ray angles remaining constant or decreasing only for refractivity gradients more negative than 157 N-units/km. With such large negative refractivity gradients, ray paths are modified so that they return to the Earth's surface, from which they can be reflected, re-refracted back to Earth's surface, reflected again, and so on. This is called the ducting propagation mechanism, and can give rise to elevated received power levels due to its guided wave nature. The required rapid decreases in refractivity are not extremely unusual, especially over the ocean, but the linear approximation to the refractivity profile is usually not applicable for these cases, so that a ray-tracing computation using the non-approximated form of Snell's law and the true refractivity profile is required to estimate ray paths. Further discussion of the likelihood of ducting events is provided in Reference 2; note that ducting is generally not a reliable propagation mechanism due to the strong dependence on meteorology, but rather is usually a source of undesired interference.

In cases with moderate refractivity gradients where the linear approximation of the refractivity profile is reasonable over the ray path, Eq. 54-9 can be recast (again with $\psi(h)$ in radians) as

$$\psi^2(h) = \psi^2(0) + \frac{2h}{k_{\text{eff}} a_E} \quad (54-10)$$

where

$$k_{\text{eff}} = \left[1 + \frac{a_E}{n(0)} \frac{dn}{dh} \right]^{-1} = \left[1 + \frac{dN}{dh} \left[\frac{1}{157} \right] \right]^{-1} \quad (54-11)$$

is called the effective Earth radius multiplier, and where the refractivity gradient again is specified in N-units/km. Using this equation, propagation over a curved Earth including atmospheric refraction is modeled in terms of a propagation over an Earth with a modified radius of $k_{\text{eff}} a_E$ and with no atmospheric refraction (so that rays propagate in straight lines). Using the global mean values of N_0 and h_0 results in a k_{eff} value of 1.3755, more commonly approximated as 4/3. It is common practice in tropospheric radio wave propagation predictions to replace the real Earth surface with a sphere of radius $4/3 a_E$ and thereafter to ignore refraction effects. This approach is valid over a wide range of frequencies, but again, must be used with care as k_{eff} depends on meteorological conditions, with smaller values of k_{eff} (values as small as 2/3 are considered in many system planning stages) resulting in a higher degree of path blockage for line-of-sight systems. For ray paths propagating at larger angles or at higher altitudes, the spherical form of Snell's law and the true refractive index profile should be used to estimate ray-path properties.

In some situations, strong refractivity gradients in the atmosphere can produce scattering effects, leading to multipath interference effects; a brief discussion of the associated fading phenomena is provided in Section 54.6. Inhomogeneities in the atmosphere can also be used as scattering sources in a transhorizon propagation link; such tropospheric scatter communications systems are not discussed further here, but information can be found in the references.⁴ Variations in the atmospheric refractive index also cause scintillation phenomena, which are short-term variations in received signal power levels that can be interpreted as fading or in terms of variations in the angle of arrival along the transmission path. Scintillation effects become more important as the path length through the atmosphere increases (for example, at lower elevation angles on Earth-space paths), and at frequencies greater than 10 GHz. More information on the probability distribution function for scintillation effects is available in the references,⁵ along with further discussion of the expected temporal properties of scintillation-induced fading.⁶

54.4 ATMOSPHERIC GAS AND RAIN ATTENUATION

In addition to causing refraction, the atmosphere can also cause attenuation. At frequencies below 350 GHz this attenuation is due primarily to the atmospheric gases oxygen and water vapor and due to hydrometeors (liquid water or ice particles in the atmosphere including clouds, rain, snow, fog, hail, and so on). Of the latter, rain produces the largest propagation influence and therefore is the only hydrometeor contribution considered in detail here. Other hydrometeor effects may not be negligible, particularly at frequencies above 10 GHz, including those due to clouds or fog.⁷

Oxygen and water vapor both have molecular resonance frequencies below 350 GHz, and therefore can produce large attenuations for systems operating near these resonant frequencies. Both also contribute to a continuum absorption outside these resonant frequencies. The amount of attenuation encountered on a path is described through an integration of a local *specific attenuation* in dB/km over the path length. The specific attenuation encountered is described as a function of air temperature, pressure, and water vapor density, and therefore remains dependent on meteorology.⁸ Figure 54-1 is a plot of the specific attenuation contributions of oxygen and water vapor for a pressure of 1 atmosphere, temperature of 15 C,

FIGURE 54-1 Specific attenuation due to atmospheric gases

and water vapor density of 7.5 grams per cubic meter (roughly 58% relative humidity). The curves show the water vapor resonant frequencies of 22.235, 183.31, and 325.15 GHz, as well as the broad oxygen resonance (composed of many individual resonances) near 60 GHz and the narrower oxygen resonance at 118.75 GHz. Note that near 60 GHz, atmospheric attenuation can be greater than 10 dB per km. Two methods for computing the specific attenuation are provided in the references: the first includes a complete summation over all known resonant lines, while the second describes a simplified curve fit to the results of the first method.⁸ The second approach was used in producing Figure 54-1; Figure 54-1 can be used to obtain a rough estimate of atmospheric specific attenuation for basic purposes; it is recommended to use the methods mentioned previously⁸ for more precise predictions.

Obtaining the total gaseous attenuation on a path requires an integration of the specific attenuation over the path length. For horizontal paths, it is usually reasonable to assume that atmospheric properties are uniform, so that the total attenuation is simply the specific attenuation (dB/km) times the length of the path (in km). However for Earth to space or other paths that travel through large heights above the surface, atmospheric properties and therefore the associated specific attenuation are not constant along the path, and an integration must be performed. Procedures are described for performing such an integration in the references, along with recommendations for sources of atmospheric meteorological information versus altitude, if such information is not available by local means.⁸

A simplified procedure for Earth-space paths is also available⁸ (for frequencies far from the resonant frequencies), in terms of an effective path length by which the specific attenuation can be multiplied to determine the attenuation for a path propagating through the entire atmosphere. Figure 54-2 illustrates results of this computation for zenith attenuation (for example, an Earth station communicating with a satellite directly overhead), again using (surface) parameter values of 1 atm pressure, 15 C, and 7.5 grams per cubic meter of

FIGURE 54-2 Zenith attenuation due to atmospheric gases

water vapor. The results continue to illustrate the strong attenuation at the resonant frequencies, and highlight the utility of the atmospheric “window” frequencies between resonances for Earth-space communications. The results of Figure 54-2 are highly dependent on the assumed altitude of the Earth station (assumed to be sea level in Figure 54-2); higher altitude stations would experience less attenuation due to the reduced atmosphere above them, as well as the likely reduced water vapor content at higher altitudes. Again Figure 54-2 should be used only for a rough estimation of total zenith attenuation, and not when more precise predictions are desired.⁸

For Earth-to-space paths where the satellite is viewed at elevation angles larger than five degrees, attenuation through the entire atmosphere can be estimated by dividing the zenith attenuation (in dB) by the sine of the satellite elevation angle. The larger values of attenuation obtained result due to the larger path lengths required to exit the atmosphere. This approach neglects the influence of refraction on the ray path: at smaller elevation angles, refraction becomes more important and a ray-tracing procedure must be used to ensure accurate calculations.

Numerous models, discussed extensively in the reference section,^{5,6,9,10} have been proposed for estimating rain attenuation. Rain attenuation is also described in terms of a specific attenuation that is integrated over the path length to obtain the total path attenuation due to rain. The specific attenuation due to rain, γ_R , has been found to be well approximated by the expression

$$\gamma_R = kR^\alpha \quad (54-12)$$

where R is the rain rate (in mm/hr) and k and α are functions of frequency and polarization; detailed expressions for k and α are provided in the references.¹¹ Figure 54-3 plots values

FIGURE 54-3 Coefficients k and α versus frequency for computation of rain specific attenuation

of k and α for horizontal (H) and vertical (V) polarizations: these plots can be used to obtain rough estimates for use in analysis of rain attenuation.

For polarizations other than horizontal or vertical, the values of k and α are given by

$$k = [k_H + k_V + (k_H - k_V) \cos^2 \theta \cos 2\tau] / 2 \quad (54-13)$$

$$\alpha = [k_H \alpha_H + k_V \alpha_V + (k_H \alpha_H - k_V \alpha_V) \cos^2 \theta \cos 2\tau] / (2k) \quad (54-14)$$

where θ is the path elevation angle and τ is the polarization tilt angle relative to horizontal polarization (45 degrees for circular polarization).

Because rain rates are not uniform horizontally or vertically, an integration of the varying specific attenuation over the path length is required to estimate total attenuation. The result of such an integration can be expressed as an effective path length by which the surface value of the specific attenuation should be multiplied to estimate total attenuation. The currently accepted ITU method for determining the effective path length on Earth-space paths⁵ is identical to that published originally¹² (although with typographical errors corrected¹²); for terrestrial links the current recommended procedure is also described in the reference section.¹⁰ The reader is referred to these references for the detailed equations.

These procedures allow attenuation to be computed given the surface value of the rain rate. Therefore a statistical model of the rain rate allows statistics of attenuation to be determined. While local measurements of rain statistics are the most desirable for use in such a procedure, there are also global methods for predicting average rain rates.^{6,9,10} The ITU models require knowledge only of the latitude and altitudes of the Earth stations and the corresponding rain rate exceeded 0.01% of the time. A probability scaling approach is

then used to map the attenuation exceeded 0.01% of the time to that exceeded at other time percentages. Note that different equations for this probability scaling are used in the case of terrestrial and Earth-space links. These values are useful in estimating the percent of time that rain attenuation may cause a system outage. In cases where some knowledge of rain attenuation is already available at a given location, equations are also provided for scaling such information to another frequency or polarization for which information is not available. Mitigation of rain attenuation through site diversity and the associated improvements in performance are described in the references.⁵

As an example of typical rain attenuation statistics, Figure 54-4 illustrates rain attenuation probability distribution functions for an Earth-space link at elevation angle 10 degrees, with the Earth station located at sea level, at latitude 40N, and with a rain rate of 49 mm/hr exceeded 0.01% of the time (these statistics roughly correspond to those for Columbus, OH, USA). The results illustrated are for circular polarization and for frequencies from 10 to 50 GHz. The results show that rain fading can cause extremely large attenuations, especially at higher frequencies. At lower frequencies, large fades are more rare (note that 0.01% of the time corresponds roughly to 1 hour per year, so the lower value on the horizontal axis corresponds roughly to six minutes per year). It is generally accepted that consideration of rain attenuation is generally required only for frequencies greater than 5 GHz. Due to the large attenuations that can be caused by rain attenuation, it is typically one of the dominant factors involved in planning system reliability, especially at frequencies greater than 10 GHz.

Both rain and ice particles can cause a change in the polarization state of a wave as it propagates, due to the non-spherical nature of these particles, which creates an effective anisotropic medium. Equations for predicting the cross-polarization discrimination (XPD)

FIGURE 54-4 Rain attenuation example: attenuation probability distribution functions using the ITU-R model⁵

parameter (which describes the ratio of the received power in the transmitted polarization to that received in the orthogonal polarization) due to rain and ice particles are provided in the reference section.⁵ XPD values of 20 dB or less are possible on Earth-space links at higher frequencies; such values limit the extent to which frequency-reuse methods based on polarization diversity can be employed in a communications network.

54.5 EMPIRICAL PATH LOSS MODELS FOR LINE-OF-SIGHT LINKS

For propagation paths near the Earth's surface, the propagation environment is not simply free space, and the effects of the Earth's surface, terrain, and other obstacles must be considered. Two distinct approaches are available: in the first, it is assumed that knowledge of the local terrain is available, and efforts are made to develop a site-specific model based on known obstacles, buildings, and so on. In the second, it is assumed that no such information is available, and an empirical model for average propagation conditions is utilized. Numerous models have been developed in both of these cases, and recommendations continue to be refined as further information is obtained.

In the site-specific case, techniques ranging from standard rules-of-thumb combined with empirical information¹⁰ up to fully numerical electromagnetic simulations of the propagation environment have been reported. While the use of numerical techniques (either based on high frequency approximations and ray tracing or on direct solution of Maxwell's equations) is increasing, and commercial tools are becoming more widely available, this approach remains vastly more computationally expensive than the empirical approach, and therefore is not discussed further.

In the empirical site-specific approach, the local terrain (usually expressed in terms of height above sea level) is first considered and added to the sea-level profile of a modified curvature Earth (to account for atmospheric refraction as described in Section 54.3). Straight lines drawn between transmit and receive locations then provide information on the amount of path clearance above the local terrain or other obstacles. Should the path clearance be less than six-tenths of the first Fresnel zone distance at any point on the path, the path is considered obstructed and methods for predicting path loss in the obstructed case are used. Note that the first Fresnel zone distance in meters as a function of d_1 , the distance in km from the transmitter to a specific point on the propagation path, is defined as

$$F_1 = 17.3 \sqrt{\frac{d_1 d_2}{fd}} \quad (54-15)$$

where d_2 is the distance in km from the specific point to the receiver, d is the total path distance in km, and f is the frequency in GHz. Reference 10 provides an estimate of A_d , the average diffraction loss in dB for obstructed paths giving 15 dB or greater diffraction loss, as

$$A_d = -20 \frac{h}{F_1} + 10 \quad (54-16)$$

where h is the minimum path clearance above any significant obstacle, and F_1 is evaluated at the location where this minimum clearance is achieved. Further empirical information on expected statistics of diffraction fading is also available.¹⁰ Possible variations due to nonstandard atmospheric refractivity conditions in the effective Earth radius multiplier must also be considered in predicting expected minimum path clearances.

For non-obstructed paths, reflections from the Earth surface are a source of multipath interference. Reflections are typically obtained from relatively smooth and horizontal portions of the terrain, such as water surfaces or roads. Given a known reflection point, the time delay between the direct ray from transmitter to receiver and the ray following a path from the transmitter to the reflection point then to the receiver can be estimated. In this process, the reflection coefficient of the Earth's surface must be considered, but for long terrestrial paths it is typical to estimate this value conservatively as -1 due to the low grazing angles involved. Knowledge of the time (or phase) delay between direct and reflected rays then allows prediction of the antenna heights for which destructive interference is obtained. A step-by-step procedure for these analyses has been developed, and it recommends that slight modifications in antenna heights be used in order to reduce multipath when possible, while still maintaining acceptable path clearances.¹⁰ In cases where multipath cannot be avoided, multiple antennas at distinct heights can be used in a diversity approach.¹⁰

Figure 54-5 provides a simple illustration of a site-specific estimation of antenna heights for avoiding terrain obstructions. Propagation over a 36 km path is considered at a frequency of 600 MHz, with the transmitter at a height of 22 m above the local terrain on the left-most portion of the plot. Local terrain height values above sea level are illustrated in the plot, as well as these terrain values added to a $4/3$ radius Earth curvature plus six-tenths of the first Fresnel zone distance. The resulting straight ray drawn through the maximum obstacle for this path allows prediction of the receiver height (around 200 m above the local terrain in this case) in order to obtain non-obstructed propagation. The high antenna height required in this example would likely suggest a search for an alternate location due to the obstructed nature of this particular path.

An alternate approach to these site-specific methods relies entirely on empirical forecasts of propagation loss averaged over a wide range of conditions. This approach is more commonly applied for mobile systems, due to the continual changes in the path that occur. It is to be expected that these methods provide less accurate predictions for a particular

FIGURE 54-5 Site-specific example: estimation of antenna height to avoid obstruction due to terrain

path than those achievable with the site specific approach, but for systems that encounter a wide range of propagation paths, description of the average performance remains useful for predictions of expected path loss.

These models are typically expressed in terms of the path loss L_p in decibels, which in free space is identified as the terms $20 \log_{10} R_{\text{km}} + 20 \log_{10} f_{\text{MHz}} + 32.44$ from the Friis equation (Eq. 54-2). If propagation over a planar Earth is considered, both direct and reflected rays must be considered and added, including the phase delay between the two rays to obtain the total received field. If the factor $\frac{4\pi h_1 h_2}{\lambda d}$ is small (where h_1 and h_2 are the transmit and receive antenna heights above the ground, respectively, λ is the electromagnetic wavelength, and d is the path distance,) and the reflection coefficient of the planar Earth surface is taken as -1 , the path loss becomes

$$L_{p,\text{flat}} = 120 + 40 \log_{10} R_{\text{km}} - 20 \log_{10} h_1 - 20 \log_{10} h_2 \quad (54-17)$$

Unlike the free space case, this path loss increases as the fourth power of the range, and is independent of frequency.

Numerous empirical studies have shown that, while basic path loss behaviors for line-of-sight links are similar to those predicted by $L_{p,\text{flat}}$, improvements in this model are required for more accurate predictions. A plethora of revised path loss models have been proposed, typically using the form

$$L_p = L_0 + 10\gamma \log_{10} R_{\text{km}} + 10n \log_{10} f_{\text{MHz}} + L_1(h_1) + L_2(h_2) \quad (54-18)$$

where n and γ are empirically determined frequency and range scale factors, respectively.

One widely used model for forecasting path loss in land-mobile systems operating at frequencies from 150 to 1500 MHz is the Hata model.¹³ The Hata model is described as applicable for ranges from 1 to 20 km and assumes that antenna h_1 is a “base station” type antenna at a height ranging from 30 to 300 m, while h_2 is a mobile receiver antenna at a height ranging from 1 to 10 m. The specified path loss parameters are then

$$\begin{aligned} L_0 &= 69.55 && \text{Urban areas} \\ &= 64.15 - 2 \left[\log_{10} \left(\frac{f_{\text{MHz}}}{28} \right) \right]^2 && \text{Suburban areas} \\ &= 28.61 - 4.78 [\log_{10}(f_{\text{MHz}})]^2 + 18.33 \log_{10}(f_{\text{MHz}}) && \text{Open rural areas} \end{aligned} \quad (54-19)$$

$$\begin{aligned} \gamma &= 4.49 \\ n &= 2.616 \end{aligned}$$

$$L_1(h_1) = \log_{10}(h_1)(-13.82 - 6.55 \log_{10} R_{\text{km}})$$

and

$$\begin{aligned} L_2(h_2) &= (1.56 \log_{10} f_{\text{MHz}} - 0.8) + h_2(0.7 - 1.1 \log_{10} f_{\text{MHz}}) && \text{Small to medium city} \\ L_2(h_2) &= 4.97 - 3.2 [\log_{10}(11.75 h_2)]^2 && f_{\text{MHz}} > 300, \text{ large city} \\ L_2(h_2) &= 1.1 - 8.29 [\log_{10}(1.54 h_2)]^2 && f_{\text{MHz}} < 300, \text{ large city} \end{aligned} \quad (54-20)$$

Note that the Hata model couples range and frequency dependencies into the antenna height and constant terms. Due to its basis on empirical data from Japan, the Hata model is often regarded as more applicable to very high density urban areas.

An extension of the Hata model to frequencies from 1.5 to 2 GHz is described in the reference section.¹⁴ The parameters of the modified model are identical to those of the original Hata model, with the exceptions

$$\begin{aligned} L_0 &= 46.3 && \text{Suburban/medium city} \\ L_0 &= 49.3 && \text{Large city} \\ n &= 3.39 \end{aligned} \quad (54-21)$$

Numerous other investigators have proposed a variety of empirical forms for average path loss,¹⁵ and in general it is found that differences among predictions of these models for supposedly similar conditions may be up to 30 dB or more! Therefore use of such empirical models should be restricted to conditions that are known to be similar to the datasets from which the models were derived.

Even given these limitations, the Hata model remains widely used for providing a first estimate of average path loss for land-mobile systems. Empirical models of the form of Eq. 54-18 have been widely proposed for a variety of propagation situations, including path losses inside buildings and rooms.

The references provide additional information on Earth-satellite mobile paths, including information on the contributions of attenuation in vegetation, diversity techniques, Earth-satellite propagation effects inside buildings, and fading properties and statistics.¹⁶

54.6 FADING AND MULTIPATH

The previous section primarily discussed methods for estimating the average path loss in either a fixed or mobile terrestrial link. However, even for a fixed link, variations in received power occur with time, often due to multipath contributions from obstacles in the vicinity of the propagation path. These variations are enhanced and more rapid for mobile systems. Because such variations are difficult to predict *a priori*, it is common to model multipath fading effects statistically, and to discuss probabilistic models for the received signals. Empirical studies have shown that the statistics of multipath fading can vary widely, depending on the propagation geometry and environment.^{5,6,10,16} Here the three most fundamental statistical models are reviewed in order to provide the reader sufficient background for further investigation.

Received power statistics for mobile systems are described here in terms of slow- and fast-fading components. The former results due to changes in the obstacles along a path as the mobile components move; this is a slow process because the dominant obstacles encountered vary slowly with time. Fast-fading effects are caused by multipath interference among a large number of received signal contributions; because these contributions are summed coherently, any small changes in the position of the receiver or the scatterers producing the multipath result in rapid changes in received power.

If the average path loss is known, it is typical to model slow fading losses in decibels L_S as a zero-mean Gaussian random variable with a specified standard deviation σ_{L_S} . This can be justified by writing the total slow fading loss as an integration of a slow fading specific attenuation over the path length; if it is assumed that the individual slow fading specific attenuations are random variables that are independent and identically distributed, the slow fading loss is then a Gaussian random variable by the central limit theorem. This analysis is reasonable only if there are many possible diffraction points that are encountered over time, as would be relevant for a mobile system. Including the effects of slow fading then simply involves modeling the received power (in dB,W) as a Gaussian random variable with a specified standard deviation. Link budgets can be assessed through use of the distribution

function of a Gaussian random variable. Values of σ_{L_S} ranging from 4 to 10 dB are typically used in propagation studies.

Fast-fading effects are more commonly treated by describing the received power in Watts (or the received voltage amplitude) as the random variable. If it is assumed that a dominant line-of-sight link exists (received power P_m watts neglecting multipath effects) to which multipath contributions from a large number of scatterers are added (received power P_f neglecting the line-of-sight term), the total received power random variable P follows Rician statistics, with a probability density function expressed in terms of an argument p of

$$f_p(p) = \frac{1}{P_f} e^{-\left(\frac{P_m+p}{P_f}\right)} I_0 \left(\frac{2\sqrt{P_m p}}{P_f} \right) \quad (54-22)$$

where I_0 is the modified Bessel function of the first kind and order zero. The associated distribution function is expressed in terms of the Marcum Q function and requires numerical evaluation. The mean value of the received power is given by $P_m + P_f$ and the standard deviation of received power by $\sqrt{P_f(P_f + 2P_m)}$. The ratio P_m/P_f is often called the Rician K-factor, and becomes larger as the line-of-sight component is more dominant.

Figure 54-6 plots Rician received power distribution functions for varying values of the K-factor (indicated in the legend), expressed in terms of the percent of time that the received power is less than X standard deviations below the mean received power. The sharp decreases for the curves at small values of K occur because the received power cannot become negative. Rician statistics are applicable when a primary path is received along with a large number of multipath contributions, and the approach is widely used in analyses of propagation channels.

FIGURE 54-6 Rician distribution functions for specified K-factor

In the case that no line-of-sight link exists but a large number of multipath contributions remain, the received power follows Rayleigh statistics. The resulting probability density function is obtained from the Rician density by setting the line-of-sight term to zero; the mean and standard deviation of the received power are then both equal to P_f . The corresponding distribution function is simple, and states that the probability of the received power falling below p watts is $1 - e^{-p/P_f}$. For small values of p/P_f , this probability is simply p/P_f , implying that the power level exceeded q percent of the time in a Rayleigh channel is $(1 - q/100)P_f$.

Other statistical models of received powers have been proposed that attempt to simultaneously incorporate slow and fast fading effects, and numerous empirical distributions have been presented.^{10,15-17}

While the previous models provide information on the likelihood of a fade occurring at any time, no information on fade dynamics (such as fade duration) is contained. Empirical models for fade temporal properties have been described.^{10,16} Fading effects are of particular concern when they occur non-uniformly across the frequency bandwidth of the transmitted signal (known as “frequency selective” fading); this, of course, happens more frequently the wider the bandwidth of the transmission. Methods for mitigating multipath contributions through signal processing techniques are described in the communications systems literature.¹⁷

54.7 IONOSPHERIC EFFECTS AT MICROWAVE FREQUENCIES

The ionosphere is a region in the Earth's atmosphere between altitudes of roughly 50 and 2000 km that contains a significant number of free electrons (due to ionization of atmospheric molecules primarily by solar radiation.) The presence of free electrons creates a plasma medium, and the resulting index of refraction neglecting the contributions of the Earth's magnetic field is

$$n = \sqrt{1 - \left(\frac{f_{P,\text{MHz}}}{f_{\text{MHz}}} \right)^2} \quad (54-23)$$

where f_{MHz} is the frequency of operation in MHz and $f_{P,\text{MHz}} = 8.9788 \times 10^{-6} \sqrt{N}$ is the “plasma frequency” of the ionosphere, where N is the number of free electrons per cubic meter at a given location in the ionosphere (typical values range from roughly 10^9 to 10^{12} or higher). Eq. 54-23 shows that the index of refraction of a non-magnetized plasma takes on purely imaginary values for $f_{\text{MHz}} < f_{P,\text{MHz}}$ but approaches unity for frequencies $f_{\text{MHz}} \gg f_{P,\text{MHz}}$. Because ionospheric plasma frequencies are usually less than 10 MHz, it is clear that ionospheric effects are greatly reduced at frequencies greater than 0.5 GHz. However, for Earth-space paths that travel long distances through the ionosphere, even the slight deviations from unity that occur can cause important effects, although at frequencies greater than about 6 GHz nearly all ionospheric contributions become negligible. Because the ionosphere is created by solar radiation and also depends on the density of the atmosphere in order to supply molecules to be ionized, the number of electrons per cubic meter is a strong function of altitude, and also has major diurnal, seasonal, latitude, and solar-cycle (due to the approximate eleven year period of the sun's sunspot number) variations. Spatial variations in the electron number density (especially with altitude) produce refraction and associated scintillation contributions.

The major ionospheric concerns for frequencies greater than 1 GHz caused by refraction effects are propagation delay, dispersion, and scintillation.¹⁸ All can be expressed in terms

of the total electron content (TEC) of the ionosphere on a given path, which is obtained by integrating N over the propagation path for a 1 square meter cross-sectional area (thereby obtaining the total number of electrons per square meter cross section). TEC values are often specified for paths integrated in the zenith direction, and values of 10^{16} and 10^{18} electrons per meter square are often used as representative of weak and strong ionospheric effects, respectively. A reference describes a procedure for predicting the TEC on a known propagation path.¹⁹ In terms of the TEC, an empirical expression for the average excess propagation delay (or group delay) in nsec relative to propagation in free space is

$$\Delta t, \text{nsec} = \frac{1.345}{f_{\text{GHz}}^2} \left(\frac{\text{TEC}}{10^{16}} \right) \quad (54-24)$$

Average time delays of 13.45 nsec are obtained, for example, at 1 GHz with a TEC of 10^{17} electrons per square meter. Because this delay is a known function of frequency, it is possible to estimate and remove its contributions by using measurements at two frequencies; this is the approach utilized in the Global Positioning System for correction of ionospheric time delays. Ionospheric dispersion and scintillation effects have also been discussed in detail.^{6,18-19}

When the effect of the Earth's magnetic field on the free electrons of the ionosphere is considered, it is found that the ionosphere is an anisotropic medium capable of producing changes in the polarization state of a wave as it propagates. As with any anisotropic medium, there are characteristic polarizations that remain unaltered by the medium; the characteristic polarizations of the ionosphere are a function of the angle between the direction of wave propagation and the Earth's magnetic field, but in many practical situations are approximately circular. Circular polarization is therefore preferred in most systems for space communications. For linear polarizations, the rotation of the linear polarization that results following propagation through the ionosphere is known as the Faraday rotation. An equation for the angle, Φ , in degrees through which a linear polarization is rotated following transit through the ionosphere is

$$\Phi = \frac{108}{f_{\text{GHz}}^2} \left(\frac{\text{TEC}}{10^{18}} \right) \quad (54-25)$$

Equation 54-25 assumes an average Earth magnetic field of 80 microteslas (a large value), but can be scaled linearly to other magnetic field values. As an example, a linear polarization is rotated 108 degrees at 1 GHz when the TEC is 10^{18} electrons per square meter. The reader is referred to the literature^{6,18-19} for a more detailed discussion of other ionospheric effects on Earth-space paths at microwave frequencies.

54.8 IONOSPHERE AND GROUND WAVE EFFECTS AT FREQUENCIES LESS THAN 50 MHZ

Though frequencies less than 50 MHz are not the focus of this chapter, a brief discussion of two major distinctions in propagation phenomena in this frequency range from those presented previously is provided. The first major change involves the ionosphere: at lower frequencies, significant changes in the ionospheric refractive index can be obtained, resulting in increased refraction of waves propagating in the ionosphere. This refraction mechanism can result in a ducting-like propagation mode in which rays broadcast upward from the ground surface can be refracted to turn back to the Earth's surface, often at large distances from the transmitter. This propagation mechanism is most effective in the HF frequency band (3-30 MHz) for long distance communications. At lower frequencies, the

ionosphere and Earth surface form the boundaries of a waveguide-like structure, so that signals can often be guided efficiently over long distances. Because ionospheric absorption tends to be reduced at higher frequencies, it is usually advantageous to operate at as high a frequency as is possible. However, given the reduced effect of the ionosphere at higher frequencies, eventually a frequency is reached at which there is insufficient refraction to return rays to the Earth's surface, and communication on a specific path is not possible. These properties result in a maximum usable frequency (MUF) for ionospheric reflections on a given path; the MUF depends on the geographical locations of the path endpoints as well as ionospheric conditions. Forecasts of MUF values and methods for their prediction are thus of importance in HF communications; numerous computer codes²⁰ have been developed for these purposes. Due to the dispersive nature of the ionospheric index of refraction (shown in Eq. 54-23), ionospheric communications over bandwidths larger than a few kHz are unusual, although frequency allocations of up to 2.7 MHz have been considered for advanced systems that can correct for propagation effects. Additional information on ionospheric propagation is available in the literature, and several recommendations in this area are available from the ITU-R.¹

The second mechanism important at frequencies less than 50 MHz is the groundwave, which is primarily important for vertically polarized transmissions with both transmitter and receiver at or near the ground. The groundwave is the dominant mechanism for local broadcasts of AM radio (around 1 MHz frequency) in the United States. Eq. 54-17, which describes propagation over a planar Earth, states that received powers vary as the fourth power of the range from the transmitter, and that the received power vanishes as both antennas approach the Earth's surface. The groundwave modifies these conclusions when it is present, and can produce a received power that varies as the reciprocal of the distance squared for a range of distances even with both antennas at or near the ground. Groundwaves are most significant when the imaginary part of the Earth's dielectric constant is high; this is typically the case at lower frequencies, and above approximately 50 MHz groundwave contributions are usually negligible at reasonable propagation distances. Ground wave field strengths can be reasonably predicted using analytical methods, based on a solution for dipole radiation in the presence of a finitely conducting Earth, combined with a theory of spherical Earth diffraction at larger distances. An overview of these theories and the associated prediction procedures and standardized plots of groundwave field strengths for simplifying system planning are available in the references.²¹⁻²² Note that at frequencies less than 50 MHz, typically both ionospheric and groundwave mechanisms can be important; in most cases, the groundwave dominates for local reception while the ionospheric term (or sky wave) dominates for long-distance reception. Variations in the ionosphere can also cause changes in these effects; in the MF band (300 kHz–3 MHz,) absorption in the lower ionosphere during the day reduces sky wave amplitudes. The return of the sky wave during night time hours typically forces a reduction in transmitted power for MF broadcast stations in order to avoid interference with other broadcasters.

55.1 PROPERTIES OF MATERIALS

The design of many types of antennas, radomes, and impedance-matching devices requires the selection of appropriate dielectric materials. Strength, weight dielectric constant, loss tangent, and environmental resistance are the primary parameters of interest. Handbooks of mechanical properties are readily available¹⁻² and will not be reproduced here. Instead, emphasis will be on electric properties. The permittivity ϵ , permeability μ , and conductivity σ must be known at the operating frequency for a material to be completely specified electrically. For the dielectrics presented in this section, permeability equals that of free space ($4\pi \times 10^{-7}$ H/m), and permittivity is a complex number given by

$$\epsilon = \epsilon' - j\epsilon'' = \epsilon' (1 - j \tan \delta)$$

where $\epsilon'/\epsilon_0 = \epsilon_r$ and $\tan \delta = \sigma/(2\pi f\epsilon')$ are the dielectric constant and loss tangent, respectively, of the material, ϵ_0 is the permittivity of free space (8.854×10^{-12} F/m), and f is the operating frequency. For the metals discussed in this section, permeability equals that of free space, permittivity is unimportant, and skin depth equals $(\pi/\mu\sigma)^{-1/2}$.

Dielectrics

Foam dielectrics may be obtained in stock shapes or can be foamed in place (see Table 55-1). They are widely used as sealers for microwave components, spacers in twist reflectors and transreflectors, and low-cross-section target support. Specially loaded foams can be used to create a variable dielectric constant which is useful in a beam-collimation device such as a Luneburg lens. Foams and other low-density materials are typically used in low-power applications.

High-average-power applications (in the kilowatt range) rule out all known dielectrics except ceramics. In addition, high-speed missiles with their high surface and internal temperatures typically require ceramic radomes. Commonly used ceramics are listed in Table 55-1.

Plastics (Table 55-1) are widely used as structural members for antennas, feeds, and mounting structures. Conducting surfaces can be added by flame spraying, painting, and so on, to form reflectors. Sandwich construction techniques are used in radomes and polarizers. Here, two or more thin skins are stabilized against buckling with a lightweight core. The core material can be rigid foam (Styrofoam), foam-in-place foam (Eccofoam S), or a honeycomb material (Hexcell HRP). The skins can be epoxy fiberglass, Teflon, or Mylar. The thicknesses of the skins and core are chosen to make the sandwich transparent electrically. Careful control of tolerances, glue-line thickness, and materials can produce repeatably accurate devices. Photoetched printed-circuit boards are used in polarizers, spatial filters, and frequency-selective reflecting surfaces. Additional information on dielectric properties is given in Von Hippel.³

Metals

Copper, brass, and aluminum are the most important metals in antenna construction today. If weight is not of primary importance, brass and copper are used extensively. These two metals machine, solder, and plate so easily, with little or no special equipment, that they are favorites of the model shop and the production shop alike. Complicated assemblies can

be built with practically no radio-frequency (RF) discontinuities due to contact between parts. Aluminum equals or surpasses both copper and brass on all counts except plating. Although special equipment is required to weld aluminum, the resulting structure is lighter in weight than brass or copper. Very complicated shapes such as flat-plate arrays can be fabricated by dip-brazing aluminum. Table 55-2 lists the conductivity of commonly used metals.

TABLE 55-2 Conductivity of Various Metals

Material	Conductivity, s/m at 20°C
Aluminum, commercial hard-drawn	3.54×10^7

Tungsten, cold-worked	1.81×10^7
Zinc	1.174×10^7
Titanium	0.182×10^7

55.2 ABSORBING MATERIALS

Microwave absorbing material is commercially available in sheet, pyramidal, block, and rod form. Pyramidal absorber is commonly used to create an RF anechoic chamber for indoor-antenna range measurements since it offers the best performance (reflected energy 50 dB down at normal incidence). Pyramidal absorber is usually constructed by loading a spongelike rubber with graphite, and it is available in 2- by 2-ft (0.6- by 0.6-m) pieces ranging in thickness from 3 in (76 mm) to 12 ft (3.7 m). It is rated in decibels of incident to reflected energy at stated frequency, polarization, and incidence angle (see Table 55-3). Performance degrades if the pyramidal tips are broken or if the absorber is exposed to weather for extended periods.

Thicker absorber is typically used only in the specular regions of a chamber, in order to reduce cost. Staggering the thickness of the absorber according to a Chebyshev distribution⁴ can be used to improve the low frequency reflectivity.

Flat sheets of absorber are available when space is limited or when the absorber will be exposed to weather, wear, or high power. The reflected energy from sheet absorber is 15 to 25 dB greater than that of pyramidal absorber. Blocks and special shapes of absorber are available for waveguide-load applications, or they can be machined to the desired shape.

The previous types of absorbers are currently available commercially from Cuming Microwave Corporation, Avon, Massachusetts and TDK RF Solutions, Cedar Park, Texas.

TABLE 55-3 Reflection Coefficient of Typical Commercial Pyramidal Absorbing Material

Nominal Thickness, in	Reflection Coefficient, dB

55.3 NONSOLID SURFACES

Antenna structures are sometimes made from nonsolid metal in order to make the structure lighter, to reduce wind loading, or for special RF purposes (for example, a frequency-selective reflector). Typical construction techniques employ metal wires, rods, strips, patches, perforated metals, and expanded mesh. How large the holes in the structure can be depends on how much transmitted or reflected loss can be tolerated.

Gratings

An array of identical parallel metal wires or rods can be used to reflect energy polarized parallel to the wires and, consequently, to shield the region on the other side of the wires for parallel polarization. The perpendicularly polarized energy is negligibly affected by the wires for most geometries. The parallel and perpendicularly polarized power-transmission coefficients are given, respectively, by⁵

$$T_{||} = 1 - \frac{1}{1 + \left(\frac{2S}{\lambda} \ln \frac{S}{\pi D} \right)^2}$$
$$T_{\perp} = 1 - \frac{\left(\frac{\pi^2 D^2}{2\lambda S} \right)^2}{1 + \left(\frac{\pi^2 D^2}{2\lambda S} \right)^2}$$

FIGURE 55-1 Transmission coefficient for parallel polarization and for perpendicular polarization for a grid of round wires of diameter D and center-to-center spacing S

Figure 55-1 is a plot of these equations, where the grating has wires of diameter D , center-to-center spacing of S , and wavelength λ . These curves are derived from Lamb's work⁶ and agree well with Mumford's nomograph.⁷ The grating can be envisioned as waveguides below cutoff. Thus to be effective, (1) the electric field of the incident wave must lie in the plane determined by the axis of the grating element and the direction of propagation, and (2) S must be less than $\lambda/(1 - \sin \theta)$, where θ is the angle between the direction of propagation and the normal to the axis of the grating element. Larger spacings result in undesirable secondary reflection lobes.⁶

The round wires may be replaced by thin metal strips of width W perpendicular to the direction of propagation by using metal bars or printed-circuit-board construction techniques. The transmission coefficients for the thin broadside strips are given in Figure 55-2, which are plots of the equations⁵

$$T_{||} = 1 - \frac{1}{1 + \left(\frac{2S}{\lambda} \ln \sin \frac{\pi W}{2S} \right)^2}$$

$$T_{\perp} = 1 - \frac{\left(\frac{2S}{\lambda} \ln \cos \frac{\pi W}{2S} \right)^2}{1 + \left(\frac{2S}{\lambda} \ln \cos \frac{\pi W}{2S} \right)^2}$$

FIGURE 55-2 Transmission coefficient for parallel polarization and for perpendicular polarization for a grid of broadside ribbons of width W and center-to-center spacing S

Increased attenuation of the transmitted signal is obtained by orienting the strips edgewise in the direction of propagation. The length of parallel-plate waveguide below cutoff is greater, resulting in greater attenuation than for the round wires or broadside strips. Figure 55-3 gives the percentage of transmitted power for infinitely long edgewise strips of width W , center-to-center spacing S , and depth t .⁸

The polarization sensitivity of the preceding wire and strip gratings can be eliminated by using (1) a grid of wires composed of two crossed gratings, preferably contacting each other or at least closely spaced, (2) a metal sheet periodically perforated by round or square holes,⁹⁻¹⁰ or (3) expanded metal mesh¹¹ (see Figure 55-4).

The previous structures are relatively broadband devices. Narrowband structures can be constructed by using a periodic array of strip-metal dipoles.¹² Operation below the resonant frequency of the dipoles results in little transmission loss versus essentially total reflection at resonance. Dipole and crossed-dipole arrays are used in dichroic subreflectors for dual-frequency operation for a reflector antenna. Frequency-selective surfaces may also be used to scan the far-field beam of an antenna.¹³

FIGURE 55-3 Grating of edgewise strips: relation between strip depth and spacing for constant transmission⁸

FIGURE 55-4 Radio-frequency properties of expanded-metal-mesh screens¹¹

Transmission-Type Circular Polarizers¹⁴

Transmission-type polarizers are anisotropic media which, when placed over a radiating aperture, convert linearly polarized signals to circularly polarized signals. They may take several forms, including those in the following list:

- Parallel-plate structures using metal slats¹⁵
- Alternating dielectric plates of differing materials¹⁶
- Lattice structures using strips or rods¹⁷⁻¹⁸
- Meander-line photoetched structures¹⁹
- Etched-dipole arrays

These types of polarizers have been applied to linearly polarized antennas when other means of achieving circular polarization cannot be economically or easily achieved. For example, simple horns, biconical horns, as well as slot, horn, and dipole arrays have been successfully equipped with these devices. Recent advances in precision-photoetching technology permit close-tolerance photoetched structures, which exhibit excellent uniformity of insertion phase and loss characteristics. This technology has also been designed for use over greater-than-3:1-frequency bandwidths and with power-handling densities of up to 100 W/in² (average). Structures 1, 2, and 3 are older approaches; the reader is referred to the References for background design information.

Structures 4 and 5, mentioned previously, consist of bonded sandwiches of alternating etched sheets of Mylar or Teflon-fiberglass copper-clad dielectric material; for example, MIL-P-631 Type G Mylar or MIL-P-13949 Type GT Teflon-fiberglass. (See Figure 55-5 for more information.) Bonding is done by using a low-loss bonding film (such as 3 M Type

FIGURE 55-5 Geometry of a meander-line circular polarizer showing meander-line and sandwich dimensions

HX-1000) and spacer material such as Hexcell Type HRH-10 honeycomb or Eccofoam SH polyurethane foam. A dielectric layer is generally added to these sandwiches for outer-surface environmental protection; this may consist of epoxy-fiberglass Type G-100 approximately 0.010 to 0.015 in (0.254 to 0.381 mm) thick. Structures of this type have been used on both flat and cylindrical aperture with essentially identical performance.

In use, these structures are oriented so that the incident electric field is 45° to the slow axis of the polarizer. That component of the field, which lies in the slow or perpendicular direction, travels through an equivalent circuit which consists of a ladder network of shunt capacitive elements. The parallel-field component travels through a network of shunt inductive elements. In meander-line polarizers, which are in predominant use today, the shunt capacitance elements arise between the parallel meandering strips²⁰ and, for some very broadband designs, also from added dipole elements which can extend the frequency bandwidth to higher frequencies for a given meander line. Shunt inductive elements are realized by meandering copper lines etched from the copper-clad material. Because of the broadband nature of the multiplayer meander-line polarizer, tolerances on the etching, alignment, and bonding of the sandwich are somewhat looser than for earlier devices such as the metal-slat or dielectric polarizers.

Etched multilayer polarizers are usually designed to be optimum in plane-wave field conditions so that they can achieve better than 2-dB axial ratios, insertion losses of less than 0.2 dB, and a return loss of better than 17 dB over more than octave bandwidths. When they are applied to apertures less than approximately one wavelength in size or when they are forced into the flares of small horns, performance can be expected to deteriorate considerably. In addition, as with all circular polarizers, the best axial-ratio performance will be achieved when provisions are made for dissipating the cross-polarized wave which scatters from the polarizers and reenters the antenna. The latter can be accomplished by the use of a terminated orthomode coupler or by the use of a resistive sheet inside the feeding horn and aligned with the H plane.

Reflection-type polarizers can be derived from the full-transmission-type polarizers described previously, by using half the number of layers, which are then mounted onto a metal sheet.¹³ For narrower-band applications, simple etched-construction transmission-type polarizers can be designed by using narrow-line-width strips as in Lerner²¹ or two-layer arrays of etched dipoles. In the latter, phase-shift quadrature is achieved by the shunt capacitance of a dipole medium only; the differential phase shift due to the longitudinal component of the incident field is negligible. For two layers, axial ratios of less than 0.5 dB can be achieved for bandwidths of a few percent.

Multilayer polarizers are best designed by formulating a model of the susceptance of the metallic circuits on each layer²²⁻²⁵ and then iterating the parameters of a ladder network by using an ABCD-matrix (or equivalent) analysis on a computer. Analysis is performed for both parallel and perpendicular field components. The network's insertion phase and reflection properties are then optimized for a minimum reflection coefficient for both field components and for an insertion phase-shift differential as close as possible to the ideal 90° . Such an analysis can readily model the thickness of the sandwich materials, their electrical properties, the incidence angle, and the frequency-varying nature of the individual susceptances. Reference 21 is useful in this respect. Examples of three documented broadband polarizers are tabulated in Table 55-4 and Figure 55-5.

Wind Loading

The primary forces to which an antenna is subjected are wind, ice, vibration, and acceleration. The wind-loading force is given in Figure 55-6 for solid and open surfaces.²⁸ Ice loading increases the stress on a structure because of the increase in areas presented to wind and because of the additional weight due to the ice loading [approximately 57 lb/ft^3 (913 kg/m^3)].

55.4 RADIO-FREQUENCY-BAND DESIGNATIONS

Historically, letter band designations originated during World War II for secrecy reasons. These designations were continued after they had been made public, but different authors used different definitions for the band edges. One set of common-usage band designations is listed in Table 55-5. Standardized bands have been defined by two official international organizations and are also listed in Table 55-5. The Institute of Electrical and Electronics Engineers (IEEE) standard is the preferred radar band designation. The International Telecommunications Union (ITU) assigns frequency allocations by international treaty. Specific frequency ranges within the ITU bands shown in Table 55-5 are assigned for radar use, and these ranges differ slightly depending on which region of the world is involved. ITU band designations are used as a general indication of the frequency of operation.

In addition, the U.S. Department of Defense has issued a directive concerning the designation of frequencies used in electronic-countermeasures (ECM) operations. Each of the 13 letter bands listed in Table 55-5 is further subdivided into 10 equal-bandwidth channels and given a phonetic and number designation such as Delta-4 (1.3 to 1.4 GHz). It is improper usage to designate a radar by an ECM band designation since the ECM designations only apply to ECM equipment.

55.5 ANTENNA-PATTERN CHARACTERISTICS

Both the initial design of an antenna and the validation of measured antenna data are greatly facilitated through the use of theoretically derived pattern characteristics. The patterns produced by a variety of one- and two-dimensional aperture distributions have appeared in the literature over the years. The task of engineers is to determine which theoretical aperture distribution best fits their physical situations so that they can assess antenna performance from the theoretical data. This can be done by measuring or calculating the actual aperture distribution and then comparing it with a variety of theoretical distributions.²⁹⁻³⁰ The three primary factors of concern to antenna designers are gain, beamwidth, and sidelobe level.

§From AFR 55-44 (AR 105–86, OPNAVIST 3430.9B, MCO 3430.1) (October 1964).

This section presents data on these three parameters for both line-source and circularly symmetric distributions.

The gain of an antenna is usually compared with that of an antenna with the same aperture dimensions but having a constant phase and amplitude distribution (i.e., uniformly illuminated). The power gain G of the antenna then is

$$G = G_0 \eta_a$$

where

$G_0 = 4\pi A/\lambda^2$ = gain of uniformly illuminated aperture

A = antenna aperture area

λ = wavelength

$\eta_a = \eta\eta_L$ = antenna efficiency

η = aperture illumination efficiency

η_L = all other efficiency factors

The aperture illumination efficiency represents the loss in gain resulting from tapering the aperture distribution in order to produce sidelobes lower than those achievable from a uniform illumination. For a circular aperture η is given by a single number. For separable rectangular aperture distributions it equals the product (sum in decibels) of the efficiencies in each of the two aperture directions.

The half-power beamwidth BW of an antenna is related to the beamwidth constant β by⁶

$$BW = 2 \sin^{-1} \left(\frac{\beta \lambda}{2L} \right) \approx \beta \frac{\lambda}{L} \quad (\text{linear aperture})$$

$$BW = 2 \sin^{-1} \left(\frac{\beta \lambda}{2D} \right) \approx \beta \frac{\lambda}{D} \quad (\text{circular aperture})$$

where L is the length of the linear aperture and D is the diameter of the circular aperture. The small-argument approximation for the arcsine is typically used for calculating BW. Values of β and η will be given as a function of sidelobe level for a number of distributions in the following subsections.

Continuous Line-Source Distributions

The problem of determining the optimum pattern from a line source has received considerable attention. The optimum pattern is defined as one that produces the narrowest beamwidth measured between the first null on each side of the main beam with no sidelobes higher than the stipulated level. Dolph³¹ solved this problem for a linear array of discrete elements by using Chebyshev polynomials. If the number of elements becomes infinite while element spacing approaches zero, the Dolph pattern becomes the optimum continuous line-source pattern³² given by

$$E(u) = \cos \sqrt{u^2 - A^2}$$

where

$$u = \frac{\pi L}{\lambda} \sin \theta$$

λ = wavelength

θ = angle from the normal to aperture

The beamwidth constant β in degrees and the parameter A are given by

$$\beta = \frac{360}{\pi^2} \sqrt{[\operatorname{arccosh}(R)]^2 - \left[\operatorname{arccosh} \left(\frac{R}{\sqrt{2}} \right) \right]^2}$$

where

$$A = \operatorname{arccosh}(R)$$

R = main-lobe-to-sidelobe voltage ratio

This Chebyshev pattern provides a useful basis for comparison even though it is physically unrealizable since the remote sidelobes do not decay in amplitude. In fact, all sidelobes have the same amplitude in the Chebyshev pattern. The aperture distribution which produces the Chebyshev pattern has an impulse at both ends of the aperture³³ and produces very low aperture efficiency. In addition, the pattern is very sensitive to errors in the levels of these impulses.

Taylor³² developed a method for avoiding the previous problems by approximating the Chebyshev pattern arbitrarily closely with a physically realizable pattern. Taylor approximated the Chebyshev uniform sidelobe pattern close to the main beam but let the wide-angle sidelobe decay in amplitude. Taylor used a closeness-parameter \bar{n} in his analysis. As \bar{n} becomes infinite, the Taylor distribution approaches the Chebyshev distribution. By using the largest \bar{n} that still produces a monotonic aperture distribution, one obtains the beamwidth constant and aperture efficiency shown in Figure 55-7 and Figure 55-8. Notice that the beamwidth from this Taylor distribution is almost as narrow as that from the Chebyshev distribution while still producing excellent aperture efficiency.

Several other common distributions^{8,34} are also listed in Figures 55-7 and 55-8. The advantage of the $\cos^n(\pi x/L)$ distribution and the $\sin(\sqrt{u^2 - B^2})/\sqrt{u^2 - B^2}$ pattern is that both the distribution and the pattern for them may be obtained in closed form. This mathematical convenience is obtained at the expense of poorer beamwidth and efficiency as compared with the Taylor distribution.

Continuous Circular-Aperture Distributions

The Chebyshev pattern of the preceding section can also be shown to be optimum for the circular aperture. Taylor has generalized his line-source distribution to the circular case,³⁵⁻³⁶ and his pattern approaches the Chebyshev pattern as his closeness-parameter \bar{n} for the circular aperture approaches infinity. The beamwidth constant and aperture efficiency shown in Figures 55-9 and 55-10 are obtained by using the largest \bar{n} that still produces a monotonic distribution.³⁷

FIGURE 55-7 Beamwidth constant versus sidelobe level for several line-source aperture distributions

FIGURE 55-8 Aperture efficiency versus sidelobe level for several line-source aperture distributions

FIGURE 55-9 Beamwidth constant versus sidelobe level for several circular-aperture distributions (after A. C. Ludwig³⁷ © GRC 1981)

FIGURE 55-10 Aperture efficiency versus sidelobe level for several circular-aperture distributions (after A. C. Ludwig³⁷ © GRC 1981)

The Bickmore-Spellmire distribution³⁸ is a two-parameter distribution which can be considered a generalization of the parabola to a power distribution.³³ The Bickmore-Spellmire distribution $f(r)$ and pattern $E(u)$ are given by

$$f(r) = p \left[1 - \left(\frac{2r}{D} \right)^2 \right]^{p-1} \Lambda_{p-1} \left(jA \sqrt{1 - \left(\frac{2r}{D} \right)^2} \right)$$

$$E(u) = \Lambda_p \left(\sqrt{u^2 - A^2} \right)$$

where p and A are constants that determine the distribution and Λ is the lambda function

$$u = \frac{\pi D}{\lambda} \sin \theta$$

The Bickmore-Spellmire distribution reduces to the parabola to a power distribution when $A = 0$ and to the Chebyshev pattern when $p = -1/2$.

A Gaussian distribution³⁷ produces a no-sidelobe Gaussian pattern only as the edge illumination approaches zero. In general, the aperture distribution must be numerically

FIGURE 55-11 Gain loss (---) and resulting sidelobe level (—) for a centrally blocked line-source distribution having a specified unblocked sidelobe level

integrated to obtain the far-field pattern. The second sidelobe of this pattern is sometimes higher than the first, which accounts for the erratic behavior of β and η in Figures 55-9 and 55-10.

Blockage

The placement of a feed in front of a reflector results in blockage of part of the aperture energy. In the geometric-optics approximation, no energy exists where the aperture is blocked, and the undisturbed aperture distribution persists outside the blocked region.³⁹ Using a line source of length L with a \cos^n aperture distribution and a centrally located blockage of length L_b produces the gain loss and the resulting sidelobe level shown in Figure 55-11. The corresponding changes are shown in Figure 55-12 for a circular aperture of diameter D and a parabola to a power distribution blocked by a centrally located disk of diameter D_b . Notice that the line-source blockage affects the pattern much more rapidly than in the circular case since it affects a larger portion of the aperture. Calculation of strut-blockage effects is given by Gray.⁴⁰

FIGURE 55-12 Gain loss (---) and resulting sidelobe level (—) for a centrally blocked circular-aperture distribution having a specified unblocked sidelobe level

55.6 ELECTRICALLY SMALL HORNS

Aperture theory does not accurately predict the pattern characteristics of electrically small horns (on the order of a wavelength or less in size). Diffraction effects from the flange or rim around the horn (also considered to be edge currents flowing on the outside surface of the horn) markedly influence the pattern. Experimental beamwidth data⁸ for small horns without a flange are given in Figure 55-13. These curves were obtained from measurements of a larger number of 10-dB beamwidths. Empirical formulas for these E - and H -plane curves are given, respectively, by

$$BW_E(10 \text{ dB}) = 88^\circ \frac{\lambda}{B} \quad \text{for } \frac{B}{\lambda} < 2.5$$

$$BW_H(10 \text{ dB}) = 31^\circ + 79^\circ \frac{\lambda}{A} \quad \text{for } \frac{A}{\lambda} < 3$$

FIGURE 55-13 Experimental 10-dB beamwidths of horns having small phase variations over the aperture ($\frac{\delta}{\lambda g} < \frac{1}{8}$): ——— E plane; - - - - H-plane sectoral horns; ——— H plane of compound horns with E-plane aperture equal to or greater than a wavelength⁸

where B and A are the E - and H -plane aperture dimensions, respectively. The actual beamwidth of any particular horn may vary from the previous values since different flare angles produce different phase variations over the aperture. Moment Method computer codes can be used to accurately predict the pattern of these horns.

56.1 INTRODUCTION

The electromagnetic properties of periodic surfaces have been widely studied for some time now. A periodic surface is generally defined as a uniform assembly of elements (or scatterers) arranged in one- or two-dimensional infinite arrays. Several arrays and material layers may be combined to produce resonant structures commonly referred to as a Frequency Selective Surface (FSS). These surfaces find a wide variety of applications over a vast range of the electromagnetic spectrum, from below UHF to the far-infrared regions. In the microwave region, periodic surfaces have been used with great success as phased array antennas,¹⁻³ artificial dielectrics,⁴⁻⁷ diffraction gratings,⁸⁻⁹ frequency selective reflectors for antennas,¹⁰⁻¹¹ dichroic surfaces,¹²⁻¹⁵ angular filters,¹⁶⁻¹⁸ and spatial filters.¹⁹⁻²² While many of the principles and design approaches described in this chapter have direct application to active structures such as phased arrays, the emphasis here is on passive frequency selective surfaces. The purpose of this chapter is to provide an overview of the field rather than a comprehensive technical exposition and therefore the interested reader is encouraged to consult the references cited in this chapter, in particular the review articles²³⁻²⁴ and most importantly, the textbooks.²⁵⁻²⁸

A frequency selective surface is essentially a filter designed to exhibit different reflection and/or transmission properties as a function of frequency. Unlike an ordinary filter, which generally considers only the frequency response, an FSS must maintain bandfilter characteristics for various angles of incidence and for various polarizations. The latter issue is readily addressed by using elements that respond to the particular polarization of interest. The former, however, represents a formidable challenge because, independent of element type, variations in angle of incidence result in both a shift in resonant frequency as well as a change in functional bandwidth (including magnitude and phase response) with incidence angle and polarization.

An FSS generally consists of a periodic arrangement of either wire or slot elements. An FSS of wire elements is composed of arbitrarily shaped conducting elements, which support electric currents. Alternatively, a slot FSS is composed of arbitrarily shaped perforations in a metallic screen, which support magnetic currents. Surfaces comprised of wire elements act as bandstop filters (Figure 56-1a), because the elements are reflective at resonance and they pass waves above and below the dipole resonant frequency. For a given incidence angle and polarization,

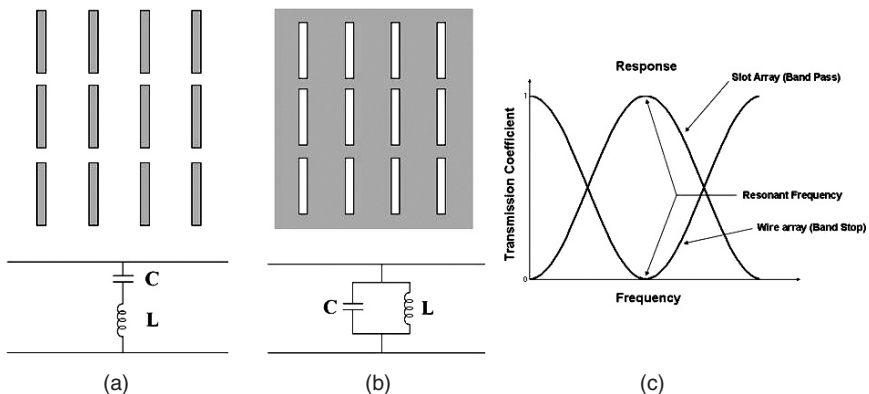

FIGURE 56-1 Generic dipole array (a) and complementary slot array (b) with equivalent transmission line circuits. Typical transmission coefficient curves are shown for both types of surfaces in (c).

an equivalent circuit for a wire FSS consists of a series-tuned LC pair on a transmission line. At resonance the LC combination results in a short circuit (reflects the energy), while away from resonance the LC combination is an open circuit (passes the energy).

Surfaces comprised of slots act as bandpass filters (Figure 56-1b), because the slot elements are transparent at resonance and they reflect waves above and below the slot resonant frequency. For a given incidence angle and polarization, its equivalent circuit is a parallel-tuned LC pair on a transmission line. Here, at resonance, the inductor and capacitor pair combine in order to yield an open circuit response (pass the energy), while away from resonance the LC combination is a short circuit. It is important to reemphasize that while an equivalent LC-circuit may be defined that closely models the behavior of an FSS, the values for the LC-circuit will generally vary greatly with angle of incidence and polarization.

It is convenient to view an FSS as consisting of two distinct regions: a central portion and the portion near the edges. When considering an FSS that consists of a relatively few number of elements, the frequency response is dominated by contributions from the edge of the surface. This means that the influence of the changes in the mutual coupling between all of the elements may easily be found by direct application of conventional computational electromagnetic approaches (Method of Moments,¹³ Finite Element Method,¹⁴ and so on). There has been significant work on finite FSS that addresses the edge effects and the reader is encouraged to consult the resulting publications.²⁸⁻³¹ More typically, Frequency Selective Surfaces are electrically very large (in that they contain many thousands of elements) and the central region of the FSS dominates the response. In this case the vast majority of the elements of an FSS appear to be in the same environment (same impedances and coupling), and it is convenient to analyze the FSS as if it were infinite. Under this condition, certain theoretical approaches may be used that allow insight into the basic behavior of the FSS in a relatively direct manner. The Plane Wave Expansion Technique³² readily lends itself to the analysis of FSS providing a deeper understanding of the nature of the FSS. This deeper understanding results in better design procedures and practices.

While manufacturing defects can lead to suboptimal performance in practical applications,³³ the discussion here assumes infinite arrays under ideal conditions to introduce the reader to the basic approaches and concepts in FSS development. The general outline for this chapter was developed with that purpose in mind. Section 56.2 describes a commonly used analysis approach for FSS—the Plane Wave Expansion Technique. This spectral domain technique provides the fundamental theoretical foundation used in the development of the subsequent material. Section 56.3 describes typical grids and elements that comprise the anatomy of an FSS. To avoid grating lobes, which can severely degrade FSS performance, approaches are presented for realizing compact elements within tight grid spacing. Section 56.4 gives approaches for addressing traditional problems that arise in FSS design. Specifically, dielectric loading techniques and cascading of multiple surfaces are shown to provide stability with angle of incidence and polarization, as well as with bandwidth control and resonance shaping in an FSS. Finally, Section 56.5 provides other applications of FSS, beyond those described previously, and highlights recent trends in this vast field.

56.2 THE PLANE WAVE EXPANSION TECHNIQUE

The plane wave expansion technique is often used to analyze frequency selective surfaces. This approach provides great insight into the scattering problem by applying the theory of antenna arrays in which elements first receive incident energy and then reradiate it to form the transmitted and reflected beams. This section will provide a brief overview of the theory behind this technique.

Consider a two-dimensional (located in the xz -plane) infinite array of linear elements with orientation \hat{p} , and interelement spacings D_x and D_z , as shown in Figure 56-2a. Now suppose the array is exposed to an incident plane wave propagating in the direction:

$$\hat{s} = \hat{x}s_x + \hat{y}s_y + \hat{z}s_z \quad (56-1)$$

The direction components are defined as follows:

$$\begin{aligned} s_x &= \sin \eta \cos \alpha \\ s_z &= \sin \eta \sin \alpha \\ s_y &= \sqrt{1 - s_x^2 - s_z^2} \end{aligned} \quad (56-2)$$

In Eq. 56-2, η is the elevation angle with respect to the y -axis and α is the azimuth angle with respect to the x -axis, as shown in Figure 56-2b.

One can assume without loss of generality that a reference element centered at the origin (0,0,0) has a current distribution defined as $I_{00}(l)$ induced by the plane wave. For an infinite array, Floquet's theorem requires that the element in the q th column and m th row of the array has a current distribution, $I_{qm}(l)$, of the same amplitude as the reference element, but with a linear phase variation resulting from the incident plane wave impinging on the displaced (relative to the origin) element. This element current is given by

$$I_{qm}(l) = I_{00}(l) e^{-j\beta_q D_x s_x} e^{-j\beta_m D_z s_z} \quad (56-3)$$

where values $\beta_q = 2\pi q/\lambda$ and $\beta_m = 2\pi m/\lambda$ are the phase velocities of the incident plane wave along the array.

FIGURE 56-2 (a) Infinite planar array of linear elements with orientation \hat{p} and interelement spacings D_x and D_z . Also shown is a reference element at the origin with current distribution $I_{00}(l)$, and an observation point \bar{R} . (b) The incident field direction \hat{s} as defined by the angles α and η .

The electric field resulting from these current excitations at an observation point \bar{R} is

$$\bar{E}(\bar{R}) = I_{00}(0,0) \frac{Z}{2D_x D_z} \sum_k \sum_{\eta=-\infty}^{\infty} \frac{e^{-j\beta\bar{R} \cdot \hat{r}_{\pm}}}{r_y} \bar{e}_{\pm} P \quad (56-4)$$

where Z is the intrinsic impedance of the medium surrounding the array. In this equation, (k,n) denote the spectral indices rather than the element location (q,m) . The pattern function, P , is derived from the current distribution of the element as follows:

$$P = \frac{1}{I_{00}(0,0)} \int_{\text{element}} I_{00}(l) e^{j\beta\hat{p} \cdot \hat{r}_{\pm}} dl \quad (56-5)$$

The field vector, \bar{e}_{\pm} , is defined as

$$\bar{e}_{\pm} = [\hat{p} \times \hat{r}_{\pm}] \times \hat{r}_{\pm} \quad (56-6)$$

Finally, the direction vector \hat{r}_{\pm} is defined as

$$\hat{r}_{\pm} = \hat{x} \left(s_x + k \frac{\lambda}{D_x} \right) \pm \hat{y} s_y + \hat{z} \left(s_z + n \frac{\lambda}{D_z} \right) \quad (56-7)$$

with

$$r_y = \sqrt{1 - \left(s_x + k \frac{\lambda}{D_x} \right)^2 - \left(s_z + n \frac{\lambda}{D_z} \right)^2} \quad (56-8)$$

where λ is the wavelength in the surrounding medium. The derivation from Eq. 56-3 to Eq. 56-4 is rather complicated, and involves a transformation using Poisson's sum formula to change the summation variables from the element (spatial) indices q and m to the spectral indices k and n . The details of this derivation are omitted here, but may be found elsewhere.²⁷

Upon examination of the term $e^{-j\beta\bar{R} \cdot \hat{r}_{\pm}}$ in Eq. 56-4, which describes a plane wave emanating from the origin, it is evident that only real values of r_y will result in propagating waves. (r_x and r_z will always be real.) Imaginary values of r_y will result in what are called evanescent waves, which attenuate exponentially as the observation point moves away from the array. When $(k,n) = (0,0)$, there are propagating waves in the direction of the incident field (both forward and backward scattering for positive and negative values of r_y). There can also be propagating waves for values of $(k,n) \neq (0,0)$; these are grating lobes and are determined by both the interelement spacing in terms of wavelengths and the direction of the incident plane wave. The evanescent waves present throughout the spectral domain represent stored energy close to the array, which greatly impacts the array impedance as well as the transmission and reflection properties of the periodic surface.³⁴

It follows from Eq. 56-4 that the voltage induced on a test element located at \bar{R} by the currents of the infinite periodic array is

$$V = I_{00}(0,0) \frac{Z}{2D_x D_z} \sum_k \sum_{\eta=-\infty}^{\infty} \frac{e^{-j\beta\bar{R} \cdot \hat{r}_{\pm}}}{r_y} \hat{p}' \cdot \bar{e}_{\pm} P' P \quad (56-9)$$

where \hat{p}' is the orientation of the test element and P' is the pattern function of the test element. From there, the mutual impedance between the array and the test element is derived as

$$Z_M = \frac{Z}{2D_x D_z} \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \frac{e^{-j\beta \hat{R} \cdot \hat{r}_z}}{r_y} \left[{}_{\perp} P {}_{\perp} P' + {}_{\parallel} P {}_{\parallel} P' \right] \quad (56-10)$$

where the pattern functions have been decomposed into parallel (\parallel) and perpendicular (\perp) components. Now if the test element is located a wire radius a from the array reference element (in the y -direction only, such that $\hat{R} = \hat{y}a$), the array self-impedance is found to be

$$Z_A = \frac{Z}{2D_x D_z} \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \frac{e^{-j\beta a r_y}}{r_y} \left[{}_{\perp} P {}_{\perp} P' + {}_{\parallel} P {}_{\parallel} P' \right] \quad (56-11)$$

If there are no grating lobes, this array self-impedance can be broken down into real and imaginary components rather simply. Under this condition, it was shown before that the only propagating waves will occur when $(k,n) = (0,0)$; this is the only term in the spectral domain with a real component, which can be denoted as R_A . The rest of the terms of Z_A (i.e., $(k,n) \neq (0,0)$) will result in purely imaginary contributions and can be summed along with the imaginary component of the $k = n = 0$ term to obtain the reactance X_A . Therefore the array impedance can be expressed as

$$Z_A = R_A + jX_A \quad (56-12)$$

If only the principal planes are considered, with no grating lobes, it can be shown that wire arrays of simple elements can be modeled by an equivalent transmission line, as shown in Figure 56-3.²⁷

From Figure 56-3, it is deduced that the reflection coefficient looking into the array can be expressed as

$$\Gamma = -\frac{R_A}{R_A + jX_A} = -\frac{1}{1 + \frac{jX_A}{R_A}} \quad (56-13)$$

While the transmission line model and reflection coefficient expression have been shown for a simplified case, these prove to be very useful tools in the design of any frequency selective surface comprised of wire arrays. The basic concepts shown here can be expanded to surfaces of complex elements, surfaces that employ multiple FSS, and surfaces that employ dielectric layers. For instance, if instead there are multiple arrays in the

FIGURE 56-3 Equivalent circuit of wire array, valid for no grating lobes and principal planes only

FIGURE 56-4 Double-array structure. The arrays are separated by a distance d , and the three regions have the same material properties.

same structure, such as the double array case shown in Figure 56-4, the scattering properties can easily be determined from well-known analysis of stratified media. The reflection coefficient looking right into the structure in Figure 56-4 is found to be²⁷

$$\Gamma = \frac{\Gamma_{1,2} + \Gamma_{2,3} e^{-j2\beta d} + (\Gamma_{1,2} + \Gamma_{2,1})\Gamma_{2,3} e^{-j2\beta d}}{1 - \Gamma_{2,1}\Gamma_{2,3} e^{-j2\beta d}} \quad (56-14)$$

where the three regions are comprised of the same medium (β is the same), d is the distance between the arrays, and the reflection coefficients of the arrays are defined as shown in Figure 56-4.

At first glance, Figure 56-4 makes it appear that $\Gamma_{1,2}$ and $\Gamma_{2,1}$ would be equal and opposite and therefore would cancel each other out in the third term of the numerator of Eq. 56-14. This would be the case if the reflection coefficients are associated with a dielectric interface, or that of widely separated wire arrays; however, in general terms this should not be assumed. If there are two or more arrays within the near field regions of each other, or if slot arrays are being analyzed (more on that later), $\Gamma_{1,2} \neq -\Gamma_{2,1}$. This is the result of interaction between the arrays. The nearfield region is defined as within the point at which the first evanescent plane wave has decayed to 1% of its original value at the array surface. This is determined to be³⁴

$$\frac{-\ln(0.01)}{\beta \sqrt{(\lambda/D_{\max})^2 - 1}} \quad (56-15)$$

where D_{\max} is the maximum of the interelement spacings. If the arrays under question are spaced outside of this nearfield region, only the propagating modes need be considered. However, when the arrays are located within the nearfield region, evanescent modes must be included in the calculation of the array mutual coupling. This mutual coupling is simply found through an extension of Eq. 56-10, and is given by³⁴

$$Z_{N,M} = \frac{-Z_0}{2D_x D_z} \sum_{k=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \frac{e^{-j\beta(\bar{R}^N - \bar{R}^M) \cdot \hat{r}_z}}{r_y} \left[\hat{p}^N \cdot \hat{e}_z^M \right] P^N P^M \quad (56-16)$$

This is the mutual impedance of array M on array N , centered at \bar{R}^M and \bar{R}^N , with element orientations \hat{p}^M and \hat{p}^N , and having element pattern functions P^M and P^N , respectively.

The intrinsic impedance of the surrounding medium is given as Z_0 , D_x and D_z are the interelement spacings of array N , and the field vector \vec{e}_\pm^M is defined similarly to Eq. 56-6:

$$\vec{e}_\pm^M = [\hat{p}^M \times \hat{r}_\pm] \times \hat{r}_\pm \quad (56-17)$$

This expression for the mutual impedance is used along with the array self-impedances (see Eq. 56-11) to construct the full impedance matrix in order to find currents along the array elements. From there, it is a simple step to calculate the scattered electric field. Examples of surfaces with multiple arrays will be explored later in this chapter.

56.3 ANATOMY OF A FREQUENCY SELECTIVE SURFACE: GRIDS AND ELEMENTS

An FSS is formed by the repetition of identical structures in two dimensions. Therefore an FSS is comprised of two components: a grid (often referred to as a lattice) which specifies the periodicity of the surface, and a reference element associated with every grid point. The grid/element combination, used in concert with tuning materials, define the frequency, bandwidth, polarization response, angular coverage, power handling capabilities, cost and mechanical durability of the FSS. As such it is important to understand the basic functionality and limitations of some common configurations used in FSS design, recognizing that obtaining good FSS performance is not assured by optimizing only performance parameters. In this section, commonly used reference elements and grids are described.

Grating Lobes

A fundamental problem with all FSS is that grating lobes will emerge when the frequency/angle of incidence combination becomes high enough for a given set of interelement spacings, D_x and D_z . To illustrate this, consider a plane wave incident on an array of elements, as shown in Figure 56-5. As described in the previous section, the incident plane wave induces currents on the elements of the FSS. In an infinite array, the current magnitude is the same for each element, while the phase differs by a linear progression (Floquet's theorem). These currents then reradiate to form the scattered fields in the forward direction (transmission) and backward direction (reflection). When the elements are closely spaced, the phase will not vary greatly from element to element and hence the contribution from each element will coherently add together in only the specular direction. These fields are given by the $(k,n) = (0,0)$ term in Eq. 56-4. Because the phase is cyclic, if the separation between the elements is large, the reradiated currents can add in other ambiguous directions in addition to the specular directions. These ambiguous directions are known as grating lobes. Depending on the resonant frequency and pattern factor of the array elements, the grating lobe direction may contain greater power density than the specular direction.

The onset of grating lobes is determined by inspection of Eqs. 56-4 and 56-8, indicating that grating lobes exist at angles represented by (s_x, s_z) given that

$$(s_x + k\lambda/D_x)^2 + (s_z + n\lambda/D_z)^2 = 1 \quad (56-18)$$

In Eq. 56-18, circles are defined with unit radius and centers $(k\lambda/D_x, n\lambda/D_z)$ in the $s_x - s_z$ plane. As shown in Figure 56-6 for $D_x = 0.75\lambda$ and $D_z = 0.49\lambda$, when these circles

FIGURE 56-5 As the interelement separation distance in an FSS gets larger, grating lobes will exist.

overlap, grating lobes for the corresponding values of s_x and s_z are obtained.³⁵ Note that the onset of grating lobes for a given angle of incidence depends only on the frequency (λ) and the interelement spacing (D_x and D_z). Further, the emergence of grating lobes in free space is independent of the presence of a dielectric media. When the FSS is inside a dielectric substrate, the electrical spacing between the elements is larger so the condition for grating lobes occurs precisely as if the entire space was filled with the dielectric (that is, at a lower frequency). As a consequence of Snell's law, total internal reflection of these grating lobes occurs until the actual spacing of the elements exceeds the onset of free space grating lobes defined in Eq. 56-18. These internal grating lobes are referred to as *trapped*

FIGURE 56-6 A graphic representation of Eq. 56-14 yields a grating lobe diagram.

grating lobes and are shown in Figure 56-5. Most of these trapped grating lobes have little impact on the FSS performance, because they are finite and do not propagate in the substrate unless they are driven (these cases are referred to as “forced” surface waves). In between the onset of trapped grating lobes and free space grating lobes, the onset of free surface waves may occur. These surface waves are dependent on the incidence angles and geometry of the dielectric substrates, and are essentially trapped grating lobes guided by the dielectric slab. This results in a lack of energy propagation to any other propagating modes. Like the onset of free space grating lobes, free surface waves are characterized by anti-resonances (nulls) in the reflection curves, which have a devastating impact on the FSS performance and should, in general, be avoided. Significant work has been done on surface wave phenomena and their impact on FSS and more details may be found in the resulting publications.^{27,31,36–37}

In principle, avoiding grating lobes is simply a matter of making the interelement spacing sufficiently small (ideally less than one-half wavelength in the dielectric). To do this effectively requires a basic understanding of the surface grid and elements and the ways that they impact the performance of the FSS.

Grids

The grid (or lattice) plays a significant role in the frequency response of an FSS. The orientation and density with which the elements of an FSS are configured impacts the bandwidth, resonant frequency, polarization response, as well as the onset of grating lobes. Symmetry is an important consideration in FSS design, in particular when low cross-polarization is required.³⁴ FSS geometries possessing greater than a two-fold rotational symmetry have reflection (transmission) coefficients that are independent of polarization at normal angle of incidence.³⁸ Furthermore, no cross-polarization component can exist for any angle of incidence in a plane of symmetry. While the elements in an FSS may have any degree of rotational symmetry (for example, a circular loop element), the grid cannot. A consequence of the crystallographic restriction theorem is that two dimensional grids (lattices) can possess only one-, two-, three-, four-, or six-fold rotational symmetry,³⁹ because the grid is required to be both rotationally and translationally invariant.

There are four grid types commonly used in a planar FSS: rectangular, regular skewed, square, and equilaterally triangular. Examples of these grid types are shown in Figure 56-7. From this figure one can observe that the rectangular and regular skewed grids have two-fold rotational symmetry, the square grid has four-fold rotational symmetry, and the equilaterally triangular grid has six-fold rotational symmetry. The planes of symmetry are indicated in

FIGURE 56-7 Four types of grids, possessing various degrees of symmetry, are typically used in FSS.

the figure. The overall degree of symmetry that an FSS possesses will depend on the grid/element combination; hence the choice of grid for a given application is highly dependent on the reference element used. Specifically, the grid/element combination should provide a lattice spacing small enough to avoid grating lobes in the frequency band of interest, while providing the maximum amount of symmetry.

In addition to delaying the onset of grating lobes, reducing the grid spacing can greatly increase the operational bandwidth of an FSS. To illustrate this, consider the widely studied “gangbuster” surface^{41–42} formed by rotating straight wire (dipole) elements in a square grid until the ends of the reference element point toward a grid location in an adjacent column ($x + D_x$) and offset an integer number of rows ($z + nD_z$), as shown in Figure 56-8. Since the elements are in a square grid, as n increases the interelement separation is smaller for the same length of dipole (as indicated in the figure insert). The reflection coefficient at normal angle of incidence for type-2, type-3, and type-4 gangbuster surfaces is shown in Figure 56-8 for a fixed reference element size. The results indicate that as the elements are more densely packed, the resultant bandwidth is increased. It is further noted that the resonant response of the surface remains quite constant, differing by less than 10% in all three cases for the same length dipole.

A careful examination of the array self-impedance term in Eq. 56-11 provides the rationale for the bandwidth increase. Note in this equation that the double summation is multiplied by a $1/D_x D_z$ term. As D_x and D_z are made smaller, the real part of the array self impedance, R_A , gets larger while the imaginary part X_A remains about the same.²⁷ The result is that $R_A \gg X_A$ and the reflection coefficient of Eq. 56-13 goes to $\Gamma = -1$ over a broader range of frequencies.

Elements

The reference element is a primary determinant of the resonant frequency, bandwidth, polarization response, and angular coverage of an FSS. While endless configurations of reference elements may be considered, the choice of element ultimately depends on the intended application of the FSS. Regardless of application, the elements of an FSS should have a stable resonant frequency with angle of incidence and should be electrically compact enough to fit within a grid that avoids both free space and trapped grating lobes. Reducing the size of a reference element generally requires loading techniques. Loading of the element is typically accomplished by encapsulating the element in a material (dielectric loading), reshaping the element (element loading), or some combination of both techniques.

FIGURE 56-8 Gangbuster surfaces of various types are shown to illustrate how reducing the grid spacing increases the operating bandwidth of an FSS.

Antenna engineers have long recognized that immersing an antenna in a dielectric material provides an effective means of reducing the size of the element. It is well known that when an FSS is immersed in an infinite medium of relative dielectric constant ϵ_r , the resonance is scaled to the frequency $f_1 = f_o / \sqrt{\epsilon_r}$, where f_o is the resonant frequency in free space. Therefore, if all dimensions of an FSS inside the dielectric are reduced by a factor of $1/\sqrt{\epsilon_r}$, the resonant frequency will remain the same. When a relatively thin dielectric substrate ($\sim 0.05\lambda_o$) is added to both sides of any FSS, all resonances will remain effectively the same as they would if the dielectric were infinite. This is because the electric field is relatively strong in the immediate vicinity of these resonant elements due to the evanescent waves (see Eq. 56-4). This resonance shift for thin dielectrics substrates is, for all intents and purposes, the same for wire and slot arrays. Furthermore, as discussed previously, the onset of free space grating lobes will occur at a higher frequency (by a factor of $\sqrt{\epsilon_r}$) than without a dielectric substrate (although as previously discussed, care must be taken to avoid free surface waves). In addition to controlling the resonant frequency of an FSS, thicker dielectric slabs ($0.25\lambda_o$ or more) are commonly used to control the shape and variation of the resonant response with angle of incidence and frequency (see Section 56.4). Contrary to the thinner slabs, thicker slabs have a different effect on the behavior of slot arrays as compared to wire arrays.

Another well-known approach for reducing the size of the elements in an FSS is applying reactive loading to the elements themselves. As shown previously in Figure 56-1a, a dipole array is seen to be essentially equivalent to a network of inductive and capacitive elements connected in series. At resonance they produce a short (or act like a ground plane producing a reflection coefficient equal to -1). As the elements are made shorter, the FSS becomes capacitive. To tune the elements back to resonance at a reduced size, reactive terms may be added. Two fundamental approaches are available: inductive center-loading and capacitive end-loading. Figure 56-9 shows the approximate physical length and equivalent circuit for these arrays of loaded dipole elements using each of these techniques. While loading may be accomplished by introducing lumped loads into the FSS, the traditional technique for loading the elements is to change the shape of the elements as will now be described.

As shown in Figure 56-9 (middle), the equivalent circuit for inductive center-loading is basically the same as a reference array of straight dipoles (Figure 56-9, left) with the exception that a larger inductance has been added to the middle of the element (denoted by more coils in the schematic) to compensate for the capacitive array reactance. This distributed inductance may be synthesized by attaching a short-circuited, two-wire, transmission line stub across the terminals of the shortened dipole, as shown in Figure 56-9 (middle). The overall length of a center-loaded dipole will be approximately a third of a wavelength, as opposed to the half wavelength required for the reference straight dipole. The reflection coefficient of an inductive, center-loaded dipole array observed at broadside and 60°

FIGURE 56-9 Loading may be used to reduce the size of a reference element at resonance. (Left) a reference dipole, (center) a center-loaded dipole, (right) an end-loaded dipole.

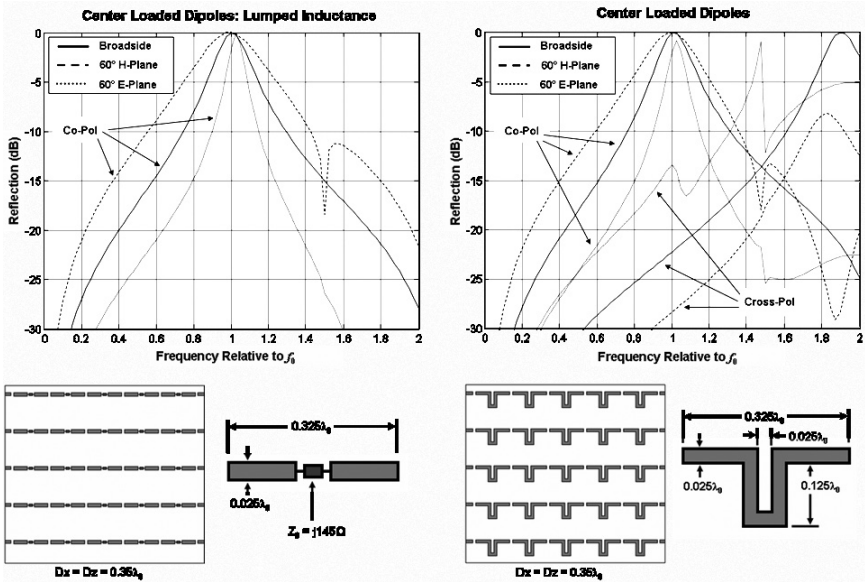

FIGURE 56-10 Comparison of the reflection coefficients for a lumped (left) and distributed (right) center-loaded dipole. Note that these elements resonate at $\sim \lambda/3$ length.

from the surface normal, for both E - and H -planes, as a function of frequency, is shown in Figure 56-10 for both the lumped (left) and distributed cases (right). It is clear from this figure that while the distributed load provides a similar shift in the resonant frequency to the lumped load, the structure associated with the distributed load has a very real contribution to the frequency response of the FSS. Specifically, as the frequency increases, the stub itself radiates, giving rise to the large cross-polarization component observed in Figure 56-10 (right). To eliminate this cross-polarization component, two mirrored center-loaded dipole elements can be connected together to form a four-legged loaded element,²⁷ because the individual cross-polarization components of each element will cancel.

A similar approach may be applied to the end-loaded dipole of Figure 56-9 (right). Here, the equivalent circuit has an inductance approximately equal to the reference array of dipoles; however, the capacitance has been significantly increased as indicated by the longer capacitor symbol. This equivalent circuit is seen to produce a lower resonant frequency (or a smaller element for the same resonance frequency). As shown in the figure, this capacitance may be obtained by the addition of an end-loading that creates a strong capacitive coupling with its neighboring element. This capacitive end-loading results in an element that is approximately a third of a wavelength, in contrast to the reference half-wavelength, straight dipole. Just as in the center-loaded case, the structure associated with the end-loading will contribute to the overall frequency response of the FSS, which should be accounted for in the element design.

In the previous discussion it was shown that reshaping the element may provide the size reduction necessary to produce an FSS operating without grating lobes. It is also clear (from Figure 56-10) that introducing this shaping by distributed loading can significantly impact the response of an FSS. This is one of the primary reasons that the large number of different element types exist for FSS. Examples of typical elements used in FSS design are shown in Figure 56-11. These elements may be broadly grouped into

FIGURE 56-11 Typical reference element types arranged in categories (after Munk²⁷ © Wiley 2003). Many combinations are possible.⁴³⁻⁴⁶

four categories²⁷—center-connected elements, loop elements, solid interior elements, and combination elements. Before discussing each of these categories, it is important to note that the electrical properties of FSS can vary dramatically due to the influence of element shape and mutual coupling.

Center-connected elements (or n -pole elements, where n is the number of legs) are formed by attaching radial “legs” from the center of the element. Examples from this category include: dipole, tripole (or three-legged element), anchor elements (or three-legged top-loaded element), and the Jerusalem cross (or four-legged top-loaded element). These elements resonate (for unloaded cases) when their length is $\sim \lambda/4$ from the center connection point to the tip of a radial leg. The simplest example of this class of elements is the straight dipole (shown in Figure 56-12 for a type-4 gangbuster surface). While straight dipole elements are capable of extremely large bandwidths because they may be packed infinitely close together (Figure 56-8), most unloaded n -pole elements are capable of modest bandwidth because they fit into a grid spacing that is just greater than a quarter of a wavelength. Typically, the parallel and perpendicular polarization patterns differ dramatically with these types of elements due to even and odd mode interactions in the parallel plane (a.k.a. modal interaction). This interaction of the even and odd mode also gives rise to a modal interaction null (Figure 56-12 insert). This is a consequence of Foster’s Reactance

FIGURE 56-12 A type-4 gangbuster surface is an example of a center-connected element. Note the modal interaction null in the E-plane between the fundamental and odd mode resonance.

Theorem,⁴⁷ which states that a null must exist between two zeros (for a lossless system). There is little that can be done with this null (an exception is to add loss to the system), but proper design of the overall FSS performance can allow the null to be placed at a frequency where the impact is small.

Examples from the loop element category include: three- and four-legged loaded elements,²⁷ square loops,⁴⁸ hexagonal loops,³⁴ and circular loops.⁴⁹ Although these elements look quite different, they all behave like loop elements with a fundamental resonance when the circumference is $\sim 1\lambda$. The second resonance occurs when the element has a circumference of $\sim 2\lambda$ for both planes of incidence. Due to their inherently small size, these elements may be packed in a grid spacing $\sim \lambda/3$. This tight grid and the lack of an odd mode second resonance makes them capable of wide band performance. Typically, the parallel and perpendicular polarized patterns of this class of elements differ very little, making them good elements for applications requiring circular polarization. Figure 56-13 shows an FSS of four-legged loaded elements formed by connecting two center-loaded dipoles (see Figure 56-10). Note that a grating lobe occurs for this configuration at $\sim 1.4f_0$ at oblique angles of incidence.

Although among the first types of elements to be investigated, by and large the solid interior elements yield poor performance and are consequently not useful for most FSS applications. Their principle shortfall is that, as most antenna engineers know, fat elements generally do not resonate. This surface can be made to resonate through element interaction with the grating lobe mechanism, but this is typically undesirable.

The final category of element is known as combination elements. These elements are generally designed to exploit one or more of the techniques discussed previously, in order to create a frequency response tailored to an application. For example, it is well known that all elements have natural resonant responses, and that they may not fall where they are needed to satisfy a required band of operation. In between these resonances a null will occur as a result of Foster's Reactance Theorem. Modification of an element by connecting various loads or dissimilar elements in order to shift these resonances leads to a virtually endless number of configurations that can be considered.

FIGURE 56-13 A four-legged loaded element is an example of a loop element. The loop is made by connecting two inductively center-loaded dipoles.

FIGURE 56-14 Concentric hexagonal elements are an example of a combination element. This element produces two resonances with a null in between as a result of Foster's Reactance Theorem.

Figure 56-14 shows an example combination element FSS, consisting of concentric hexagonal loop elements used to produce two resonances at $0.8f_0$ and $1.4f_0$.

Slot Arrays

Slot arrays can be understood as complementary surfaces of wire arrays. A complementary surface has conductor and aperture interchanged relative to the original design (see Figure 56-1). Using duality and the equivalence principle, the plane wave expansion technique described earlier in this chapter can be applied to analyze slot arrays. One would simply replace the impedance Z , with admittance Y , and evaluate the pattern factors associated with the elements using magnetic rather than electric currents. The admittance of slot arrays is related to the impedance of complementary wire arrays by the well-known Babinet's principle.

Using this approach in design will produce slot arrays with similar but dual characteristics as wire arrays (admittance and impedance are interchanged; reflection and transmission coefficients are interchanged), but only if the arrays are in free space. For duality to be applicable when dielectric materials are used with wire arrays, materials with relative magnetic permeability equal to the relative electric permittivity (and vice versa) must be used with slot arrays. This is not practical in general, especially over any range of frequencies and with low loss. Although duality does not perfectly apply, the addition of dielectric material to slot arrays does in general result in similar stabilization properties as it does with wire arrays, specifically in terms of scan angle and polarization. This is demonstrated by the example shown in Section 56.4, and is explained in detail in the reference section.²⁷ Also, because of the equivalence principle, a slot array must be considered as two isolated arrays of magnetic current placed on each side of a PEC ground plane. Therefore, two or more cascaded slot arrays will behave much differently than a corresponding cascade of wire arrays. The isolation between adjacent arrays means that cascaded slot arrays will reradiate only from the outer surfaces, whereas cascaded wire arrays will have forward and backward scattering from each array, leading to interference nulls.

All of this must be taken into consideration when employing slot arrays for designing band-pass filters or active antenna arrays. In the active antenna case, the differences between slot arrays and wire arrays becomes painfully clear when a ground plane is introduced.⁵⁰

56.4 STABILITY OF FSS WITH ANGLE OF INCIDENCE AND POLARIZATION

This section introduces two tools used to tailor the performance of FSS. The first is the use of dielectric slabs to stabilize bandwidth over angle of incidence and polarization. The second is cascading two or more FSS to shape the transmission or reflection curve for a flatter pass/stop band and a sharper roll-off.

Upon examination of Eq. 56-11, it can be seen that for cases exhibiting no grating lobes (i.e., $k = n = 0$ is the only propagating mode), the real part of the array self-impedance can be expressed as

$$R_A = \frac{Z}{2D_x D_z} \frac{1}{r_y} \left[{}_{\perp}P {}_{\perp}P' + {}_{\parallel}P {}_{\parallel}P' \right] \quad (56-19)$$

where the exponential term in Eq. 56-11 has been approximated as unity. It is evident from the $1/r_y$ term in Eq. 56-19 that R_A will vary greatly with scan angle. It is also noted that the pattern factor, a property of the elements themselves, contributes to changes in impedance with polarization as well as scan angle. Here R_A will be examined for two different element types: a simple Hertzian element of length Δl and a square loop with circumference of one-wavelength. Table 56-1 shows the pattern factor of these two elements for both perpendicular and parallel polarizations. The pattern factor expressions for the square loop element are found in the reference section.⁵¹ Figure 56-15 shows R_A plotted for these two cases. Each curve is normalized so that R_A is equal to unity at broadside. Looking at the curves for the Hertzian element, one can see that R_A changes with $1/\cos\eta$ for perpendicular polarization and changes with $\cos\eta$ for parallel polarization. For the case of the square loop element, the R_A curves are different than that of the Hertzian element, but the overall shapes are similar and it results in the same conundrum. In short, there is a divergence with scan angle of the terminal impedance of the two polarizations. The rest of this section will demonstrate how to mitigate this effect and stabilize impedance with respect to polarization and scan angle.

Dielectric Slabs

One common method of stabilizing impedance is the use of dielectric slabs. To understand the utility of dielectric slabs, it is instructive to examine an array in a semi-infinite medium, as shown in Figure 56-16. The array is located in the medium with intrinsic impedance Z_2 a distance d_2 from the dielectric interface.

TABLE 56-1 Pattern Factors of Both Perpendicular and Parallel Polarizations for Both a Hertzian Element and a One-wavelength Square Loop Element

	\perp Polarization (<i>H</i> -Plane)	\parallel Polarization (<i>E</i> -Plane)
Hertzian Element	Δl	$\Delta l \cos \eta$
Square Loop	$\cos[(\pi/4)\sin \eta]$	$[\sin \eta \sin[(\pi/4)\sin \eta] - \cos[(\pi/4)\sin \eta]]/\cos \eta$

FIGURE 56-15 Terminal resistance R_A plotted against scan angle for both parallel and perpendicular polarizations, for arrays of Hertzian elements and one-wavelength square loop elements.

It can be shown²⁷ that the overall reflection coefficient looking into the dielectric interface can be expressed as

$$\Gamma_{1,2}^a = \frac{\Gamma_{1,2} + \Gamma_A e^{-j2\beta_2 d_2 r_{2y}}}{1 - \Gamma_{2,1} \Gamma_A e^{-j2\beta_2 d_2 r_{2y}}} \quad (56-20)$$

where $\Gamma_{1,2}$ and $\Gamma_{2,1}$ are as shown in Figure 56-16. Γ_A is the reflection coefficient of the array, the simple form of which is given by Eq. 56-13. To simplify Eq. 56-20, it is beneficial to eliminate the exponential terms in the numerator and denominator. To do this, the spacing of the array in the dielectric is chosen such that $d_2 r_{2y} \approx \lambda/4$, leading to $2\beta_2 d_2 r_{2y} \approx \pi$ and

FIGURE 56-16 Array in semi-infinite medium located a distance d_2 from dielectric interface, with reflection coefficient expressions provided

hence $e^{-j\beta_2 d_2 r_{2y}} \approx -1$. Using this approximation, the reflection coefficient of Eq. 56-20 after manipulation can be expressed as

$$\Gamma_{1,2}^a = \frac{1 + \frac{jX_A}{R_A} \frac{\Gamma_{1,2}}{1 + \Gamma_{1,2}}}{1 + \frac{jX_A}{R_A} \frac{1}{1 + \Gamma_{1,2}}} \quad (56-21)$$

If it is assumed that the intrinsic impedances Z_1 and Z_2 are reasonably close in value, then the reflection coefficient $\Gamma_{1,2}$ will be small and the second term in the numerator of Eq. 56-21 can be ignored. Comparison of Eqs. 56-21 and 56-13 shows that the variance of the real part of the terminal impedance, termed the Dielectric Stabilization Factor (DSF),³⁷ for this asymmetric case is

$$_{\perp, \parallel} DSF_A = \frac{1}{_{\perp, \parallel} R_A} \frac{1}{1 + _{\perp, \parallel} \Gamma_{1,2}} \quad (56-22)$$

Figure 56-17 shows the DSF of an array of Hertzian elements (a) and an array of square loop elements (b) for both polarizations as a function of scan angle for different dielectric constants of the second medium. It is assumed that $\epsilon_1 = 1.0$ for each case. The spacing is $d_2 = \lambda/4$ in the dielectric material for each case as well. The case of $\epsilon_2 = \epsilon_1 = 1.0$ corresponds to the array being in free space, and the curves are identical to those shown in Figure 56-15. It is evident that the addition of dielectric material can be utilized to stabilize impedance (and hence reflection and transmission) properties of a FSS. Comparing Figure 56-17a and Figure 56-17b clearly indicates the importance of the pattern factor in determining the stabilization of the response, with respect to the dielectric constant of the medium chosen. The method used here can be extended to find the DSF of the symmetric case (or identical dielectric slabs of both sides of the array).

FIGURE 56-17 Asymmetric Dielectric Stabilization Factor (DSF_A) for an array of Hertzian dipoles (a) and an array of square loop elements (b) in a semi-infinite medium placed one quarter-wavelength from dielectric interface

FIGURE 56-18 Transmission curves of FSS of hexagonal slot elements

Figures 56-18 and 56-19 demonstrate this dielectric stabilization. Figure 56-18 shows the transmission properties of an array of hexagonal slot elements. Note the discrepancies of the curves at parallel and perpendicular polarizations at a 60° scan angle. Figure 56-19 shows the transmission properties of the same array but with additional dielectric slabs.

FIGURE 56-19 Transmission curves of FSS of hexagonal slot elements with dielectric slabs

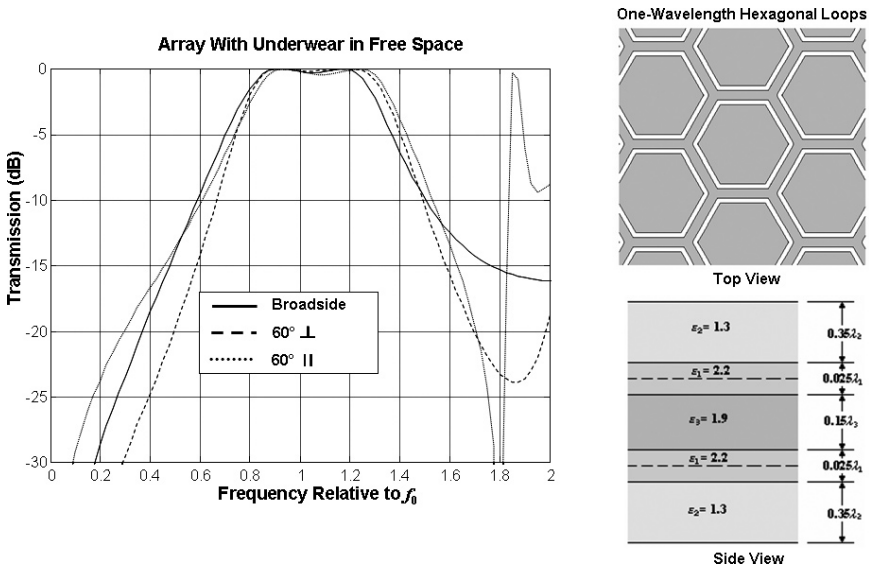

FIGURE 56-20 Transmission curves of cascaded FSS of hexagonal slot elements with dielectric slabs

Cascading FSS

While the bandwidth achieved by the FSS shown in Figure 56-19 is significant, there is (as with all single-layer FSS) essentially only one fundamental resonance. Multiple cascaded arrays can be used to shape the response curve so that it has more of a flattened top as well as a sharper roll-off. Analysis of multilayered FSS has been mentioned earlier in Section 56.2, and an in-depth discussion can be found in the reference section.²⁷ The choices in the number of layers, the separation between the arrays, and the dielectric properties of the material separating them all have effects on FSS performance. Figure 56-20 shows the transmission response for a FSS of two cascaded arrays. The arrays shown in Figure 56-20 are the same as the ones in Figures 56-18 and 56-19. Clearly, the addition of the second array has the desired effect of flattening the top of the transmission curve and sharpening the roll-off on both the lower and upper frequencies.

56.5 OTHER APPLICATIONS

Frequency selective surfaces are used in a variety of applications beyond those described in the preceding material. This final section will briefly touch on a few of those applications, in particular the ones that have been enabled by technological advances not originally developed for frequency selective surface applications. Undoubtedly, as time proceeds, more and more advanced applications will make use of frequency selective surfaces.

Reconfigurable arrays have received considerable interest at the dawn of the 21st century. A reconfigurable array has some means to change the performance of the array as needed for an application, which means that antennas or scattering arrays no longer need be considered stationary, but that they can be adapted to meet evolving needs. For example, there are some cases where an array is designed for wide bandwidth applications.⁵²

In others,⁵³ the array is reconfigured using magnetic field actuation, while in still others,⁵⁴ a static electric field is used to modify the array properties. Varactor diodes have also been used to tune the array performance.⁵⁵ One design method utilizes optimization techniques presented for a reconfigurable array without a specific implementation technology (for example, a type of switch).⁵⁶

Generally, optimization methods have been used more and more for designing frequency selective surfaces that would not have been developed using traditional intuition and knowledge of electromagnetics. In one case⁵⁶ a genetic algorithm is used, while in another a particle swarm optimization approach is used.⁵⁷ These optimization techniques typically require multiple incarnations of the array during the design procedure, and therefore efficient computational models are useful. For example,⁵⁸ a model-order reduction procedure is used to parameterize the response of the surface. Undoubtedly, advancing computational design methods will generate a variety of applications that provide niche solutions to challenging problems.

Although the majority of this chapter dealt with designs suitable for microwave and millimeter applications, significant work on shorter wavelength applications has been published.^{22,59} A significant application for periodic array surfaces is in forming reflectarrays. The literature is extensive^{60–64} on this topic, and the reader is encouraged to consult it, among other sources, for designs utilizing patch antennas and designing utilizing slots.⁶⁵

57.1 BASIC MIMO IDEAS

Recently, the employment of antenna arrays at both sides of the link has become popular in both radar and communications. These so-called Multiple Input Multiple Output (MIMO) systems involve the combination of antenna arrays, sophisticated signal processing, and wave propagation. For radar systems, the main applications are interference reduction and beamforming, in order to increase the resolution and the quality of the signals. In communication systems the aims are similar, but here the enhancement of the spectral efficiency is an additional, very important topic. The idea was first published by Winters¹ in 1987, but not much attention was paid at that time. In 1998, Foschini et al² showed that MIMO systems reach much higher spectral efficiencies than today's communication systems. Much research has since been devoted to the field of MIMO.

Wireless systems operate via the transmission of electromagnetic waves. Various propagation effects, such as the reflection of electromagnetic waves at walls, occur depending on the environment. Various means by which the waves reach the receiver are referred to as propagation paths. Usually, waves are received through various paths. This phenomenon is called *multipath propagation*. Transmission systems suffer from multipath, because the waves coming from different directions at different times interfere. This causes signal distortions called *fading*.

Multipath propagation is not a drawback, but is beneficial for MIMO, which makes use of the spatial dimension of the propagation channel. With each antenna, the energy from all waves is collected and the incoming streams are processed for coherent summation. In the case of uncorrelated reception, fading can be overcome. If two or more antennas at the receiver are spaced far enough apart that their fading envelopes are uncorrelated, the probability of system failure is dramatically reduced. In case of weak reception at one antenna, the other antenna can still provide a sufficient signal. The same effect can be utilized at the transmitter. The total transmit power is distributed between the transmit antennas and transmitted from more than one antenna. One major question is figuring out the ways that multiple antennas should be positioned for uncorrelated reception.

With multiple antennas, the spatial structure of the channel may be well exploited by using combinations of diversity and digital beamforming techniques. It is possible to transmit several datastreams simultaneously, in parallel, and at the same frequency as shown in Figure 57-1.

Figure 57-1 demonstrates how MIMO exploits the multipath structure. It shows the top view of an urban scenario with several buildings. The dominant paths between a transmitter and a receiver, which are indicated as rays, experience various phenomena such as reflection or diffraction. By employing antenna arrays at both transmit and receive, the antenna patterns can be adapted to the dominant propagation paths. If this beamforming is done in the digital domain, two (or more) different antenna patterns can be created, such that each antenna pattern focuses on different propagation paths. One datastream is transmitted by each antenna pattern. Hence multiple datastreams can be transmitted in parallel at the same frequency—spatially separated via different propagation paths—leading to a tremendous spectral efficiency.

MIMO systems exploit the multipath structure of the propagation channel by adapting the antennas to the current situation. The exploitation of the spatial structure of the propagation channel leads to an efficient use of the basic resources time, spectrum, code, and space.

A discussion of the MIMO propagation channel in Section 57.2 is followed by a description of channel modeling approaches (Section 57.3). Section 57.4 deals with antennas for MIMO systems and, finally, future prospects are given in Section 57.5.

FIGURE 57-1 MIMO exploiting the multipath structure in an urban scenario

57.2 THE MIMO PROPAGATION CHANNEL

The propagation channel is the heart of any wireless system. It is the principal contributor to many of the problems and limitations that beset mobile radio systems.

Spatial Properties and Angular Spread

A signal propagating through the wireless channel is affected by phenomena such as scattering, reflection, refraction, and diffraction of the radiated energy. Due to the large number of different propagation mechanisms, a large number of different paths usually exist between the transmitter and receiver that the signal has propagated on. These phenomena give rise to fading and path-loss.

There are two different kinds of fading. *Slow fading* arises due to shadowing effects of, for example, buildings, trees, and terrain variations, which cause the signal to fluctuate around the mean path-loss. *Fast fading* is caused by the addition of multiple paths, arriving at slightly different times, with different amplitudes and with different phases. These signal paths sometimes add constructively and sometimes destructively at the receiver, and may cause a variation in the power level of up to 20-30 dB over a distance of half a wavelength. The mean path-loss depends on the transmission distance and the environment. The loss in free space is 20 dB/decade, but in a more complex environment a loss of 40 dB/decade is common.

Due to the multipath, a signal will arrive at the receiver by different paths. Since these paths have different lengths and angles of arrival, there will be a spread of the signal in time and direction. The spread in direction is referred to as angular spread, a fundamental means to describe the spatial properties of transmission channels. The power azimuth spectrum describes the spatial wave propagation properties found at a transmit or receive antenna.

It is a statistical distribution function, modeling the power distribution versus the azimuth angle. A similar spectrum can be defined for the elevation angle.

For MIMO systems, the directions of departure and arrival of the paths are crucial, because different signals are separated by these angles. The more directions that exist, the better it is for MIMO. In indoor scenarios there are usually many reflecting objects between the transmitter and receiver, resulting in a large angular spread. Depending on the environment, the angular spread may vary in outdoor scenarios. Rural environments lack interacting objects, which means that the angular spread is much smaller than in urban environments with many buildings. Satellite links are usually very directive, leading to a very small angular spread.

Channel Transfer Matrix

The small scale variations of a radio signal can be directly related to the impulse response of the radio channel. The impulse response is a wideband channel characterization and contains all the information necessary to analyze any type of radio transmission. This stems from the fact that a radio channel may be modeled as a linear filter with a time-varying impulse response $h(t, \tau)$, where the temporal variation (described by the variable t) is due to spatial receiver motion or time-varying propagation conditions (for example, moving obstacles). Alternatively, the radio channel can be characterized by the Fourier transform of the impulse response, for example, the time-varying channel transfer function $h(f, t)$. It is defined as the ratio of the receive voltage V_R to the transmit voltage V_T (voltages at the antenna feeds).

$$h(f, t) = \frac{V_R(f, t)}{V_T(f, t)}$$

Under certain conditions, the equivalent baseband impulse response can be written as

$$h(\tau, t) = \sum_{i=1}^{P(t)} b_i(t) e^{j\phi_i(t)} \delta(\tau - \tau_i)$$

This is very intuitive. The received signal for an impulse $\delta(t)$ exciting the channel consists of a series of attenuated (b_i), phase-shifted (ϕ_i), and time-delayed ($\tau - \tau_i$) replicas of the signal, each corresponding to one of the P paths. However, in reality the channel is always band-limited. Thus the Dirac impulse has to be replaced by some filter function characterizing the finite bandwidth of the channel. If the multipath components arrive at the receiver almost at the same time compared to the symbol duration, the channel is called *flat fading channel*. In this case, the channel transfer function merges into a complex channel coefficient h describing the attenuation and phase shift of the channel.

Figure 57-2 shows the radio frequency link of a MIMO system. It consists of several transmit antennas, the physical channel, and several receive antennas. Each transmitted signal is received by all receive antennas. The channel is described by the complex channel coefficient for the flat fading case. For each pair of transmit (T, j) and receive (R, i) antennas, the channel coefficient is

$$h_{ij}(t) = \frac{V_{R,i}(t)}{V_{T,j}(t)}$$

the ratio of the complex voltage at the receive antenna to the complex voltage at the transmit antenna.

FIGURE 57-2 MIMO system

For a MIMO system with M transmit and N receive antennas, the channel is described by the channel matrix

$$\mathbf{H} = \begin{pmatrix} h_{11} & h_{12} & \cdots & h_{1M} \\ h_{21} & h_{22} & & \vdots \\ & & \ddots & \vdots \\ h_{N1} & \cdots & \cdots & h_{NM} \end{pmatrix}$$

which contains the channel coefficients linking all different pairs of transmit and receive antennas. The channel matrix \mathbf{H} is the fundamental means of describing the MIMO transmission channel. It serves as the input for the calculation of the spectral efficiency, which is often referred to as the *MIMO capacity*.

In a MIMO system there is not a single transmit signal, but a whole transmit signal vector \mathbf{s} whose elements describe the signals transmitted by the single antennas. Hence the receive signal is also a vector \mathbf{y} . The whole MIMO system is described by

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n}$$

where \mathbf{n} is an N -dimensional additive Gaussian noise vector.

57.3 MIMO CHANNEL MODELING

For system design, testing, antenna development, and evaluation, a model of the propagation channel is necessary. Early classical models, which were developed for narrowband transmission systems, only provided information about the signal power level distribution and Doppler shifts of the received signals. An example is the Hata-model,³ which is widely used in GSM network planning. It predicts the log-normal path-loss and thereby provides an estimate of the mean signal level.

As wireless systems became more complex and more accurate models were required, additional concepts such as time delay and angle of arrival were incorporated into channel models. For MIMO systems the spatial structure, temporal structure, the joint spatial and temporal structure, and polarization behavior have to be modeled as well. There are many studies addressing the properties of the MIMO propagation channel. These efforts have resulted in realistic characterizations of the propagation channel for different environments, for example, indoor or outdoor.

Stochastic Models and the Extrapolation Method

Stochastic models reflect time-variant channel behavior and have the advantage of short simulation times. Most channel models consider only channel impulse responses without any more detailed multipath information. MIMO systems require the consideration of the radiation directions of the multipath components at the transmitter and their angles of arrival at the receiver. Zwick et al⁴ have introduced a stochastic channel model based on physical wave propagation, which allows a fully polarimetric wideband description of the multipath channel including path directions. Each multipath component is characterized by its transfer matrix (including loss), delay, direction of arrival, and departure. The appearance and disappearance of multipath components over time is modeled as a birth and death process (a marked Poisson process), which enables the correct modeling of spatial and temporal correlations. In each modeling step, path properties change according to the motion of the transmitter and receiver. The changing delay times of propagation paths yield a realistic Doppler behavior for the channel. Data sets, which are required for the statistical evaluation of the parameters of the model have been obtained by ray tracing simulations and narrow-band, wideband, and directional channel measurements. The azimuthal power profile of the stochastic channel model is composed of several Laplacian functions, each modeling a cluster of scatterers. The elevation profile is also modeled by Laplacian functions for paths with a short delay time, changing to a sinusoidal function for paths with a long delay time. The channel model delivers the channel impulse response, the angle of departure of all paths at the transmitter, and the angle of arrival of all paths at the receiver for the SISO (system with one transmit and one receive antenna) case.

With knowledge of the channel for the SISO case, the MIMO channel matrix can be derived,⁵ as long as, first, the antenna spacings do not extend several wavelengths (for example, when the same plane waves impinge at all antenna elements), and second, the distances between transmitter and receiver and any obstacles in the channel are large enough to assume plane waves impinging at the arrays. With these assumptions the MIMO channel matrix results from the coherent addition of the impinging waves at the different antenna positions. The channel impulse responses, or in the flat-fading case the channel coefficients h , are derived by placing virtual antennas in the vicinity of the SISO transmit and receive antennas. The phase difference of the incident plane waves at the different antenna positions is described by $\Delta\varphi$ (illustrated in Figure 57-3), which is a function of the angle of arrival of the waves and the antenna positions:

$$\Delta\varphi = \frac{2\pi}{\lambda} ((x_{\text{SISO}} - x_{\text{vir}}) \cos\phi \sin\theta + (y_{\text{SISO}} - y_{\text{vir}}) \sin\phi \sin\theta + (z_{\text{SISO}} - z_{\text{vir}}) \cos\theta)$$

The difference of the amplitude of the plane wave at the positions of the virtual antennas is neglected; that is, the amplitude is assumed to be constant for all antenna positions. The result is the channel coefficient for all virtual receive and transmit antennas

$$h = \sum_{i=1}^{P(t)} b_{1,i} e^{j\varphi_{1,i}} e^{-j\Delta\varphi_{1,i}^{\text{Tx}}} e^{-j\Delta\varphi_{1,i}^{\text{Rx}}}$$

where $b_{1,i}$ is the attenuation of the i -th path in the SISO channel and $\varphi_{1,i}$ is its phase.

Deterministic Characterization

Ray tracing provides an adequate means to model the multipath wave propagation for MIMO channels. A channel model for outdoor environments has been introduced by

FIGURE 57-3 A plane wave is impinging on the array. The phase difference of the plane wave at the different antenna positions is $\Delta\phi$.

Maurer et al,⁶⁻⁷ which allows for an accurate narrowband and wideband characterization of outdoor MIMO channels. The propagation phenomena taken into account are combinations of multiple reflections, diffractions and scattering from trees. Modified Fresnel reflection coefficients, which account for slightly rough surfaces, are used to model the reflections. Diffractions are described by the uniform geometrical theory of diffraction (UTD) and the corresponding coefficients for wedge diffraction. Scattering from trees is considered to be totally incoherent, i.e., no distinct specular component is present. This assumption holds if the wavelength is smaller than the dimensions of the randomly distributed leaves and branches.

Depending on the propagation phenomena, different approaches to ray tracing exist. In order to trace pure reflection paths, the method of image transmitters (image theory) is implemented. Since the proposed propagation model supports full 3D diffraction, Fermat's principle is used to determine the diffracted ray paths. For mixed paths, image theory and Fermat's principle are combined. As only single scattering from trees is taken into account, the scattering paths are defined by the position of transmitter and receiver and the position of the central point of the tiles into which the tree model is subdivided.

Figure 57-4 shows the result of the ray tracing for one snapshot of an urban road traffic scenario. The receiver and transmitter are positioned on two cars with a truck between them resulting in a non-line-of-sight condition. In order to keep track of the result, only the 30 strongest propagation paths are indicated (bright lines). It can be seen that part of the transmitted energy is diffracted around the truck. Since there are many buildings next to the road, the expected street canyon effect arises. Scattering from single trees contributes to the received signal as well.

For MIMO systems, ray tracing can be applied for the calculation of the channel linking each pair of transmit and receive antennas.⁸

Geometry-Based Stochastic Channel Modeling

Spatial properties of the radio channel—such as the directions of departure and arrival of paths—are crucial for MIMO systems. If MIMO is employed by several users, the

FIGURE 57-4 Ray tracing result

spatial properties of the channel experienced by adjacent users are similar. This means that for decreasing distance between neighboring links the correlation of the channel parameters should increase. Also these spatial dependencies should be incorporated in a channel model. Ray tracing is the best means to include all spatial properties. For MIMO systems, each channel coefficient of the channel transfer matrix has to be calculated for each user; thus, the calculation effort is extensive. The so-called geometry-based stochastic channel models provide a solution—the fast calculation time of stochastic models is combined with spatial properties and dependencies provided by ray tracing.

A geometry-based stochastic channel model has been introduced by Fügen et al.⁹ The propagation environment is randomly generated in pre-processing and stays fixed during the whole simulation. It is an urban environment consisting of buildings and streets, which are arranged as a Manhattan-like street grid. All buildings are placed along the streets. A number of fixed scatterers are distributed uniformly in the whole 3D simulation environment. The simulation environment may contain several MIMO transmitters and MIMO receivers. Each mobile station is located in a circular/elliptical cylinder that defines the local cluster (as shown in Figure 57-5). The cylinder serves as a search function—only scatterers within the cylinder are active scatterers and contribute to the channel transfer function. Scatterers are modeled as ideal conductive and rectangular plates. The single-bounced rays between the mobile station and the base station can be calculated according to the scattering models also applied in ray tracing.

To account for a time variant channel behavior, the channel model is combined with a mobility model. Mobile stations move linearly along the street and may change their direction at each intersection. When the mobile station MS moves to the point MS', a number of new scatterers contribute to the received signal, while at the same time some old scatterers fade out. The shape and the size of the local cluster is adjusted depending on the position of the mobile station. If the mobile station is located in a street canyon, the local cluster is modeled as an elliptical cylinder aligned parallel to the street. If the mobile station is positioned at an intersection, the local cluster is approximated by a circular cylinder.

FIGURE 57-5 Scatterers and the local cluster

In macro-cellular environments, the street grid with adjacent buildings on both sides represents a waveguide. Interaction points in the surrounding of an intersection are placed as additional scatterers in a circular cylinder at each intersection, as shown in Figure 57-6. The rays propagate from the base station towards these scatterers. If the scatterer is visible from the mobile station, the scattered ray propagates as a guided wave along the street canyon towards the mobile station. This can be calculated by the 3D image theory.

To give a complete description of the wireless channel, models for far-distance clusters and line-of-sight are included as well.

FIGURE 57-6 Scattering in a street canyon calculated by 3D image theory

57.4 ANTENNAS IN MIMO SYSTEMS

MIMO is associated with exploiting the spatial domain of the propagation channel and involves sophisticated signal processing. The employment of antenna arrays at both sides of the link is essential for MIMO, and finding feasible antenna configurations is an integral part of enabling the MIMO technology. The channel coefficients are influenced by the antenna properties. As the antennas are colocated in a MIMO array, mutual coupling effects may occur. All these effects should be considered when designing an antenna array for MIMO systems.

Antenna Evaluation

MIMO systems take advantage of the spatial properties of the propagation channel. Therefore, in the evaluation of MIMO antenna arrays, it is necessary to use a proper characterization of the spatial channel properties. Parameters, such as the angular spread of the waves impinging at the receiver, have a significant influence on the MIMO system performance. A meaningful conclusion from a comparison of MIMO antenna arrays can only be drawn if the spatial properties of a realistic propagation channel have been taken into account.

The combination of sophisticated signal processing and multiple antennas leads to an adaptation of the MIMO system to the multipath structure of the channel. In environments where MIMO systems can be applied, the propagation situation changes rapidly. Hence it is not sufficient to investigate the performance of MIMO antennas at one specific moment and use only one realization of the propagation channel. The performance of a MIMO array is determined by the ability of the array to adapt to the changing channel conditions. As such, antenna evaluation is not possible in a simple manner. Both the antenna arrays and the propagation channel should be treated together, with a statistical description, to take into account different channel realizations of a given propagation environment. To obtain statistically relevant performance data when comparing multi-antenna configurations, several hundred meters of measurement routes in several types of propagation environments would be needed for each prototype antenna. This is almost impossible in practice due to the large amount of measurements needed, but also due to restrictions imposed by the authorities on the usage of the frequency bands in which commercial communications networks are already operating. Channel models allow for simulations required to evaluate MIMO antennas.

For the development of MIMO antenna arrays, evaluation mechanisms are needed in order to draw comparisons between different antenna arrays. There are several antenna properties that can be assessed by classical antenna measures, for example, radiation pattern, antenna gain, self and mutual coupling impedances, half-power beamwidth, bandwidth, frequency range, and resonant frequency. If an antenna array is employed in a MIMO system, some more specific figures of merit that can take into account the propagation channel are required. These figures of merit are statistical measures, which describe the antenna array performance for specific propagation channels. The following is an overview of MIMO-specific evaluation criteria for antenna arrays.

As MIMO systems are known for their capacity enhancement for future mobile communications, the instantaneous channel capacity is the most important measure for the evaluation of MIMO systems. It is described in the following paragraph. There are two main properties that determine the capacity of a MIMO system: correlation properties and the power level or efficiency in terms of power. Hence evaluation criteria are needed both for the correlation properties and for the efficiency in terms of power which will be introduced in subsequent paragraphs.

The channel capacity depends on the number of transmit and receive antennas M and N , the channel matrix \mathbf{H} , and the signal-to-noise ratio (SNR). The channel matrix is often

normalized so that it is independent of the channel attenuation. \mathbf{H}_F is the channel matrix that is normalized with the Frobenius matrix norm, so that the mean attenuation of each channel matrix trace $(\mathbf{H}_F \mathbf{H}_F^*)/MN$ is equal to one. The capacity is expressed as a function of the SNR at the receiver. For the sake of simplicity only MIMO systems without channel state information at the transmitter are considered in the following. With this assumption, the transmit power is equally (but not optimally) spread among the transmit antennas. The instantaneous channel capacity of a MIMO system in the presence of spatially uncorrelated Gaussian distributed noise can be calculated by

$$C = \log_2 \left(\det \left(\mathbf{I} + \frac{\text{SNR}}{M} \mathbf{H}_F \mathbf{H}_F^* \right) \right)$$

where \mathbf{I} is the identity matrix and $(\cdot)^*$ denotes the complex conjugate transposition. The channel attenuation, which is included in the channel matrix, has to be expressed in the SNR when normalizing the channel matrix. The attenuation is influenced by the antennas and the radio channel. With this normalization, the influence of the correlation properties on the capacity becomes visible, but any interrelation between the SNR and the correlation properties of \mathbf{H} is neglected. As the antennas have an impact on both the SNR and the correlation properties, this normalization does not predict the behavior of different antenna arrays properly. In real systems, the effect of antennas is included in the channel matrix and the normalization of the channel matrix eliminates some of the antenna effects. Therefore another approach is needed to preserve the antenna effects, allowing for a fair comparison of MIMO antenna arrays. If \mathbf{H} is not normalized, as in if the path loss and the gains of the single antenna elements are included in \mathbf{H} , the capacity of a MIMO system can be written as

$$C = \log_2 \left(\det \left(\mathbf{I} + \frac{P_T}{\sigma_n^2} \mathbf{H} \mathbf{H}^* \right) \right)$$

This equation expresses the capacity as a function of the transmit power P_T . The attenuation of the transmission link, influenced by the antennas and the radio channel, is taken into account. σ_n^2 is the noise power. This formula allows for a comparison of different MIMO systems, including the influence of the transmission gain and the SNR. Without normalization the capacity is an appropriate figure of merit for the comparison of MIMO systems employing different antenna arrays.

The correlation properties of \mathbf{H} influence the capacity. The different definitions commonly used are the complex signal (ρ_s), envelope (ρ_e), and the power correlation (ρ_p) coefficients. One can express the complex signal correlation coefficient as

$$\rho_s = \frac{E\{h_1 h_2^*\}}{\sqrt{E\{h_1 h_1^*\} E\{h_2 h_2^*\}}}$$

where h_1 and h_2 are complex channel coefficients and E is the expectation operator. h_1 and h_2 represent any two channel coefficients of the channel matrix \mathbf{H} . The definition of the envelope and the power correlation coefficients are

$$\rho_e = \frac{E\{|h_1| \cdot |h_2|\}}{\sqrt{E\{|h_1| \cdot |h_1|\} E\{|h_2| \cdot |h_2|\}}}$$

$$\rho_p = \frac{E\{|h_1|^2 \cdot |h_2|^2\}}{\sqrt{E\{|h_1|^2 \cdot |h_1|^2\} E\{|h_2|^2 \cdot |h_2|^2\}}}$$

In literature, the most common reference to MIMO performance is in terms of the power and envelope correlation.¹⁰ It is a widely held assumption that $|\rho_s|^2 \approx \rho_e$. It has been both experimentally and analytically shown that $\rho_e = \rho_p$ for all practical purposes. The power correlation coefficients can be calculated for MIMO systems with different antenna arrays, leading to a comparison of antenna arrays for MIMO. The number of correlation coefficients between all elements h_{ij} in \mathbf{H} is N^2M^2 , and thus it is a large effort to assess the correlation properties. It is difficult to show the direct relationship between the capacity distribution and the correlation properties. Correlations also play an important role in diversity systems with multiple antennas at one side of the link only.

The power level is the second important property influencing the capacity. To assess single antennas in an array, the mean effective gain (MEG) can be used.¹¹ The MEG is defined as the ratio of the mean received power of an antenna under test to the mean received power of a reference antenna, when both antennas are used in the same channel with the same transmit antenna. To ascertain that the MIMO system works properly, all antennas need to have an MEG that is approximately equal and as high as possible. If the antenna elements in a MIMO array do not have similar mean effective gains, a branch power imbalance may occur, deteriorating the system performance. The definition of the MEG can be extended to assess arrays. The mean effective array gain (MEAG) is the ratio of the mean received power of an array to the mean received power of a reference antenna in the same channel with the same transmit antenna. Mutual coupling among closely spaced antennas not only influences the signal flow and the correlation properties, but can also strongly reduce the efficiency in terms of power of an array. This is undesirable since most handheld devices are battery powered.

The power transmission gain is a figure of merit for the whole MIMO link, including the antenna arrays at the transmitter, the propagation channel, and the antenna arrays at the receiver. The power transmission gain is the ratio of the power received at the signal drain to the power fed into the transmit antennas. The latter is not equal to the power which is radiated from the transmit antennas if the efficiency of the transmit array is not 100%. Conclusions on the performance of the arrays in terms of power can be drawn by comparing the power transmission gain of MIMO systems with different arrays in the same channel.¹²

The channel capacity measured in a reverberation chamber has been used as a figure of merit instead of quality measure for the antenna configurations.¹³ The measurements are repeatable, allowing for the comparison of different antenna arrays, although the environment does not necessarily correspond to real propagation channels.

Mutual Coupling and Radiation Efficiency

As mentioned before, the antennas have an impact on efficiency in terms of power. The mean effective gain, mean effective array gain, and power transmission gain are figures of merit for the efficiency of MIMO antenna arrays. The antenna configuration has a significant influence on the total received power. Mutual coupling effects found among the antenna elements in a MIMO array have an influence on power and capacity still under investigation. Seemingly conflicting reports on mutual coupling between antenna elements increasing¹⁴ or reducing¹² capacity might not be conflicting at all. Both effects are, in principle, plausible. On one hand, mutual coupling changes the individual antenna patterns. This creates diversity as each antenna “sees” different portions of the surrounding scatterers (pattern diversity). But the effect seems to be small unless the antennas are located very close to each other. On the other hand, mutual coupling may, by re-radiation of received power, result in higher spatial correlation between antenna signals; a possible cause for reduced capacity. However, correlation is not solely caused by mutual

coupling and depends on a number of other factors as well. Antennas in close proximity to each other and to lossy material, like human tissue, also suffer from reduced radiation efficiency. This is an effect which is intricate to measure, but it becomes extremely important when comparing the performance of an antenna array with that of a single antenna. One way to tackle this problem is the description of the MIMO communication link including transmit antennas, propagation channel, and receive antennas by scattering parameters.¹² Current findings indicate that spatial correlation has little effect in comparison with radiation efficiency.

Antenna Configurations

Due to the fact that the antennas and the propagation channel interact in MIMO systems, the antenna configuration has to be chosen carefully. The antenna type as well as the arrangement of the elements in a MIMO array strongly influences performance. Goals are a high efficiency in terms of power and a low correlation by exploiting various propagation paths. A major challenge is the integration of multiple antennas in small handheld devices as space for placing the antennas is extremely limited.

The following example uses half-wavelength dipole antennas to demonstrate how the antenna configuration affects MIMO capacity. In Figure 57-7, the capacity calculated without normalizing the channel matrix is shown for several antenna configurations. The propagation channel is modeled by a path-based indoor channel model. Various dipole arrangements are compared, for example, parallel dipoles, orthogonal dipoles, and other arrangements employing various orientations of the dipole elements. The capacity is shown with respect to the total size of an array, which is indicated in grey. This array size is very important for the integration of multiple antennas in handhelds. It is remarkable that for small array sizes an array with two elements outperforms arrays with three or four elements. Systems employing polarization diversity are robust against polarization mismatching, which is demonstrated by a rotation of the transmit array relative to the receive array. Three dipole antennas arranged as a triangle lead to the best result for small array sizes. This arrangement combines spatial, pattern, and polarization diversity, and thus the combination of different diversity techniques leads to capable solutions.

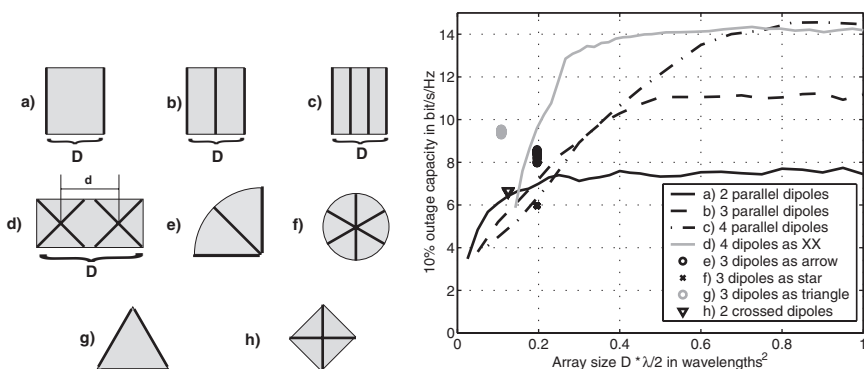

FIGURE 57-7 Arrangement of dipole antennas and MIMO capacity (after C. Waldschmidt et al¹² © IEEE 2004)

Integration of MIMO Antennas into Handhelds

Very compact antenna arrays are needed for the integration of antennas for MIMO into handheld devices. In this section, the integration of MIMO antenna arrays into handheld devices is demonstrated by two examples. The first example is a model of a portable device such as a mobile phone.¹⁵ It is equipped with three inverted-F antennas operating at a frequency of 2 GHz. The aim of the antenna configuration was to combine all the different diversity techniques described previously, such as pattern, spatial, and polarization diversity. The simulation model of the small handheld consists of a metallic block, representing the battery and the display of the device, and a PVC housing with a wall thickness of 2 mm, (as shown in Figure 57-8). The size of the housing is $55 \times 115 \times 27 \text{ mm}^3$ with the metallic block measuring $40 \times 80 \times 10 \text{ mm}^3$. Three antennas were mounted onto the metallic block, spatially separated and with different orientations. Usually inverted-F antennas require an infinite ground plane, which is not available in the small handheld. Thus the metallic block is effectively a finite ground plane, which influences the shape of the patterns and the mutual coupling impedances. The whole device was simulated with a standard EM code based on method of moments. The pattern of the coupled antenna system, as well as the mutual coupling and self-impedances of the antennas, were calculated and served as an input for the model of a MIMO transmission link.¹² The channel model is a stochastic, fully polarimetric, three-dimensional and path-based indoor channel model. On the other side of the link an antenna array setup, consisting of three half wavelength dipole antennas arranged as a triangle, was used.

For comparison, Table 57-1 presents figures of merit for the MIMO system mentioned previously, a much larger reference MIMO system with three vertical half-wavelength dipoles with half-wavelength spacings on each side of the link, and a single antenna system as reference. The correlation is very low for both MIMO cases. However, the capacity differs due to the fact that the mean effective gain is worse for the three small inverted

FIGURE 57-8 Model of a mobile phone with three inverted-F antennas (after C. Waldschmidt et al¹⁵ © IEE 2005)

TABLE 57-1 Performance Comparison of MIMO Systems¹⁵

	Power Correlation Coefficients	Mean Effective Gain (MEG)	10 Percent Outage Capacity
3 × 3, handheld and dipole triangle	all < 0.1	all antennas –2.5 dB	4.7 bit/s/Hz
3 × 3, parallel dipoles, half-wavelength spacing	all < 0.1	all antennas –1.2 dB	5.7 bit/s/Hz
1 × 1, dipole	–	0 dB	1.1 bit/s/Hz

F-antennas because of mutual coupling. Compared with a single antenna system, a huge capacity gain is possible, even if three antennas are integrated into a small handheld.

Another example¹⁶ discusses the case in which three antennas were integrated in a personal digital assistant measuring $80 \times 120 \times 15 \text{ mm}^3$. Each dual band antenna element covers the IEEE 802.11a/b frequency bands at 2.45 GHz and 5.2 GHz. Again the antennas are placed such that spatial, polarization, and pattern diversity are combined. Hence the power correlation is on the order of 0.1, which is sufficient for MIMO. This MIMO system outperforms a single antenna reference system in an indoor channel, even if one or two antennas are covered by the hand of a user.

When evaluating MIMO antenna configurations, both antennas and the propagation channel have to be treated simultaneously. Comparisons can be drawn employing special figures of merit for MIMO antenna arrays. The efficiency in terms of power has to be taken into account to assess arrays for MIMO. Several effects have an impact on the power transmission gain and on the MIMO performance, for example, the polarization of the antennas, the user of the handheld device, and mutual coupling effects between the antenna elements. These examples show that it is possible to effectively integrate several antennas into handhelds for MIMO operation. MIMO systems are realizable even in compact configurations.

57.5 MIMO SYSTEM ASPECTS

The potential of MIMO systems brings along several topics, not only concerning antennas and channel modeling. A question currently arising is the impact of MIMO on the complete RF transmission, including antennas, propagation channel, and RF front-ends.

RF and Digital Subsystems

Despite all the benefits of MIMO transmission, there is one major drawback: the increased complexity in both digital and analog systems. This complexity impacts both the cost of hardware and power consumption. Especially the analog part of the MIMO transceiver has to be designed carefully to avoid performance loss. Implementing MIMO techniques is a challenging task in conventional RF circuit design. The true test of the practicality of any communication system design is the performance of the system when taking into account the non-idealities of analog RF components. Although mutual interference between adjacent RF chains of a multi-antenna system causes additional performance degradation, a certain level of front-end integration will be required. MIMO techniques bring along some computational effort in the digital signal processing. The introduction of MIMO in future wireless systems leads to consequences for both RF and digital subsystems. A trade-off has to be found between quality and effort of implementation.

“Dirty” RF

The trade-off especially concerns the tough requirements for the quality of RF front-ends, as devices for the consumer market have to be affordable. Low power consumption, small size and low cost are important goals for the design of radio transceivers. However, these design goals partly contradict the demand for high performance. New problems arise in the practical implementation. Due to the finite accuracy of the analog hardware, the transmitted or received signals are threatened by several RF non-idealities such as jitter, non-linearities, phase noise, DC offset and I/Q imbalance. According to the conventional RF design paradigm, these effects have to be avoided by a proper system design leading to an increased power consumption, size or cost. Allowing the RF components to introduce analog impairments —“dirty effects”—and compensating the resulting effects in the digital domain will therefore be essential for achieving low production costs in the future.

When further integrating a complete MIMO transceiver on a single chip, these dirty effects reach into a new problem level, which requires a paradigm shift in the design of transceivers.¹⁷ “Dirty RF” means to design digital signal processing such that the system can cope with a new level of non-idealities, reducing the requirements of future RF subsystems. The “Dirty RF” design paradigm proposes to accept the RF non-idealities to a certain degree, and to compensate them digitally. Thus, power consumption, size, and cost of the transceiver can be kept at a low level.

58.1 INTRODUCTION

Mobile wireless terminals, such as handsets or phones, are subject to strong fading due to multipath propagation, particularly when used in urban and indoor environments. The performance of the terminals in such environments can be significantly improved by making use of antenna diversity. This means that the signals on two antennas (with different positions, polarizations, or radiation patterns) are combined in such a way that there are shallower fading minima on the combined signal than on each of the two contributing signals. Thereby, the signal-to-noise ratio (SNR) in the fading dips will be better, so that the fading margins in the system link budget can be reduced. The increased SNR can also be used to increase the capacity of the communication channel, if the system allows this. If there are several antennas on both the transmitter and the receiver side, it is possible to establish several communication channels through the multipath environment, which allows for even larger capacity increase. Such systems are often referred to as multiple input multiple output (MIMO) systems. This chapter describes how to characterize both single-port and multipoint antennas for use in multipath and in particular for achieving diversity and MIMO performance.

The so-called reverberation chamber¹ has, for a couple of decades, been used for the EMC testing of radiated emissions and immunity. This chamber is a metal cavity that is sufficiently large to support many resonant modes, and it is provided with means to stir the modes so that statistical field variations appear. It has been shown that the reverberation chamber represents a multipath environment of a similar type to what is found in urban and indoor environments. Therefore, in the last six years it has been extended to characterize antennas and terminals designed for use in environments with multipath propagation. This chapter will therefore also describe how reverberation chambers work and how they can be used to measure performance of antennas and active terminals, in particular when used with diversity and MIMO capability.

58.2 MULTIPATH ENVIRONMENT WITHOUT LINE-OF-SIGHT (LOS)

Traditionally, antennas were designed for use in environments where there is line-of-sight (LOS) between the two sides of the communication link. Therefore, antennas were characterized in the equivalent of a free space environment, by measurements in anechoic chambers. Still, there may in reality be additional wave paths between the transmitting and receiving sides. For example, large smooth objects located outside the LOS will cause reflection, edges of large objects will cause diffraction, and small or irregular objects will cause scattering of the waves originating from the transmitting antenna. The wave contributions via these paths will add at the receiving side. They have independent complex amplitudes (i.e., amplitudes and phases) that may add up constructively or destructively, or to anything between these two extremes. The wave paths and their complex amplitudes will also change fast with time, due to the moving of the terminal or parts of the environment, and thereby signal variations will be present at the receiver as a function of time, referred to as fading. The largest signal variations appear when the LOS is blocked. The previous type of fading is more accurately referred to as *small scale fading*, to distinguish it from the signal variations appearing only due to variations in distance from the transmitting antenna or due to partly shadowing and similar of the LOS, referred to as *large-scale fading*.²

Rayleigh Fading

The multipath environment can, at the receiving side, be characterized by several independent incoming plane waves. This independency means that their amplitudes, phases,

FIGURE 58-1 Example of a fading signal (left) and its cumulative probability distribution (CDF) function (right). The signal levels are presented in dB after being normalized to the time averaged power.

and polarizations as well as the angles of arrival (AoA) are arbitrary relative to each other. If the LOS is absent, and if the number of incoming waves is large enough (typically a few hundred), or if the antenna is moved around in a less rich environment, the in-phase and quadrature components of the received complex signal become normally distributed (Gaussian). From this, their associated magnitudes get a Rayleigh distribution, the power an exponential distribution, and the phases a uniform distribution over 2π . This is a direct result of the central limit theorem. Figure 58-1 shows an example of a Rayleigh faded signal. The signal varies by more than 25 dB. The Rayleigh fading is most conveniently illustrated by a cumulative probability density function (CDF), showing the cumulative probability of signal amplitudes in dB, also shown in Figure 58-1. The reference level for the dB values is in the figure taken to be the average received power, i.e., the total received power divided by the number of samples. There is a probability of 1‰ of having deeper dips than -30 dB, and of 1% of having deeper dips than -20 dB.

Angle of Arrival (AoA) Distribution, XPD and Polarization Imbalance

The arriving waves may have a certain AoA distribution in the elevation and azimuth planes. It is natural to assume that the mobile terminal can be oriented arbitrarily, relative to directions in the horizontal plane, which means that the azimuth angle is uniformly distributed. The terminals may, under normal use, have a certain preferred or most probable orientation relative to the vertical axis, and common environments (in particular outdoor) have larger probability of waves coming in from close-to-horizontal directions than close-to-vertical. Therefore, there may be a need for an elevation distribution function to describe real multipath environments. Real environments normally also have a larger content of vertical polarization than horizontal, because most base stations are vertically polarized. This is characterized, in propagation literature, by a cross-polar power discrimination (XPD).³ Instead, this chapter refers to XPD as a polarization imbalance in the environment, because it represents a deterioration of the isotropic reference environment defined in the next subsection. Both the AoA distribution and XPD are different in different real environments. This is problematic because the performance of the antennas and wireless terminals then depend on where they are used or measured, so that results of measurements in one environment cannot directly be transferred to another. Therefore, it is convenient to define a reference environment, which can easily be reproduced in practice, and which gives a repeatable result for the performance. The isotropic environment with polarization balance and a uniform AoA distribution over the whole sphere has this characteristic.

Isotropic Reference Environment

As explained previously, it is desirable to have an isotropic reference environment with polarization balance and a uniform distribution of AoA in both azimuth and elevation, i.e., an environment in which all polarizations and AoAs over the whole unit sphere are equally probable. This simplifies the characterization of antennas and terminals in the sense that the performance becomes independent of the orientation of the antenna in the environment. The reverberation chamber emulates such an isotropic environment. This reference environment has no true counterpart in reality, but it is still quite representative as any environment will appear isotropic if the terminal is used with arbitrary orientation in the environment. It is important here to point out that the antenna normally is not located symmetrically on the phone. Therefore, the phone has different orientations in the environment when used on the left and right sides of the head, as opposite sidewalls of the phone will point upwards for these two talk positions.

58.3 CHARACTERIZATION OF SINGLE-PORT ANTENNAS IN MULTIPATH

This section will describe how to characterize single-port antennas for use in multipath with Rayleigh fading. Naturally, this is strongly related to characterization in LOS.

Antenna Impedance, Port Impedance, and Reflection Coefficient

All antennas are characterized by their far field function $\mathbf{G}(\theta, \varphi)$ and input impedance Z_a . The far field function can be used to plot the co- and cross-polar radiation patterns and to find traditional LOS quantities such as directivity and sidelobe levels. For antennas operating in an isotropic multipath environment, the shape of the far field function does not play any significant role, particularly not for single-port antenna systems. In multipoint antennas it has some significance as it determines the correlation between received signals on the ports. Therefore, we will need to define $\mathbf{G}(\theta, \varphi)$ as well. In order to connect to other components like receivers and transmitters, the antenna must have a well-defined port (or ports), often in the form of a transmission line or a connector for a transmission line. The characteristic impedance Z_c of this transmission line then defines the port impedance, normally 50 Ohms. When the port impedance is known, the antenna impedance Z_a can be transformed to a complex reflection coefficient r on the transmission line, where

$$r = (Z_a - Z_c) / (Z_a + Z_c) \quad (58-1)$$

In an S-parameter representation of the antenna, $r = S_{11}$.

Definition of Far Field Function

If the far field function is mathematically formulated in transmit mode (caused by a given source current at the antenna port) as a complex vector field function, it can be included in the equivalent circuit of the same antenna in receive mode, as given in the next subsection. This complete complex radiation field function (containing even phase information) is also needed in theoretical multipath characterization in order to add the received voltages (with correct amplitudes and phases) from several simultaneous incident waves with different AoAs.

The far field of any antenna will have the form

$$\mathbf{E}(r, \theta, \varphi) = \frac{1}{r} e^{-jkr} \mathbf{G}(\theta, \varphi) \quad (58-2)$$

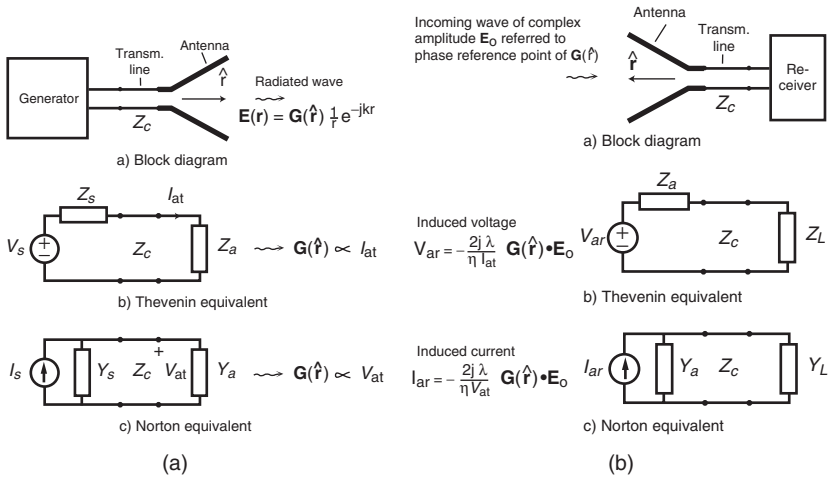

FIGURE 58-2 Transmit (left) and receive (right) equivalent circuits of antenna with far field function $\mathbf{G}(\hat{\mathbf{r}})$, input impedance $Z_a = 1/Y_a$, and port impedance Z_c . The receive case is from Section 2.5.5.⁴ The parameters in the formulas are explained in the text.

where r is the distance from the phase reference point (center of coordinate system) to the observation point, and $\mathbf{G}(\theta, \varphi)$ is the far field function.⁴ $\mathbf{G}(\theta, \varphi)$ is a complex vector function of direction (θ, φ) from the phase reference point to the observation point. It is written alternatively as $\mathbf{G}(\hat{\mathbf{r}})$, where $\hat{\mathbf{r}}$ is a unit vector in the direction (θ, φ) . The far field function is shown in the equations in Figure 58-2. The total radiated power expressed by $\mathbf{G}(\theta, \varphi)$ becomes

$$P_{\text{rad}} = \frac{1}{2\eta} \iint_{\Omega} |\mathbf{G}(\theta, \varphi)|^2 d\Omega \quad (58-3)$$

with η the free space wave impedance. The $1/2$ factor comes because of the use of peak-valued complex vectors rather than effective-valued ones.

The far field function can be determined analytically, by measurements, or by simulations. In the latter case in order to avoid mistakes, it is safest to use a realizable source at the port, i.e., either of the two generator models (Thevenin or Norton) in the left part of Figure 58-2. The source impedance Z_s must be chosen to be equal to the defined port impedance Z_c . Often, the far field $\mathbf{E}(\mathbf{r}) = \mathbf{E}(r, \theta, \varphi)$ is computed at chosen directions (r, θ, φ) on a sphere of fixed radius r around the antenna. The far field function is then determined from the far field in these points by

$$\mathbf{G}(\theta, \varphi) = \mathbf{E}(r, \theta, \varphi) r e^{jkr} \quad (58-4)$$

provided r is large enough. The far field function in receive mode is the same as in transmit mode.

Equivalent Circuits of Transmit and Receive Antennas

The equivalent circuit of an antenna is well known when it is transmitting, as shown in the left part of Figure 58-2. But, when there is a need to analyze diversity and MIMO

antennas theoretically, the equivalent circuit in receive mode is needed. Receive equivalent circuits are given in many textbooks, but they are often not complete. The formulas for induced open-circuit port voltage V_{ar} in the Thevenin equivalent and the induced short-circuit port current I_{ar} in the Norton equivalent can be given explicitly from the far field function and the incident wave E_0 . Such complete equivalent circuits can be found though,⁴ and they are also included in the right part of Figure 58-2. The formula for V_{ar} (alternatively I_{ar}) is given in terms of the following parameters: the wavelength λ , the free space wave impedance η , the far field function $G(\theta, \varphi)$ calculated for the transmit mode as explained previously, and finally by the current I_{at} into the antenna port (alternatively the voltage V_{at} at the antenna port) when the far field function $G(\theta, \varphi)$ of the antenna was calculated. See the definitions I_{at} (alternatively V_{at}) in the left part of Figure 58-2.

Far field functions should, as explained previously, always be calculated when the antenna is excited by a complete Thevenin or Norton equivalent circuit for an impedance-matched generator at the input, i.e., using $Z_s = Z_c$ or $Y_s = Y_c = 1/Z_c$. Then,

$$I_{at} = V_s / (Z_c + Z_a) \quad (58-5)$$

in the formula for V_{ar} in the Thevenin equivalent circuit for the receiving case, and

$$V_{at} = I_s / (Y_a + Y_c) = I_s Z_a Z_c / (Z_a + Z_c) \quad (58-6)$$

in the formula for I_{ar} in the Norton equivalent circuit for the receiving case.

Mean Effective Gain (MEG) and Mean Effective Directivity (MED)

Antennas in fading environments are sometimes characterized by the so-called mean effective gain (*MEG*). The formula for *MEG*^{3,5} can be calculated from the far field function of the antenna, and it is a function of the orientation of the antenna, its polarization, and the azimuth and elevation distributions of the AoA in the environment, as well as the XPD of the environment. For the isotropic environment, the *MEG* becomes equal to half the classical total radiation efficiency e_{rad} , i.e.,

$$MEG = e_{rad} / 2 \quad (58-7)$$

Actually, for an arbitrary environment the *MEG* can be separated in two factors: the classical total radiation efficiency and a mean effective directivity (*MED*),⁶ i.e.,

$$MEG = MED \cdot e_{rad} \quad (58-8)$$

In this way the *MED* solely contains the effect of the environment and the shape of the radiation pattern, whereas the radiation efficiency contains the effects of losses and impedance mismatch. The formula for *MED* is the same as for *MEG*, but the realized gain for the far field functions in the formula for *MEG* must be replaced by directive gain far field functions in the formula for *MED*, where the realized and directive gains are standard IEEE definitions. Thereby, the relationship between *MEG* and *MED* becomes the same as the relationship between the classical realized and directive gains for LOS systems (radiation efficiency). The radiation efficiency can, for instance, be measured in a reverberation chamber. The formulas for the *MEG* and *MED* are not shown here, because the consideration here is isotropic environments.

Total Radiation Efficiency

From the previous subsections, it can be stated that for antennas in an isotropic multipath environment the performance is determined only by the total radiation efficiency and not by the shape of the radiation pattern or the realized gain. The definition for the total radiation efficiency used here is the ratio between the total radiated power and the maximum available power that can be delivered from the generator. Thus,

$$e_{\text{rad}} = P_{\text{rad}} / P_{\text{in,max}} \quad (58-9)$$

where the maximum available power appears when $Z_a = Z_c$ and becomes either

$$P_{\text{in,max}} = \frac{1}{2} Z_c |I_{\text{at}}|^2 \quad \text{or} \quad P_{\text{in,max}} = \frac{1}{2} |V_{\text{at}}|^2 / Z_c$$

with I_{at} and V_{at} defined previously, depending on whether the Thevenin or Norton equivalents are used, respectively. For a lossless antenna, this is known to be

$$e_{\text{rad}} = 1 - |r|^2 \quad (58-10)$$

where r is the complex reflection coefficient at the antenna port defined in Eq. 58-1.

58.4 CHARACTERIZATION OF MULTIPORT ANTENNAS IN MULTIPATH

In LOS systems it is possible to increase the signal-to-noise ratio by increasing the directivity of the antennas, because the received signal increases with the gain of both the transmit and receive antennas. However, in the previous section it was shown that antennas in isotropic multipath environments do not get improved performance by increasing directivity. Still, several antenna elements can be used to form a diversity or MIMO system, but to get improved performance the signals must be processed in a more advanced way than in classical arrays.

To realize antenna diversity and MIMO systems, several antenna elements need to be located together in an array. This is not a classical array, in which the antennas are combined with certain amplitude and phase relations between them. Therefore, the diversity or MIMO antenna is called a multiport antenna rather than an array, meaning that each port can be characterized as a single antenna, and that the signal inserted (transmitting case) or being present (receiving case) at each port has no prescribed amplitude and phase relation to the signals on the other ports. Instead, the signals are processed incoherently to optimize system performance.

Definition of Channel When Using Multiport Antenna Systems in Multipath

The propagation channel is defined with the antennas included. Therefore, a channel starts at one transmit port connected with one element or beam of the transmit antenna and ends up at a receive port connected with one element or beam of the receive antenna. Thus, if the transmit antenna has M ports and the receive antenna has N ports, $M \times N$ channels can be generated through the environment, as illustrated in Figure 58-3.

FIGURE 58-3 Definition of MIMO system with multipoint antennas on both the transmitting and receiving sides. There are in total $M \times N$ channels through the environment, each one defined between one input port of the transmit antenna and one output port of the receive antenna.

Isolated Elements

Classical single-beam array antennas for LOS systems have one port and are characterized by their far field functions and antenna impedances, in the same way as other single-port antennas. The latter is the impedance seen at the array port when all elements are excited with the amplitude and phase that give the desired shape of the far field function. The far field function of a classical array antenna is the product of two factors: the far field function of an isolated element (which is equal for equal elements at different location) and the array factor. The far field function of one isolated element is the far field function of this element when all the other elements are removed, but with the ground plane on which they are located present.

In theoretical work on diversity and MIMO systems, the element antennas are sometimes treated as if they were isolated, even though an array factor cannot be defined because the signals at every element are processed independently. However, this treatment must be done with care because the isolated element approach is strictly not valid when analyzing multipoint antennas. It will only give correct results if the ports are completely uncoupled, which they rarely will be in reality, except for two-port antennas with orthogonal polarizations on the two ports. The correct analysis is done by using the embedded element approach as described next.

Embedded Elements

The embedded element approach also has its background in classical array analysis. However, because it is regarded as an advanced topic compared to the isolated element approach, it is rarely covered in introductory antenna courses. The embedded element approach considers the far field of each single array element when all the other elements are present, but they are not excited and instead terminated with their port impedances. The far fields of such embedded elements are sometimes called *active element patterns*, a terminology introduced previously,⁷ but they are now more commonly and descriptively referred to as *embedded element patterns*.^{6,8} The excited antenna will induce radiating currents on the terminated non-excited antennas. Therefore, the far field function of the embedded element may be very different from that of the isolated element, in particular if the elements are closely spaced with large mutual coupling. The far field functions of the embedded elements are used to describe scan blindness in classical arrays, whereas in MIMO and diversity antennas they

play an even more significant role. In a multipath environment the received signal on each port is transmitted or detected independently relative to the signals on the other ports, and therefore each port transmits or receives signals through their embedded far field functions. In such a way, the radiation efficiency at each port as well as the correlation between the signals at all ports, are determined by the far field functions of the corresponding embedded elements. Both these quantities (radiation efficiency and correlation) are needed in order to quantify performance of diversity and MIMO antenna systems. Such analysis in terms of far field functions of embedded elements was introduced^{6,8} based on the analysis of a diversity antenna consisting of two parallel dipoles.⁹ The far field functions of embedded elements can be computed by most commercial computer programs, by exciting the port to be computed and terminating all non-excited ports with their port impedances (normally 50 Ohm). The embedded element patterns can also be measured in anechoic chambers. However, it is also possible to characterize diversity and MIMO antennas without knowing the embedded element patterns explicitly. For example, the reverberation chamber provides a way of measuring radiation efficiency and correlation without going via the embedded element patterns. It can also be used to provide measured estimates of complete communication channels, and from these the diversity gain and maximum available capacity of complete diversity and MIMO antenna systems can be obtained.

Embedded Radiation Efficiency

This subsection starts with an explanation of how to calculate the total radiation efficiency of an embedded element of a multiport antenna. Figure 58-4 illustrates a diversity antenna consisting of two dipoles and with receivers and/or transmitters on both ports. This means that the diversity combination is implemented after the receivers, and that the diversity separation is implemented in front of the transmitters. This configuration was analyzed¹⁰ by using a classical semi-analytical approach represented by the equivalent circuit in the upper part of Figure 58-5. The equivalent circuit is generally applicable to any two-port antenna consisting of single-mode radiating elements, such as dipoles, slots, and—to some degree—patches. The most accurate way to calculate this is to perform a complete numerical computation using a full-wave code of any kind. This way there is no restriction to the elements being of single-mode type. The general form of the equivalent circuit is shown in the lower part of Figure 58-5. This latter equivalent circuit doesn't show the induced currents, so it cannot be used to calculate or understand why the far field function is different from that of an isolated antenna element. This general simplified equivalent circuit is simply an illustration of the result of a numerical calculation of Z_a and $\mathbf{G}(\theta, \phi)$.

FIGURE 58-4 Illustration of diversity antenna consisting of two parallel dipoles. There are receivers and/or transmitters at each of the two dipole ports.

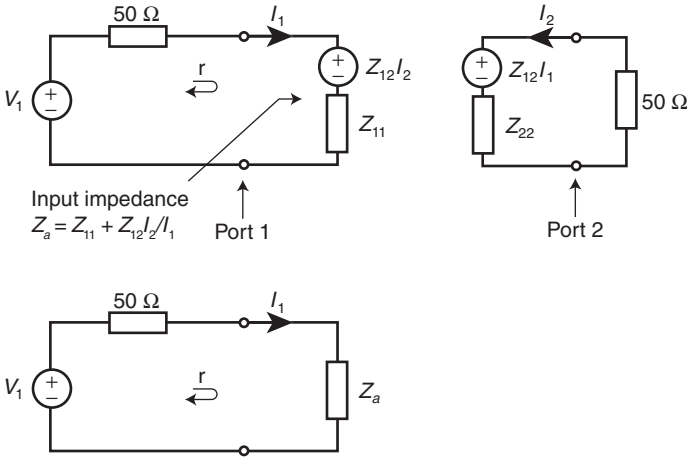

FIGURE 58-5 Upper figure: Complete equivalent circuit of a diversity antenna consisting of two single-mode elements with ports 1 and 2, respectively, when port 1 is excited and port 2 terminated with the port impedance ($50\ \Omega$), for calculation of the far field function and radiation efficiency of the embedded element 1. Lower figure: The same equivalent circuit on the general Thevenin form in Figure 58-2b, left case. The port impedance is $Z_c = 50\ \Omega$.

If the diversity antenna itself consists of materials with very small or no losses, the only contributions to the total radiation efficiency of the embedded element will be the absorption in the termination on port 2, and the reflections on the excited port 1. Using the upper equivalent circuit in Figure 58-5, the input impedance of the embedded element at port 2 is

$$Z_a = Z_{11} + \frac{Z_{12}I_2}{I_1} = Z_{11} - \frac{Z_{12}^2}{Z_{22} + Z_c} \quad (58-11)$$

where the rightmost expression is obtained by using the equivalent circuit of port 2 in Figure 58-5 (upper figure). Z_{11} and Z_{22} are the impedances of the two isolated element antennas and Z_{12} is their mutual impedance. Note that Z_a is the impedance when the equivalent circuit of port 1 has the general Thevenin form as shown in Figure 58-5 (lower figure). The power absorbed in the antenna impedance Z_a represents both the radiated power and the power absorbed in the $50\ \Omega$ termination on port 2. The reflection coefficient r at port 1 and the corresponding mismatch efficiency e_{ref} become

$$r = \frac{Z_a - Z_c}{Z_a + Z_c} \quad \text{and} \quad e_{\text{ref}} = 1 - |r|^2 \quad (58-12)$$

The total power that is accepted by port 1 is found as $P_{\text{acc}} = \text{Re}\{Z_a\}|I_1|^2/2$. The difference between this and the power $P_2 = Z_c|I_2|^2/2$ absorbed in the load on port 2 is the radiated power P_{rad} , i.e. $P_{\text{rad}} = P_{\text{acc}} - P_2$. Finally, the total radiation efficiency becomes

$$e_{\text{rad}} = e_{\text{ref}}e_{\text{abs}} \quad \text{with} \quad e_{\text{abs}} = \frac{P_{\text{rad}}}{P_{\text{acc}}} = 1 - \frac{Z_c|I_2|^2}{\text{Re}\{Z_a\}|I_1|^2} \quad (58-13)$$

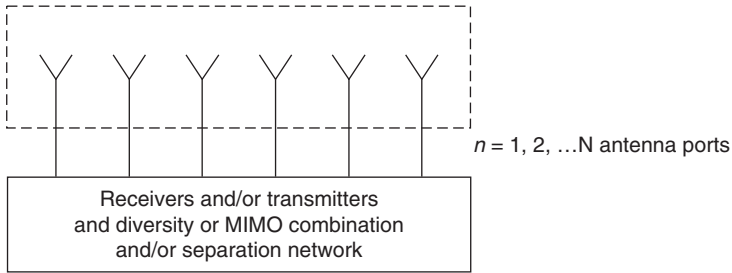

FIGURE 58-6 Illustration of N -port antenna that can be characterized by its S -parameters between all ports

where e_{abs} is the efficiency due to the power dissipated in the load on port 2. This can be expressed much simpler by using the S -parameters between ports 1 and 2, according to

$$e_{\text{rad}} = 1 - |S_{11}|^2 - |S_{12}|^2, \quad e_{\text{refl}} = 1 - |S_{11}|^2, \quad e_{\text{abs}} = \frac{1 - |S_{11}|^2 - |S_{12}|^2}{1 - |S_{11}|^2} \quad (58-14)$$

The S -parameter representation can readily be extended to any multiport antenna, such as that illustrated in Figure 58-6. The total embedded radiation efficiency of embedded element number i —when there are a total of N ports—becomes

$$e_{\text{rad}} = 1 - \sum_{j=1}^N |S_{ij}|^2 \quad (58-15)$$

There will be an additional efficiency factor if there are losses in the materials that the antenna is made from. The last equation defines a fundamental limitation also of elements in classical dense arrays.¹¹ If the elements are very close (typically closer than 0.5 wavelengths), the mutual couplings cause a severe efficiency reduction. In a classical array this fundamental limitation causes the gain not to increase proportional to the number of elements unless the element spacing is kept larger than 0.5 wavelengths.

Correlation Between Ports

The correlation coefficient ρ between received signals on two ports can be calculated from the correlation between the induced voltages in the receive equivalent circuits of the two ports, when these voltages are a result of multipath due to incident plane waves with uniform AoA distribution and polarization balance. This formula for evaluating the correlation by using a statistical distribution of induced voltages can readily be transformed to deterministic integrals in terms of the normalized coupling between the far field functions of the two ports:³

$$\rho = \frac{\iint_{4\pi} \mathbf{G}_1(\theta, \phi) \cdot \mathbf{G}_2^*(\theta, \phi) d\Omega}{\sqrt{\iint_{4\pi} \mathbf{G}_1(\theta, \phi) \cdot \mathbf{G}_1^*(\theta, \phi) d\Omega \iint_{4\pi} \mathbf{G}_2(\theta, \phi) \cdot \mathbf{G}_2^*(\theta, \phi) d\Omega}} \quad (58-16)$$

where $\mathbf{G}_1(\theta, \phi)$ and $\mathbf{G}_2(\theta, \phi)$ are the embedded far field functions of ports 1 and 2, respectively.

58.5 CHARACTERIZATION OF DIVERSITY AND MIMO PERFORMANCE

With diversity, two antennas are used, which are located sufficiently far from each other (space diversity) or with different polarizations (polarization diversity) or radiation patterns (pattern diversity). The received signal will then be uncorrelated on the two ports, and it is very unlikely that there will be a fading dip simultaneously on both ports. Therefore, by an appropriate combination of the two signals, the probability of a fading dip in the combined signal will be strongly reduced. There are several different possible combination schemes, such as switch diversity, selection combining, or maximum ratio combining, and the improvement of the CDF can be as large as 10 to 12 dB at 1% value of the CDF. The details of the different diversity schemes are not covered here.³ Selection combining will be assumed in the discussions to follow.

Diversity Gains (Apparent, Effective and Actual)

As an example, the two parallel dipoles in Figure 58-4 were characterized at 900 MHz and with a given separation between them. Figure 58-7 shows the cumulative distribution function (CDF) of fading signal amplitudes measured in a reverberation chamber. The curve of the reference antenna (a dipole with known radiation efficiency) follows the theoretical Rayleigh distribution very closely (because the curve is corrected for the known radiation efficiency of the reference antennas), which is the guarantee for a rich scattering environment. The CDF at each port of the diversity antenna also has the same shape as a theoretical Rayleigh distribution, but they are shifted to the left because their total radiation efficiency is lower. Actually, the horizontal spacing between the CDFs of the two ports of the diversity antenna and the CDF of the ideal reference is equal to the embedded radiation efficiency of the diversity antenna ports. If selection combining is applied to the signal samples on the two ports, an improved CDF is shown in the figure. The diversity gain is the difference between the selection-combined CDF and a reference CDF at a certain CDF-level, normally chosen to be 1%. It is possible to distinguish between apparent, effective, and actual diversity gains¹²⁻¹³ depending on the reference.

- **Apparent diversity gain** Difference between power levels in dB (at certain CDF level), between CDF of combined signal, and CDF of signal at the port with the strongest average signal levels.
- **Effective diversity gain** Difference between power levels in dB (at certain CDF level), between CDF of combined signal, and CDF of signal at the port of an ideal single antenna (corresponding to radiation efficiency of 100%), measured in the same environment.
- **Actual diversity gain** Difference between power levels in dB (at certain CDF level), between CDF of combined signal, and CDF of signal at the port of an existing practical single antenna that is to be replaced by the diversity antenna under test, measured at the same location (for example, relative to a head phantom).

An ideal single antenna means that the antenna has 100% total radiation efficiency, or the equivalent thereof, obtained by correcting the CDF of a practical reasonable well-matched antenna with its finite radiation efficiency. In the case of actual diversity gain, the practical antenna reference shall be located in the position relative to an object (for example a head phantom) that corresponds to the desired position of operation for the existing antenna as well as the replacing diversity antenna. Under these definitions, the actual diversity gain in dB is the effective diversity gain in dB minus the radiation efficiency in dB of the single existing

FIGURE 58-7 Cumulative probability distribution function (CDF) of measured transmission function in reverberation chamber for ideal reference antenna (corrected for its finite radiation efficiency) and diversity antenna consisting of two parallel dipoles⁶

antenna that the diversity antenna shall replace. The effective diversity gain represents the gain over a single ideal reference antenna, where the latter is measured with no additional antenna close to it.

As shown in Figure 58-7 the apparent diversity gain at 1% CDF level is 8 dB, whereas the effective diversity gain compared to the ideal single antenna reference is only about 3 dB. This means that in a system specified for a fading margin of 20 dB to be able to receive with sufficient quality 99% of the time (for example, 1% CDF level), the fading margin can be reduced by 3 dB if this specific diversity antenna (two parallel dipoles with 15 mm spacing) is used instead of a very good single antenna. The diversity gain could easily be made larger by using larger dipole spacing, or by choosing two orthogonal antennas. The theoretical maximum is 10 dB by selection combining. The discrepancy between 3 dB and 10 dB is, in the example, mainly due to the low radiation efficiency when the dipoles are spaced 15 mm apart. This is caused by mutual coupling, giving large absorption in the 50 Ohm load of the not-excited dipole. The reduced diversity gain due to correlation has, in comparison, a small effect, as explained next.

There are published results of diversity gains as a function of dipole spacing.⁶ There is also significant actual diversity gain for antennas used near the human body (a simple cylindrical head phantom). The actual diversity gains at 900 MHz is shown to be more than 6 dB, even when the dipole separation is only 2 cm. This is very promising for the use of diversity in mobile phones. Larger diversity gains will naturally be present for antennas with uncoupled orthogonally polarized ports.

Theoretical Determination of Diversity Gain

Theoretically, the effective diversity gain G_{eff} can be determined by the following formula:

$$G_{\text{eff}} = e_{\text{rad}} G_{\text{app}} \quad (58-17)$$

where G_{app} is the apparent diversity gain. This depends on the correlation coefficient ρ obtained from Eq. 58-16 by using the far field functions of the two embedded ports. The relation is approximately given by the following formula.¹⁴

$$G_{app} = 10 \cdot e_{\rho} \quad \text{with} \quad e_{\rho} = \sqrt{1 - |\rho|^2} \quad (58-18)$$

where 10 is the maximum apparent diversity gain at 1% CDF level with selection combining, and e_{ρ} is an approximate expression for the correlation efficiency, i.e., the reduction in diversity gain due to correlation between the signals on the two ports. This formula is not very accurate for correlations close to unity when compared with the correct formulas.¹⁴ However, if ρ is scaled with a factor 0.99, the formula becomes

$$e_{\rho} = \sqrt{1 - |0.99 \cdot \rho|^2} \quad (58-19)$$

which differs from the correct expression for the apparent diversity gain at 1% CDF by less than 0.1 dB (as shown in Figure 58-8). According to the graph, the correlation must be very strong in order to get significant reduction of the diversity gain.

Maximum Available Spectral Capacity of MIMO System from Shannon

Future mobile communication systems propose to make use of multiport antennas on both the base station and terminal sides to form several communication channels, i.e., a MIMO system. For example, six antennas on both sides form $6 \times 6 = 36$ possible communication channels. The data is then on transmit distributed among the channels and combined again after reception, in such a way that the overall channel capacity is maximized. This means that those of the 36 channels that provide fading maxima transfer much more bits per second than those having fading minima.

The capacity of a communication link is measured in terms of the bit rate, i.e., the number of bits per second (bits/sec). When comparing different types of communication

FIGURE 58-8 Correlation efficiency at 1% CDF, i.e., reduction of diversity gain at 1% cumulative probability level, as a function of the correlation ρ in Eq. 58-16, obtained with the approximate Eq. 58-19 and the correct expression¹⁴

systems and modulation methods, it is also important to know how efficiently they use the allocated frequency spectrum. This can be quantified in terms of a spectral capacity (bits/sec/Hz), i.e., how many bits per second that can be transferred per frequency unit Hertz. The spectral capacity will naturally increase with SNR , which therefore must be specified or known. The spectral capacity (bits/sec/Hz) is in communication engineering sometimes also called the spectral efficiency, but in this text we will use the former expression to avoid confusion with antenna efficiencies.

The maximum possible average spectral channel capacity in a MIMO system can be calculated by using a version of Shannon's fundamental formula for capacity that is extended to multiport systems. This formula and the results for a 1×6 and a 3×6 MIMO system measured in a reverberation chamber will be discussed next.

Single-Port System

The maximum available spectral capacity of a communication channel through any environment is given by Shannon's classical formula

$$C = \log_{(2)} |1 + SNR| \quad (\text{bits / sec / Hz}) \quad (58-20)$$

where SNR is the signal-to-noise ratio at the receive side, and where $\log_{(2)}$ means the logarithm with base 2. This means that the capacity of a system does not only depend on its bandwidth, but also on the SNR . Thus, if the transmit power is increased, it is possible to transfer more bits/sec/Hz over the channel. However, in order to benefit from this we have to know the SNR on the channel. Therefore, estimation of the SNR is important in communication engineering, as is the feedback of this estimate to the transmit side for controlling the capacity. The Shannon formula is also valid under fading, but then the SNR of the channel varies with time, in which case channel estimation must be performed continuously and thereby becomes a very important topic.

Parallel Channels in LOS

If two parallel communication systems are used instead of one, the capacity can be naturally doubled if they are mounted in such a way that there is no interference. This can be done by locating the antennas of the extra system in the nulls of the radiation patterns of the other. Thus, the maximum spectral capacity of two such systems corresponding to two parallel channels becomes

$$C = C_1 + C_2 = \log_{(2)} \left| 1 + \frac{1}{2} SNR_1 \right| + \log_{(2)} \left| 1 + \frac{1}{2} SNR_2 \right| = \log_{(2)} \left(\left| 1 + \frac{1}{2} SNR_1 \right| \left| 1 + \frac{1}{2} SNR_2 \right| \right) \quad (58-21)$$

where the indexes on C and SNR denote systems 1 and 2. The factor $\frac{1}{2}$ on all the SNR s means that the total power has been divided equally between the two channels. Next is a discussion of whether or not it is possible to increase the capacity by combining the two antennas on each side to a classical directive array so that a single communication system with larger SNR is formed.

The signal to noise ratio of a LOS system is given by

$$SNR = \frac{P_r}{N} = \frac{P_t G_t G_r \left(\frac{\lambda}{4\pi r} \right)^2}{N} \quad (58-22)$$

where P_r is the received power, P_t is the transmitted power, G_r is the realized gain of the receive antenna, G_t is the realized gain of the transmit antenna, N is the noise power, and $\lambda/4\pi r$ is the free space attenuation. The gains on both the transmit and receive sides are now doubled by combining on each side two equal uncoupled directive antennas to a classical directive array with the double gain. Then, the SNR of the new system with classical two-element arrays on both sides is

$$SNR_{2 \times 2 \text{ arrays}} = 4SNR \quad (58-23)$$

or four times larger than the SNR of each of the two systems alone. The condition for this equation to be valid is that the noise power is independent of antenna gain.

The spectral capacity for the two cases, two parallel systems (which we may call two 1x1 systems), and the array case (for example, the 2x2 case) become (when the power is equally distributed between the two transmit antennas)

$$C_{\text{two } 1 \times 1} = 2 \log_{(2)} \left| 1 + \frac{1}{2} SNR \right| \xrightarrow{SNR \text{ large}} -2 + 2 \log_{(2)} |SNR| \quad (\text{bits / sec / Hz}) \quad (58-24)$$

$$C_{2 \times 2 \text{ array}} = \log_{(2)} |1 + 4SNR| \xrightarrow{SNR \text{ large}} 2 + \log_{(2)} |SNR|$$

These two equations can be plotted and compared to show that as long as $SNR > 11$ dB in each channel it is advantageous (for maximizing capacity) to use parallel systems with low gain antennas rather than one system with high gain antennas, and the maximum available spectral capacity increases by up to a factor 2 when the number of channels (for large SNR) is doubled. These are theoretical results. In practice there will be other limitations that may change this conclusion, such as hardware and cost constraints.

Parallel Channels in Rayleigh Fading

In a fading environment, the instantaneous spectral capacity is given by the same formulas as for the LOS case, but the formula for the SNR is different. The space attenuation is much larger due to the scattering from all blocking objects, and the SNR will fade with the fading signal level. Therefore, it is common to use an average maximum spectral capacity in characterization of systems for multipath, obtained by averaging the Shannon capacity over the statistical distribution of the power samples of the signal. The power samples are distributed exponentially in Rayleigh fading.

In a MIMO system with multiple ports on both the transmitting and receiving sides, there are many communication channels through the environment. Now, the signal (from one of the two transmit antenna ports in the example in the previous section) will be received on both the receive antenna ports. However, the signals on the two receive ports will be more or less uncorrelated (even if they are the same in terms of system modulation) due to the statistics of the fading. If it is assumed that they are uncorrelated, the maximum instantaneous spectral capacities for the similar cases as in the LOS example become

$$\tilde{C}_{1 \times 1} = \log_{(2)} (1 + \tilde{SNR}_{t1r1})$$

$$\tilde{C}_{1 \times 2 \text{ MIMO}} = \log_{(2)} (1 + \tilde{SNR}_{t1r1} + \tilde{SNR}_{t1r2})$$

$$\tilde{C}_{2 \times 2 \text{ MIMO}} = \log_{(2)} \left(\left(1 + \frac{1}{2} \tilde{SNR}_{t1r1} + \frac{1}{2} \tilde{SNR}_{t1r2} \right) \left(1 + \frac{1}{2} \tilde{SNR}_{t2r1} + \frac{1}{2} \tilde{SNR}_{t2r2} \right) - \text{channel coupling terms} \right) \quad (58-25)$$

The \tilde{C} and \tilde{SNR} notation with the tilde symbol means that C and SNR fade with time. The \tilde{C} 's need to be averaged over the distribution function of the signal level in order to compare the channels. It can be shown that the largest average capacity will be obtained if the different channels fade independently, so that the correlations between their received signals are low. Still, by comparing the spectral capacity formulas it can be seen that a MIMO array in a multipath environment has corresponding spectral capacity increase as parallel channels in a LOS environment, when compared to using single channel systems in the same two environments, respectively. The general formula for the maximum available capacity of a MIMO system with a transmit antenna with M ports and a receive antenna with N ports is

$$\tilde{C} = \log_2 \left(\det \left(\mathbf{I}_{N \times M} + \frac{SNR}{M} \tilde{\mathbf{H}}_{N \times M} \tilde{\mathbf{H}}_{N \times M}^* \right) \right) \quad (58-26)$$

where $\mathbf{I}_{N \times M}$ is a unit matrix, $\tilde{\mathbf{H}}_{N \times M}$ is a normalized complex channel matrix, and $\tilde{\mathbf{H}}_{N \times M}^*$ is the complex conjugate transpose of $\tilde{\mathbf{H}}_{N \times M}$. The channel matrix contains fading samples of the channels which means that we need to average \tilde{C} over the distribution of $\tilde{\mathbf{H}}_{N \times M}$.

Normalization of Channel Matrix

The normalization of the channel matrix must be done with respect to the square root of the time average received power of a single reference antenna with 100% radiation efficiency located in the same environment, when the same total power is transmitted from the opposite side of the environment. The next subsection will show how typical channel matrices can be computed, and thereafter in Section 58.6 how they can be measured.

Numerical Simulation of Channels in Isotropic Fading Environment

Next is an explanation for simulating a fading environment numerically. First, distribute a set $\{E_k\}$ of $k = 1, 2, \dots, K$ plane wave sources with AoAs (θ_k, φ_k) randomly and uniformly distributed over a sphere surrounding the MIMO array. The sources E_k in the set have independent and normal-distributed complex amplitudes of the θ - and φ -polarized components. Calculate the received voltage V_i on each embedded antenna port i due to the set of such incident plane waves by using the equivalent circuit on reception:

$$V_i = -\frac{2j\lambda}{\eta I} \sum_{k=1,2,\dots}^K \mathbf{G}_i(\theta_k, \varphi_k) \cdot \mathbf{E}_k \quad (58-27)$$

where all parameters have been explained previously and $\mathbf{G}_i(\theta, \varphi)$ is the embedded far field function of port i . The power absorbed in the load R_L becomes

$$P_L = \frac{1}{2} R_L \left| \frac{V_i}{Z_a + Z_L} \right|^2 \quad (58-28)$$

which has its maximum value when $Z_L = Z_a^*$.

In order to determine the performance of a specific multiport antenna with N ports in an $M \times N$ MIMO system, it is assumed that the M ports at the opposite transmit side are completely uncorrelated. Next this is modeled by generating $M \times 1000$ sets of sources, with $k = 1, 2, \dots, 20$ sources in each set, and calculating $M \times 1000$ values of received voltages V_i .

The channel matrix \mathbf{H} should preferably be normalized in such a way that $|\mathbf{H}|^2$ represent power normalized to the average received power of a single ideal matched lossless reference antenna located in the same environment. In theoretical works we must be sure that this normalization is unaffected by possible differences in input impedances seen on the ports of the MIMO antenna and the reference antenna. This can be done by first introducing a normalized voltage

$$A_i = \sqrt{\frac{R_L}{2}} \frac{V_i}{(Z_a + Z_L)} \quad (58-30)$$

that by comparison with Eq. 58-28 is seen to represent the received power on port i when its absolute values is squared. Therefore, the appropriate normalization of the elements of the channel matrix \mathbf{H} becomes

$$H_i = A_i / \sqrt{P_{\max, \text{ref}}} \quad (58-31)$$

where $P_{\max, \text{ref}}$ is the maximum available average received power on the port of the reference antenna, i.e., the received power averaged over all $M \times 1000$ source configurations when we have corrected for the mismatch and ohmic losses in the reference antenna. In this way, the total radiation efficiency and mutual coupling of the elements of the MIMO antenna is included in the channel matrix \mathbf{H} . There are a total of $1000 \mathbf{H}_{M \times N}$ matrices in our above example of a $M \times N$ MIMO system in which values of V_i are found for each of the $M \times 1000$ source configurations and each of the N ports of the MIMO antenna under study.

$P_{\max, \text{ref}}$ can be found in the following way:

1. Expose a single reference antenna, for example, a single dipole, to the same sets of sources as the simulated radiation patterns of the embedded ports of the MIMO antenna.
2. Calculate the received voltage $V_{i, \text{ref}}$ at the port of the reference antenna using Eq. 58-27.
3. Determine the maximum available received power $p_{i, \max, \text{ref}}$ of the reference antenna using Eq. 58-28 with matched ports, i.e., $Z_L = Z_a^*$, where Z_a is the input impedance of the reference antenna, which gives

$$p_{i, \max, \text{ref}} = \frac{1}{2} R_a \left| \frac{V_{i, \text{ref}}}{2R_a} \right|^2 \quad (58-29)$$

4. Average this over all $M \times 1000$ sets of source configurations to get $P_{\max, \text{ref}}$.

Figure 58-9 shows an example of how the average maximum available spectral capacity varies with SNR for a circular array of monopoles with different spacing.

58.6 EMULATION OF MULTIPATH AND FADING USING REVERBERATION CHAMBER

The reverberation chamber is a large metal cavity provided with mode stirrers and one or more antennas, as shown in Figure 58-10. It has been used for more than 20 years for EMC measurements of electromagnetic susceptibility and radiated emissions of electronic devices.¹ The basic theories of it have also been well understood.¹⁴⁻¹⁷ The main EMC

FIGURE 58-9 Example of average maximum available capacity for 6-port antenna in 1x6 (solid lines) and 3x6 MIMO systems (dashed lines). The multiport antenna consists of six monopoles located with equal distance in a circle. The distance between the neighboring monopoles were 0.24λ , 0.14λ , and 0.06λ . The “theoretical” curves represent ideal theoretical values for isolated independent MIMO elements.

application has been to generate high field strength for susceptibility testing. The last six years the reverberation chamber has been developed to a more accurate instrument for also measuring the characteristics of desired radiation of small antennas and active mobile terminals, in particular when these are intended for use in Rayleigh fading, such as for wireless/mobile communications in urban or indoor environments. Here we will describe how the reverberation chamber works, and how to measure the performance of antennas as defined in previous sections of this chapter.

FIGURE 58-10 Drawing (left) and photo (right) of reverberation chamber, shown with open door.²⁰ The drawing shows the setup for measuring MIMO system capacity, and the photo shows the setup for measuring radiated power of mobile phone close to head phantom. The chamber size shown allows for use down to 850 MHz with 25 MHz frequency stirring.

Mode Stirring (Mechanical, Platform, and Polarization Stirring)

The basic measurement setup is illustrated in the left parts of both Figures 58-10 and 58-11. This is used both for calibration and measuring passive antenna performance. The transmission coefficient S_{21} is measured between two antennas in the chamber. One of these is the calibration antenna or the antenna under test (AUT), and the other is part of the chamber and could be wall-fixed. The chamber is so large that several modes are excited at the frequency of test, so the level of S_{21} may be larger than in free space, but it may also be lower, depending on how the modes are excited and how they combine (fading). Reverberation chambers are provided with different ways of stirring the modes and thereby the S_{21} level varies, i.e., emulation of fading. The most common mechanical stirring means are with fans or other large rotating or translating mechanical structures.

The chamber in Figure 58-10 has the following stirring capabilities:

- **Mechanical stirring** This is achieved by means of two plate-shaped mechanical stirrers, which can be moved along a complete wall and along the ceiling by means of step motors. The larger volume the stirrers cover, the better.
- **Platform stirring**¹⁸ The antenna under test is located on a rotatable platform which moves the antenna to different positions in the chamber. This stirring method is very effective in small chambers.
- **Polarization stirring**¹⁹ There are three orthogonal wall-fixed chamber antennas, and S_{21} is successively measured between each one of them and the AUT. Thereby, the chamber gets a good polarization balance.

There is also a fourth, very effective stirring method, referred to as *frequency stirring*. This corresponds to averaging S_{21} or $|S_{21}|^2$ over a frequency band during the processing of the results. This will be treated in the next section.

Measured S-parameters and Their Relation to Free Space Antenna Characteristics

Figure 58-11 illustrates how S_{11} and S_{21} are measured between two antennas inside a reverberation chamber. It can be physically argued that S_{11} of the AUT must consist

FIGURE 58-11 Example of measured S -parameters of two antennas in a reverberation chamber as a result of mode stirring, and an illustration of the deterministic and random contributions to them.

of two contributions; one contribution being the S_{11}^a from the antenna itself as if it was located in free space, and another S_{11}^c from the chamber:

$$S_{11} = S_{11}^a + S_{11}^c \quad (58-32)$$

The former of these contributions is deterministic, whereas the latter is random as a result of the stirring. If the number of independent values of S_{11}^c is large enough, it must get a complex Gaussian distribution with zero mean. Therefore, it is possible to determine S_{11}^a by complex averaging of the measured S_{11} over all stirrer positions, and if needed by additional complex frequency stirring:²¹

$$S_{11}^a = \frac{1}{M} \sum_{\substack{\text{stirrer} \\ \text{pos.}}} S_{11} = \overline{S_{11}} \quad (58-33)$$

where $\overline{S_{11}}$ is a compact way of writing the average of S_{11} . Similarly S_{22}^a of the wall-mounted chamber antenna can be found.

It can also be argued that S_{21} must consist of two contributions, one deterministic coupling S_{21}^d being the same as in free space, and another statistic contribution S_{21}^c coming from the chamber, i.e.,

$$S_{21} = S_{21}^d + S_{21}^c \quad (58-34)$$

Rayleigh Fading, Rice fading, and AoA Distribution

It is desirable that the reverberation chamber provide the isotropic reference environment with Rayleigh fading. Therefore, the direct coupling in Eq. 58-34 should be as low as possible. The direct coupling follows the free space transmission formula, also referred to as Friis transmission formula,⁴ which gives

$$|S_{21}^d|^2 = \left(\frac{\lambda}{4\pi r} \right)^2 G_t G_r \quad (58-35)$$

where r is the distance between the antennas, λ is the wavelength, and G_t and G_r are the realized gains of the wall-mounted antenna and AUT, respectively, in the direction of the opposite antenna. Therefore, the main lobes of the antennas should not point towards each other. The platform stirring is very effective to reduce direct coupling, as the direction of the AUT will be different in different platform positions. The direct coupling, together with loading the chamber, can also be used to get a controlled Rician distribution for test purposes.²²

From the discussion in the previous subsection, it is clear that the reverberation chamber provides Rayleigh fading if the direct coupling is reduced so much that it is much smaller than the chamber contribution to S_{21} . This can be done by platform stirring, or by using a wall-fixed antenna that has a null in the direction of the AUT. It was shown that each mode in a rectangular cavity can be expressed as eight plane waves, and that the directions of arrival of these plane waves are uniformly distributed over the unit sphere if there are enough modes excited.²³ Therefore, the reverberation chamber represents an isotropic multipath environment, i.e., the desired reference environment defined previously.

Average Transmission Level and Calibration

The transmission between two antennas in free space follows Friis transmission formula shown in Eq. 58-35. The corresponding formula for transmission between two antennas located in a reverberation chamber is Hill's transmission formula.¹⁶ This is valid when there is no direct coupling, and it presumes a large chamber with many excited modes. In the present text Hill's formula is referred to as the chamber transfer function and is presented in the following form:

$$G_{\text{chamber}} = \frac{P_r}{P_t} = \frac{c^3 e_{\text{rad}1} e_{\text{rad}2}}{16\pi^2 V f^2 \Delta f} \quad (58-36)$$

where f is the frequency, c is velocity of light, V is the chamber volume, $e_{\text{rad}1}$ and $e_{\text{rad}2}$ are the radiation efficiencies including mismatch of the two antennas, and Δf is the average mode bandwidth. The latter consists of four additive contributions due to wall losses, leakage, antennas in the chamber, and absorbing objects:

$$\Delta f = \sum_{\text{all walls}} \Delta f_{\text{wall}} + \sum_{\text{all slots}} \Delta f_{\text{leakage}} + \sum_{\text{all antennas}} \Delta f_{\text{antenna}} + \sum_{\text{all lossy objects}} \Delta f_{\text{object}} \quad (58-37)$$

with

$$\Delta f_{\text{wall}} = \frac{2A}{3V} \sqrt{\frac{c\rho f}{\pi\eta}}, \quad \Delta f_{\text{leakage}} = \frac{c\sigma_l}{4\pi V}, \quad \Delta f_{\text{antenna}} = \frac{c^3 e_{\text{rad}}}{16\pi^2 V f^2}, \quad \Delta f_{\text{object}} = \frac{c}{2\pi V} \sigma_a \quad (58-38)$$

and where V is the chamber volume, η the free space wave impedance, A the area of a conducting surface (such as a chamber wall) with surface resistance ρ , σ_l is the leakage cross section of a narrow slot in the chamber wall, and σ_a is the absorption cross section of an absorbing object. σ_l and σ_a ¹⁶ have slow frequency variation compared to the explicit frequency variation in the formulas. It should be noted that here the average chamber transfer function is expressed in terms of the average mode bandwidth rather than like Hill did in terms of the average Q of the modes.¹⁶ The reason is that the formula for Δf is much more compact because the different Δf contributions are additive, whereas Q contributions are not. Also, for specific chambers (at least loaded ones), the average mode bandwidth will not vary much with frequency, and therefore the value of Δf characterizes the chamber better than Q over a large frequency band. The total Δf s appearing in different practical chambers can be very different, corresponding to chamber Q s of between 30 and several thousands ($Q = f/\Delta f$). When measuring active terminals it is important that Δf is larger than the modulation bandwidth of the communication channel, otherwise measurement errors can appear.

In practice, a measurement of radiation efficiency, radiated power, or receiver sensitivity is based on first determining the chamber transfer function by calibration, using a reference antenna with known radiation efficiency $e_{\text{rad}2}$, with the AUT present in the chamber with its port matched terminated. The actual measurement will then be done by match-terminating the reference antenna and mounting the cable to the port of the AUT. The ratio between the two average transfer functions of the chamber in the two cases will be equal to the ratio between the radiation efficiency of the reference antenna and the AUT. The radiation efficiency $e_{\text{rad}1}$ of the chamber-fixed antenna (in this case wall mounted) does not need to be known, because it will be the same both when measuring the reference antenna and the AUT.

It is also possible to calibrate the chamber without having the AUT inside. However, the reference antenna must then also be removed when the AUT is measured. This is a simplified procedure, because the same calibration can be used when measuring several AUTs, and in particular it is simpler when measuring many active terminals. However, this simplified procedure only works if the chamber is loaded so much that the reference antenna and AUT does not represent any significant contribution to the total Δf of the chamber. If they do, the results of the measurements may be wrong, as the chamber transfer function no longer has a linear dependence on e_{rad} of the antenna. This fault may happen in particular if the reference antenna or AUT are made of materials which absorb radiation and thereby increase the total Δf even when the antenna ports are open or short-circuited.

Frequency Stirring on Mismatch-corrected Transfer Function

It has been found that if the free space mismatch efficiencies are removed from S_{21} in Eq. 58-36, the result is an average chamber transfer function that varies slower with frequency. This can then be frequency stirred for better accuracy without losing resolution due to variations in the mismatch efficiency. The free space input reflection coefficients of the two antennas can be obtained by complex averaging of the S_{11} and S_{22} measured in the reverberation chamber, as explained previously. Therefore, the mismatch-corrected chamber transfer function can be calculated using

$$G_{\text{chamber}} = \frac{1}{N} \sum_N \frac{|S_{21}|^2}{(1 - |S_{11}|^2)(1 - |S_{22}|^2)} \quad (58-39)$$

where N is the number of stirrer positions. This function can be frequency stirred to improve accuracy.

Number of Independent Samples & Accuracy

In order to perform accurate measurements in the reverberation chamber, the chamber transfer function in Eq. 58-39 needs to be proportional to the radiation efficiency independent of which antenna or terminal is used, just like in Hill's theoretical transfer function in Eq. 58-36. This is possible only if the mode stirring creates enough independent samples. The S_{21} samples are complex normally distributed (for sufficient independent samples). Then, the relative accuracy by which we can estimate G_{chamber} has a standard deviation of⁵

$$\sigma = 1/\sqrt{N_{\text{ind}}} \quad (58-40)$$

where N_{ind} is the number of independent samples. This means that $N_{\text{ind}} = 100$ is needed for an accuracy of $\pm 10\%$, i.e., ± 0.5 dB. Thus, it is crucial that at least 100 independent samples are obtained by the mode stirring.

The number of independent samples is determined primarily by the mode density in the chamber—in other words, by the number of modes per MHz. This is a good approximation given by the classical formula

$$\partial N_{\text{mode}} / \partial f = V f^2 8\pi / c^3 \quad (58-41)$$

The number of independent samples is proportional to the mode density, but the proportionality constant is not known. It depends on chamber loading, mode stirring methods,

mechanical stirrer shapes, and chamber shape (at least for small chambers). The purpose of ongoing numerical studies is to determine these constants.²⁴⁻²⁵ A preliminary experimental study has been performed,²⁶ but it requires more work to get unique and simple conclusions. However, the following approximate relation between the mode density and number of independent samples can be preliminarily stated:

$$N_{\text{ind}} \leq 8[\partial N_{\text{mode}} / \partial f](\Delta f + B) \quad (58-42)$$

where B is the bandwidth of the frequency stirring and Δf is the same as in Eq. 58-36. The factor eight is due to platform stirring and is rooted both empirically and by physical reasoning. The latter argument goes as follows: Each cavity mode can be written as a sum of eight plane waves,²³ and the result is eight times more independent samples than modes. This is achieved by moving the antenna or terminal under test around in the environment, which is accomplished by platform stirring. The \leq sign in Eq. 58-42 means that this is an upper limit when there are enough samples and the mechanical mode stirring is sufficient.

It should be noted that the effect of the mechanical stirring can be so strong that N_{ind} will be larger than in Eq. 58-42. This will normally only appear when there is no or very small frequency stirring, and for high Q chambers, i.e., when Δf is small. Such conditions are common for EMC measurements, as high Q is needed in order to produce high field strength, so therefore, experiences with accuracy from EMC measurements are not directly transferable to accurate antenna and terminal measurements.

It is clear from Eq. 58-42 that the accuracy in a given chamber can be controlled by changing Δf and B . However, there may be other effects coming in when the loading is very large so some care must be taken. Still, a good Rayleigh distribution with many independent samples has been experienced even when the Q is as low as 30.²⁷ The problem with frequency stirring B is that the resolution becomes worse (resolution bandwidth increases). This means for antenna measurements that we cannot resolve variations in the radiation efficiency which are faster than B . In practice the resolution is somewhat better by using the mismatch correction to the transfer function before frequency stirring, like in Eq. 58-39. The reason is that mismatch efficiencies normally vary faster with frequency than efficiencies due to ohmic losses.

Normally, the chamber needs to be loaded in order to measure terminals of broadband systems, otherwise the modulation may be distorted. It has been shown that it is possible to measure systems with 25 MHz bandwidth in the chamber shown in Figure 58-10.

For smaller chambers the accuracy cannot be predicted based on Eqs. 58-41 and 58-42. The reason is that the mode density will not be accurate enough using Eq. 58-41 alone. The formula is approximate, and in reality the modes appear unevenly distributed as a function of frequency, depending on the shape of the chamber. However, the average mode density is quite well predicted by Eq. 58-41. The uneven mode distribution can be used to tune in a certain small chamber to good performance in a specific frequency band. This was done to determine the optimum height of a reverberation chamber for best accuracy in the GSM 900 transmit band.²³ To do this meant to actually count the number of modes for a rectangular box with the same size as the chamber that appears within a certain bandwidth B , instead of using Eq. 58-42. The frequency stirring values in Table 58-1 are based on such mode counting.

Accuracy and Resolution in Two Practical Chambers

The theoretical and empirical considerations in the previous sections have been used to generate the results for accuracy and resolution of two practical chambers with different sizes, as shown in Table 58-1. The results are obtained by counting modes based on the analytical formula for the resonance frequencies of modes in a rectangular cavity of the

TABLE 58-1 Performance of Two Different Reverberation Chambers (All values are empirical rooted in theoretical mode densities for a measurement accuracy of 0.5 dB STD.)

	Chamber 1	Chamber 2
Inner dimensions (DxHxW)	1.0 m × 1.75 m × 0.8 m	1.2 m × 1.75 m × 1.8 m
Isolation (shielding)	50 dB	100 dB
Lowest useful frequency	870 MHz with 25 MHz stirring	500 MHz with 20 MHz stirring
Resolution when meas. antennas*	cir. 12.5 MHz from 870 MHz	cir. 10 MHz from 500 MHz
Lowest frequency for full resolution	no frequency stirring needed above 2250 MHz	no frequency stirring needed above 1300 MHz
Resolution when measuring active terminals **		
GSM850/Cell TX 824-849	30 MHz, must average 6 channels 5 MHz apart, (not recommended)	10 MHz, must average 2 channels 5 MHz apart
GSM850/Cell RX 869 – 894	25 MHz, must average 5 channels 5 MHz apart	10 MHz, must average 2 channels 5 MHz apart
GSM900 TX 880 – 915	25 MHz, must average	10 MHz, must average
GSM900 RX 925 – 960	5 channels 5 MHz apart	2 channels 5 MHz apart
GSM1800 TX 1710 – 1785	10 MHz, must average	Single channel
GSM1800 RX 1805 – 1880	2 channels 5 MHz apart	
GSM1900 TX/PCS 1850 – 1910		
GSM 1900 RX /PCS 1930 – 1990		
Lowest frequency for full single channel resolution	2250 MHz	1300 MHz

* The resolution for antennas are a factor 2 better than the stirring bandwidth, due to access to S_{11} and S_{22} .
 **To get the specified 0.5 dB accuracy we must frequency stir by averaging results over channels as specified. The channels must be uniformly distributed over the specified resolution bandwidth. The chamber must be loaded to obtain an average mode bandwidth of about 4-5 MHz.

same size as the chamber. From this counting, the number of modes within different frequency stirring bandwidths is determined, as a function of frequency. Then, at a specific frequency of test, the stirring bandwidth needed to get more than 20 modes excited can be determined. Then, $N_{ind} > 8 \times 20 = 160 > 100$, which should be more than sufficient to get 0.5 dB RMS accuracy. In the case of measuring active phones, frequency stirring is obtained by averaging the results of several channels, as explained in Table 58-1.

58.7 MEASURING ANTENNAS AND ACTIVE TERMINALS IN REVERBERATION CHAMBER

Procedure for Calibration and Characterizing Multiport Antennas

The procedure for measuring a single- or multiport antenna in a reverberation chamber is briefly described as follows. The AUT is located inside the reverberation chamber in

such a way that it is more than 0.5 wavelengths from the walls and mechanical stirrers (for directive antenna longer distances will be needed in the main lobe direction). A single reference antenna with known radiation efficiency must be located far enough away from the AUT to avoid significant direct coupling (for non-directive antennas a spacing of half to one wavelengths is sufficient). One of the AUT ports is connected to a source, such as a network analyzer, and terminates all the other ports and the reference antenna in 50 Ohms. S -parameters are gathered between the port and the three wall-mounted antennas (used for polarization stirring) for all positions of the platform and the mechanical stirrers and for all frequency points. The measurement procedure is then repeated for every antenna port, also with the unconnected ports terminated in 50 Ohms, for exactly the same stirrer positions and position of the array inside the chamber. Thus, the field environment is exactly the same when measuring every port. The complex transmission coefficients S_{21} between the connected port and each of the three fixed wall antennas, as well as the reflection coefficients S_{11} of each of the wall antennas and S_{22} of the array port, are stored for every stirrer position and frequency point. Finally, the reference antenna is connected to the network analyzer and performs the same measurements as for the array. During the reference measurements, the AUT with all its ports terminated in 50 Ohms must be present in the chamber. This is necessary because the loading of the chamber (and thereby the Q -factor) needs to be the same during the measurements of both the reference antenna and the AUT, and because the AUT itself loads the reverberation chamber noticeably even when there is a lossy object such as a head phantom inside the chamber. In a small chamber it is advantageous to use frequency stirring (averaging) to improve accuracy. In such cases, the complex samples of S_{21} are corrected with mismatch factors due to both S_{11} and S_{22} before the frequency stirring, as shown in Eq. 58-39. The corrected S_{21} samples are normalized to the reference level corresponding to 100% radiation efficiency. This is obtained from the corrected S_{21} samples measured for the reference antenna, and its known radiation efficiency. These corrected and normalized samples of S_{21} are briefly referred to as the normalized S_{21} values. The normalized S_{21} values represent estimates of the channel matrix H of multipath communication channels set up between the wall antennas and the AUT inside the chamber. Therefore, from the measured S -parameters the diversity gain and capacity can be obtained as explained in previous sections.

In the previous explanations, the MIMO channel is set up between the chamber-fixed often wall-mounted antennas and the multiport AUT. It is of course also possible to locate two multiport antennas inside the chamber and set up the MIMO channels between the ports of these two antennas, and evaluate them as a complete MIMO system.

Radiated Power, Active Implemented Diversity Gain, and Receiver Sensitivity

Complete mobile terminals like cell phones can also be measured in reverberation chambers. The total radiated power is readily measured by first finding the chamber transfer function in Eq. 58-39 by using a reference antenna with known efficiency, and thereafter measuring the radiated power from the phone by connecting a spectrum analyzer to the chamber-fixed antennas.²⁸⁻²⁹ The radiation from the phone must be controlled by using a base station emulator or mobile communication test instrument. Phones with implemented diversity antennas can also be measured to determine the actual implemented diversity gain.³⁰

Even more important for wireless internet and multimedia terminals is the receiver sensitivity, as it will directly affect the time for downloading data. The receiver sensitivity is characterized by the signal level needed to reach a certain specified bit error rate (BER) or frame error rate (FER), the latter for CDMA systems. The limiting static signal level is, when averaged over many directions in the radiation pattern, referred to as the total isotropic sensitivity (TIS). An alternative in reverberation chambers is to measure BER/FER during

continuous fading to determine what is referred to as average fading sensitivity (AFS).³¹ The AFS can also be used to determine the TIS, as there is a system specific relation between the two values. The AFS is a more realistic performance parameter than TIS, and, it is much faster to measure.

59.1 INTRODUCTION

Computational electromagnetics (CEM) has perhaps had the greatest impact on antenna design than any technology since the invention of the cavity magnetron. That is a strong statement; however, it is now common for antenna designers to make use of either commercial or custom-design CEM codes in nearly all design cycles. Indeed, calculated performance is often required in addition to measured results! These tools are used to predict performance as well as to better understand the sometimes complex physical interactions that occur between the antenna itself, the source of radio frequency (RF) signal, and the structure in the vicinity of the antenna. Traditional antenna design considered the antenna in isolation (for example, an idealized feed and free space environment) and made assumptions necessary for determination of engineering significant quantities such as the voltage standing wave ratio (VSWR), driving-point impedance, efficiency, axial ratio, and directivity, amongst others. CEM methods, both computationally exact ones based on a full-wave solution of Maxwell's equations and approximate ones based on some physically justifiable assumptions, have considerably improved design methodologies available to antenna engineers. Namely, these CEM tools allow much greater fidelity for the designer so that the goal of a virtual design environment with sufficient accuracy and included physics is within reach during the first decade of the 21st century.

Examples of improved fidelity include the addition of surrounding structure, realistic feed models, non-trivial materials (for example, dispersive, dissipative, anisotropic, and so on), finite conductive metals, and even active and/or passive electronic components. It stands to reason that the environment in the vicinity (within the near-field) of an antenna will have a strong impact on the performance of that device. Nevertheless and by necessity, antennas were traditionally designed assuming free space. This considerably simplified the mathematics; however, often designers found dramatically altered performance, especially for near-field quantities such as VSWR, when the antenna was placed in its operating environment (for example, on an automobile, aircraft, ship, or in the vicinity of buildings). Likewise, the interactions between the feed and electronics within the antenna structure itself can dramatically impact actual versus predicted performance. Since one of the main rationales for investing in a CEM design tool is the reduction—and even elimination—of costly prototype testing, improved fidelity is obviously necessary for instilling confidence in the computed results. Finally, traditional antenna designs have either approximated or ignored the impact of dielectric or magneto-dielectric materials on antenna performance. With the introduction of advanced CEM design tools these assumptions are no longer necessary.

The tremendous advances in computer resources over the past several decades have made the inclusion of these important physical mechanisms possible. An impact of Moore's Law, "doubling the number of transistors on an integrated circuit every eighteen months," is that computational power increased exponentially. CEM, among many other computational science and engineering disciplines, has reaped the benefits of the power law growth in affordable computing power, primarily via the inclusion of greater fidelity. With the emergence of commercially available multicore processors in 2005, the power of parallel programming, as applied to CEM methods, will become commonly available allowing the inclusion of even more physical mechanisms.

The scientific literature over the past 20 years or so is rich in advances made in computational methods that can be (and often are) applied to antenna design and analysis. It is not the intent of this chapter to give a detailed list of the most important papers; doing so would rapidly consume the chapter resulting in a bibliography rather than a practically useful introduction to CEM methods for antenna design and analysis. Rather, the cited references will primarily be a subset of the books and journal papers that have emerged over the past decade

or so usually based on scientific papers, conference publications, and technical reports. The interested reader can go to the references in those texts for primary sources.

Abbreviated Summary of Progress since the 1960s

A brief summary of the progress in computational modeling for antennas is in order prior to proceeding. There are, arguably, five major advances in CEM that have had a profound impact on antenna design. These are (in roughly chronological order):

- The development of the finite difference-time domain (FD-TD) method
- The release of the Numerical Electromagnetics Code (NEC) computer program by Lawrence Livermore National Laboratory (LLNL)
- The discovery of the Rao-Wilton-Glisson (RWG) basis function
- The development of three-dimensional vector finite elements
- The discovery of fast solver acceleration methods

A brief summary of each of these items is provided to give the reader a feeling for the interplay between research discovery and its impact on antenna design.

The FD-TD method really became a practical CEM tool with the development of the Yee cell in 1966.¹ As will be discussed in detail in the next section, the point-form of Maxwell's equations are a set of continuous, coupled, partial differential equations in both space and time. To solve these equations on a digital computer, a method for approximating these exact equations with differences in both space and time is needed. The Yee cell provided a construct for doing so, in that both the electric field and magnetic field are represented spatially with offset grids, while temporally, they are represented half a time step apart. This allowed for the specification of second-order recurrence relationships thereby reducing the continuous partial differential equation to a manageable set of difference equations implemented as recurrence expressions. The result is a practical method for modeling three-dimensional structures in the time-domain; one of the most efficient methods for wide bandwidth antenna study.

The release of the frequency-domain integral equation program NEC-1 in 1980² initiated a flurry of activity in utilization of a CEM design tool for antennas. Previous to NEC, various research organizations (primarily universities but also research laboratories with a variety of affiliations) developed and utilized CEM codes for antenna design and analysis. However, these codes were proprietary and thus had very limited market penetration. Since LLNL made NEC widely available (indeed NEC-2 is freely available worldwide and has spawned a variety of support program packages, some of which are listed later in this chapter), it dramatically impacted antenna design. NEC utilizes wire and surface patches in defining the geometry and over which the unknown currents are computed.

Surface patches were one of the more challenging aspects of modeling antennas with an integral equation formulation. The reason for this is that the expansion functions at the time did not correctly model current continuity from patch-to-patch (as compared to the wire elements in NEC that did indeed enforce current continuity at wire junction nodes). The development of vector basis functions by Rao, Wilton, and Glisson (RWG) in 1982³ resulted in a flurry of new integral equation codes, both commercial and non-commercial. The inclusion of surface currents allowed simulation of an entirely new class of antennas and improved modeling of the surface structure in the vicinity of the antenna. Heretofore, the environment in the vicinity of an antenna was modeled with a collection of wire grid elements rather than a solid surface. The results of using such a wire grid model were

sometimes acceptable and sometimes not. This meant that the introduction of the RWG basis function was a substantial improvement.

Most integral, equation-based design programs were suitable for simulation of perfect electric conductors, and with some approximation, imperfect conductors in free space. They were not able to efficiently model dielectric antenna loading materials. FD-TD design codes could model materials, but being time-domain formulations, FD-TD codes are not efficient for simulation of resonant antennas. The finite element (FE) method, long a staple in the computational fluid dynamics and the computational heat transfer communities, had the potential for including materials. However there were two serious limitations that had to be overcome: (1) the need for an electromagnetically correct vector expansion function and (2) the need to efficiently truncate the computational domain for open problems as is the case for an antenna. The first limitation was overcome with the development of a suitable basis function,⁴ while the second was solved for a class of problems by combining the finite element method with a boundary integral (the so-called FE-BI method).⁵ Later, more accurate local mesh truncation conditions became important for commercial applications, due to the generally lower memory requirements as compared to a boundary integral termination. These two innovations meant that for the first time, the interactions between a material and the antenna can be rigorously included in the model, yet do not require an excessive computational burden. (Note: In 1990, the computational cost of a volume integral equation method was too high to be practical, but in the 21st century that burden can be accommodated for practical simulation tasks with high performance computers.)

The final trend-setting innovation for antenna modeling was the introduction of *fast solvers*. These are based on one of a handful of observations. In one incarnation—the fast multipole-based methods (FMM)—the interactions between elements are computed from the interactions between local groups. This reduces the computational burden, both storage and computation, depending on how many levels are included in the multipole method⁶ for both frequency-domain and time-domain formulations. In another popular implementation of a fast method, based on different assumptions and mathematics, the interactions between the unknowns are computed based on the results, using auxiliary unknowns. The computation of these values is much more efficient than a brute-force approach, using RWG functions due to the uniform spatial arrangement of these auxiliary unknowns. For some important antenna structures, the use of this Adaptive Integral Method (AIM) can dramatically increase the efficiency of a simulation through the use of fast Fourier transforms (FFT) during the calculation of matrix-vector products within an iterative matrix solver.⁷ The impact of these efficient solution techniques is a dramatic increase in the electrical size of a geometry that can be practically computed within a design time-frame.

The remainder of the chapter is divided in four parts:

- Time-domain methods
- Frequency-domain methods
- A brief survey of commercial and public domain computer programs
- A brief discussion of parallel programming methods and sources

The first two categories represent the bulk of the material in this chapter, and they are further subdivided into solution techniques: finite difference, integral equation, finite element, and alternative methods as appropriate. The reader will notice that much more space in the chapter is devoted to a discussion of the frequency-domain methods as compared to time-domain methods. There are two reasons for this: (1) as of publication of this edition of the handbook, frequency-domain CEM tools are more widely used than time-domain methods for a variety of reasons (not the least of which is that most antennas are resonant structures rather than wide bandwidth radiators) and (2) the author is more familiar with

frequency-domain methods. With the increased importance and market penetration of wide bandwidth antennas, time-domain simulators will become increasingly more important to the community.

59.2 TIME-DOMAIN METHODS

Formulation of Maxwell's equations in the time-domain is the most natural approach, for the simple reason that all physical electric and magnetic fields are time-dependent. As stated previously, Maxwell's equations are a set of coupled, first-order, time-dependent expressions that originally were presented in integral form

$$\begin{aligned}\oint_C \mathbf{E} \cdot d\mathbf{L} &= -\frac{\partial}{\partial t} \int_S \mu \mathbf{H} \cdot d\mathbf{S} \\ \oint_C \mathbf{H} \cdot d\mathbf{L} &= \frac{\partial}{\partial t} \int_S \epsilon \mathbf{E} \cdot d\mathbf{S} + \int_S \mathbf{J} \cdot d\mathbf{S} \\ \oint_{\partial V} \epsilon \mathbf{E} \cdot d\mathbf{S} &= \int_V \rho_e dV \\ \oint_{\partial V} \mu \mathbf{H} \cdot d\mathbf{S} &= 0\end{aligned}\quad (59-1)$$

In this, the electric field (\mathbf{E}), magnetic field (\mathbf{H}), and current density (\mathbf{J}) are three-dimensional vector fields that are dependent on both time and space. The material properties are denoted by the permittivity (ϵ) and permeability (μ). For simplicity, an isotropic material is assumed for these expressions; however, in the case of an anisotropic material (such as ferrimagnetic material, namely saturated yttrium iron garnet or YIG), a suitable formulation can be derived that includes the anisotropy of the material. The integration domains are over a spatial volume (V), the boundary surrounding that volume (∂V), an open surface (S), and the contour that bounds that open surface ($C = \partial S$). Finally, the electric charge density (ρ_e) is, like the current density, a source of electromagnetic fields and is a function of both time and space. Although there are solutions that utilize the integral form of Maxwell's equation, most notably the Finite Integral Technique (FIT),⁸ most time-domain Maxwell equation solvers utilize the point-form of the equations. These are given by

$$\begin{aligned}\nabla \times \mathbf{E} &= -\frac{\partial}{\partial t}(\mu \mathbf{H}) \\ \nabla \times \mathbf{H} &= \frac{\partial}{\partial t}(\epsilon \mathbf{E}) + \mathbf{J} \\ \nabla \cdot (\epsilon \mathbf{E}) &= \rho_e \\ \nabla \cdot (\mu \mathbf{H}) &= 0\end{aligned}\quad (59-2)$$

These are a set of first-order, coupled partial differential equations (PDE) with two vector-valued unknown fields: \mathbf{E} and \mathbf{H} . There are three prevailing methods for solving these equations besides the aforementioned FIT approach: finite differences, integral equations, and finite element methods. These will each be discussed with minimal detail.

Finite Difference-Time Domain (FD-TD) Method

The FD-TD method is the most widely developed and popular time-domain Maxwell equations solver. There is a plethora of codes available (both commercial and in the public domain) that can be utilized for antenna design and analysis. See the end of

Section 59.4 for a brief discussion of these sources. Many people believe that the FD-TD method is the most natural way to solve Maxwell's equation. With this method differential operators are approximated using difference operators resulting in both the electric and magnetic field as a function of time, for example, a direct solution of Eq. 59-2. However, the reader should be cautioned that the most prevalent implementations of the FD-TD method (those using leap-frog methods) do not provide both the electric and magnetic fields at the same instant in time. Also, these fields are not provided at the same point in space, since the solution is given over two offset grids such as with the Yee-cell case.¹ Nevertheless, FD-TD solutions are popular for at least two reasons: (1) They provide considerable physical insight into the radiation mechanism of an antenna when the method is combined with a visualization capability and (2) it is relatively easy to program a simple two-dimensional and even three-dimensional FD-TD program. (This is not to say that it is easy to write efficient code or to provide many of the necessary features—such as dispersive media and accurate feed models—that are now incorporated in commercial codes.)

The simplest FD-TD formulation to consider is the one-dimensional case. In this case, all waves are plane waves that travel along the single dimension, parallel to the x -axis. For the one-dimensional case, Maxwell's point form equations reduce to⁹

$$\begin{aligned} \frac{\partial H_y}{\partial t} &= \frac{1}{\mu} \frac{\partial E_z}{\partial x} \\ \frac{\partial E_z}{\partial t} &= -\frac{1}{\varepsilon} \frac{\partial H_y}{\partial x} \end{aligned} \quad \text{TM polarization} \quad (59-3)$$

or

$$\begin{aligned} \frac{\partial E_y}{\partial t} &= -\frac{1}{\varepsilon} \frac{\partial H_z}{\partial x} \\ \frac{\partial H_z}{\partial t} &= \frac{1}{\mu} \frac{\partial E_y}{\partial x} \end{aligned} \quad \text{TM polarization} \quad (59-4)$$

Note that in Eqs. 59-3 and 59-4, the material constitutive parameters, ε and μ , are not relative terms; it is a common mistake to use material parameters that are relative to free space. In addition, since these are time-dependent field quantities, the constitutive parameters are real-valued. Loss is represented by a conductivity that has been suppressed in Eqs. 59-3 and 59-4 for clarity's sake. To solve these coupled, first-order equations, the differences will be replaced with second-order central differences. For example, the PDE $\partial H/\partial t = (\mu^{-1})\partial E/\partial x$ is approximated as

$$\left. \frac{H\left(t_n + \frac{\Delta t}{2}\right) - H\left(t_n - \frac{\Delta t}{2}\right)}{\Delta t} \right|_{x=x_i} = \frac{1}{\mu_i} \left. \frac{E\left(x_i + \frac{\Delta x}{2}\right) - E\left(x_i - \frac{\Delta x}{2}\right)}{\Delta x} \right|_{t=t_n} \quad (59-5)$$

where the time step is indicated by (Δt) and the spatial increment is given by Δx . Note that the permeability is evaluated at the i th spatial sample location, x_i . The n th time step is denoted by t_n . This difference equation (Eq. 59-5) is implemented as a recurrence relation as

$$H\left(t_n + \frac{\Delta t}{2}\right)\bigg|_{x_i} = H\left(t_n - \frac{\Delta t}{2}\right)\bigg|_{x_i} + \frac{\Delta t}{\mu \Delta x} \left[E\left(x_i + \frac{\Delta x}{2}\right) - E\left(x_i - \frac{\Delta x}{2}\right) \right]\bigg|_{t_n} \quad (59-6)$$

or more typically written as

$$H_i^{n+1/2} = H_i^{n-1/2} + \frac{\Delta t}{\mu \Delta x} \left[E_{i+1/2}^n - E_{i-1/2}^n \right] \quad (59-7)$$

where the superscript indicates the instance in time and the subscript indicates the spatial location of the grid point. Notice that the electric field is not ever evaluated at the same point in time or space as the magnetic field, and vice versa. The companion formula for the electric field is given by

$$E_{i+1/2}^{n+1} = E_{i+1/2}^n + \frac{\Delta t}{\epsilon \Delta x} \left[H_{i+1}^{n+1/2} - H_i^{n+1/2} \right] \quad (59-8)$$

The fields are evaluated as time increases by alternating between these two equations, increasing time a half step between use of either Eq. 59-7 or Eq. 59-8. This is graphically depicted in Figure 59-1.

One of the issues that must be considered in any time-domain solution method is its stability. Specifically, whether the algorithm is guaranteed not to generate non-physical, increasing fields as time progresses. The core issue is the relationship between the time step (Δt) and the spatial step (Δx). If the time step is too long, then a field can pass through more than one cell during a time step as it propagates, generating an unstable solution. For the one-dimensional case, the so-called magic time step¹⁰

$$\Delta t = \frac{\Delta x}{c} \quad (59-9)$$

can be defined as the results in a grid velocity (the velocity of propagation within the numerical grid used to approximate real space) that *exactly* reproduces the velocity of propagation in real space with c being the speed-of-light in a vacuum. Because of this, grid dispersion (the phenomena that a signal propagates in the discretized space at a different velocity than in real space) does not occur. In Eq. 59-9, if the magic time step is

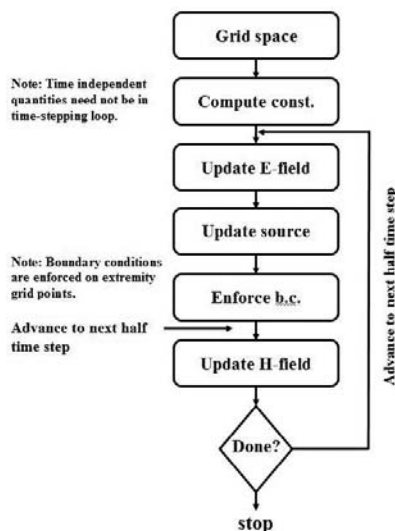

FIGURE 59-1 Flow-chart for FD-TD algorithm

not used, the time step must be less than the spatial step divided by the highest speed of propagation to maintain stability. In all other dimensions, the grid velocity only approximately represents the true continuous domain velocity and therefore numerical dispersion will occur. The Courant Stability Criterion for two- and three-dimensional grids is given in many texts.⁹⁻¹¹

As an example of the power inherent in FD-TD simulations, consider the temporal snapshot of a plane wave incident on a multilayered dielectric shown in Figure 59-2. In this two-dimensional simulation, the Gaussian plane wave is injected at the left boundary of the figure and propagates to the right. The simulation was halted as the wave was partially reflected by the first material discontinuity (located at $x = 0.15$) and partially transmitted at that boundary. As seen, one of the powerful features of any time-domain simulation is the ability to stop the simulation to capture relevant physics. Another powerful feature of time-domain simulations is the physical insight gained when the FD-TD simulation includes graphics. Notice that in this case, the reflected field is inverted while the transmitted field is not (as required by the transition conditions at the material discontinuity). Examples of using FD-TD for antenna analysis—both far-zone quantities such as directivity and near-zone quantities such as VSWR—are given.⁹ The MATLAB-code used to create Figure 59-2 is provided on the Internet (directions for obtaining all the computer programs used in here can be found at the end of the chapter). The computational cost of an FD-TD simulation can be large, especially if the grid is dense (a very large number of spatial points) and the signal is resonant. For a resonant signal, the ring-down time is very long and so the simulation must be run for many time steps. FD-TD, fortunately, is well-suited for parallelization, allowing the power of multiple processors to be brought to bear on a computationally intense problem. That is not to say that parallelization is trivial—domain decomposition and sharing of domain boundary information must be done well. However, it is somewhat more amenable to parallelization as compared to other methods (such as the FMM), which require very specialized parallelization skills.

Time Domain-Integral Equation (TD-IE) Method

The time domain-integral equation method solves integral equations directly in the time-domain. It contains the same essential elements of the FD-TD method (spatial discretization using basis function and some type of time stepping procedure). TD-IE was a topic of relatively early investigation (see the example of transient radiation by wire antennas¹²);

FIGURE 59-2 Snapshot of a plane wave striking a multilayer surface (Compliments of Mr. Steven Cossmann)

however, it suffered from stability issues that quite frankly are an issue of continuing concern. Recently, the CEM community has made substantial progress in both the flexibility of TD-IE methods and their stability. For example, surfaces are now represented using surface expansion functions rather than a porous collection of wires. The key to improving stability lies in the use of advanced expansion methods and representations in addition to very accurate calculation of integral quantities. Examples of recent innovations are given in the reference section.¹³⁻¹⁶ Note that most of the published work indicates that TD-IE methods were initially developed for scattering problems; however, they are being adapted for radiation and electromagnetic compatibility (EMC) applications.

Time Domain-Finite Element (TD-FE) Method

Another powerful time-domain CEM method is one that solves the partial differential equations (such as Eq. 59-2) using a finite element procedure rather than finite differences. Typically, these methods are referred to as the finite element-time domain (FE-TD) method. They are loosely related to the finite volume-time domain (FV-TD) method.¹⁷ The TD-FE method is undergoing continued development and is, in some ways, the most immature of CEM techniques described in this chapter. In 1997, a review paper¹⁸ discussed the state-of-the-art which has undergone considerable improvement since that time.¹⁹⁻²¹ One paper that is particularly interesting describes a hybrid method combining the best features of FD-TD, FE-TD, and TD-IE.¹⁹ The field quantities are functions of both time and space. Hence, the spatial field variation is represented by basis functions that have support only over limited portions of the geometry (typically only a few, adjacent finite elements). These are so-called subdomain basis functions. The temporal response is typically represented using temporal expansion functions. Both explicit and implicit methods have been proposed in the literature. Based on the power of the method—time-domain simulations with very flexible geometrical and material capabilities—and recent activity in the scientific literature, it can be expected that the TD-FE method will become an important, and possibly major, component in any complete CEM tool suite for antenna applications.

Additional Time-Domain Methods

Other widely used time-domain methods include implementation of the finite integration technique (FIT).²² This method, as briefly mentioned previously, implements solutions of the integral form of Maxwell's equations. FIT is widely used in designing the linear accelerator cavities; however, it is also finding increased use in antenna design. Undoubtedly there are more time-domain methods than those presented previously (for example, time-domain versions of the Uniform Theory of Diffraction²³). With apologies to the many contributions made around the world, this section focused on the most widely used and developed approaches.

59.3 FREQUENCY-DOMAIN METHODS

Two of the most frequently used frequency-domain methods are the Method of Moments and the Finite Element Method. In this section, each of these methods is presented in some detail although the interested reader should consult one of the many excellent textbooks on the subject. Other frequency-domain methods are introduced in a cursory manner at the end of this section.

Method of Moments (MoM)

Integral equations formulated and solved in the frequency-domain, colloquially referred to as the Method of Moments (MoM), is one of the most popular and widely used methods for antenna design and analysis. From the first major textbook on the subject,²⁴ the MoM method has been improved in terms of capability and fidelity since the 1960s. Other terms commonly used for these solution methods are integral equations and boundary element methods, among others.

A typical feature in the derivation and solution of such formulations involves the specification of an appropriate Green's function in the formulation of integral relations. These integral relations are then used to enforce appropriate boundary conditions resulting in an integral equation. The conversion of a continuous domain integral equation into a linear system of equations involves a discretization process, commonly known as the method of moments. One consequence of the use of a Green's function, with the resulting global communication between elements (also known as unknowns), is the resulting fully populated matrix. In general, the storage requirement of a MoM formulation scales as $O(N^2)$ where N is the number of degrees-of-freedom (unknowns). This can severely limit the scaling potential of a MoM-based computer program with increasing operating frequency or model complexity. For example, the storage requirement for a fully-populated matrix developed using a full three-dimensional current formulation, such as you might have for a volume integral equation, will scale to the sixth power! So, for a given physical problem, a doubling of the operating frequency will require eight times the number of unknowns and the matrix storage will be 64 times greater.

There is a plethora of excellent sources of information concerning integral, equation-based methods for simulating the performance of antennas. There are two recent books^{25–26} that are particularly useful for novice CEM users, because they were written to complement the commonly available MoM computer programs. Note that Davidson's text²⁵ has accompanying code (available from the text web site maintained by Cambridge University Press) including MATLAB scripts. In addition to these, popular antenna textbooks^{9,27–28} contain sections describing how the method of moments can be used to model specific types of antennas (typically wire antennas, though others are mentioned as well). For that reason, this section will only touch on the essentials for utilizing the MoM for antenna modeling, leaving the details for the interested reader who may choose to review these excellent textbooks and the references contained therein.

One of the most commonly used integral equations for antenna applications is the electric field integral equation (EFIE) given for metallic bodies as

$$jk_0 Z_0 \hat{n} \times \int_S \left[\mathbf{J}(\mathbf{r}') G_0(\mathbf{r}, \mathbf{r}') + \frac{1}{k_2} [\nabla'_s \cdot \mathbf{J}(\mathbf{r}')] \nabla G_0(\mathbf{r}, \mathbf{r}') \right] dS' = \hat{n} \times \mathbf{E}^{\text{inp}}(\mathbf{r}) \quad (59-10)$$

where the normal (\hat{n}) points out of a closed surface (if the surface is closed; otherwise, it points in consistent direction), $\mathbf{J}(\mathbf{r}')$ is a vector-valued unknown equivalent current, $G_0(\mathbf{r}, \mathbf{r}')$ is the free space three-dimensional Green's function while k_0 and Z_0 are the free space wave number and wave impedance, respectively. The excitation for the problem is provided by the impressed electric field, \mathbf{E}^{inp} . For an antenna, this is typically a local source such as a filamentary current, a voltage gap, or a magnetic frill current. Alternatively, it may be an impinging wave. In the former case, the antenna is operating in the transmitting mode, while for the latter case, it is operating in the receiving mode. Since most antennas are reciprocal devices, these two modes of operation are equivalent.

Solution of Eq. 59-10 exactly is not generally possible except for special cases that do not represent real-world antenna structures. Therefore a systematic approach for *numerically approximating* the solution is necessary. This is precisely what the method

of moments provides. Usually, subdomain bases (or expansion functions) are used to represent the unknown current via a collection of unknown coefficients and simple functions that are non-zero only over a portion of the computational domain (and subdomain). For example, the unknown current can be represented by

$$\mathbf{J}(\mathbf{r}') = \sum_{n=1}^N J_n \mathbf{w}_n(\mathbf{r}') \quad (59-11)$$

where the unknown, complex-valued coefficient is denoted as J_n while the generally real-valued, vector basis function is given as $\mathbf{w}_n(\mathbf{r}')$. When this is substituted into Eq. 59-10 and suitable testing (or enforcement of the boundary conditions) is performed, the resulting linear system

$$[Z_{nm}][J_n] = \{f_m\} \quad (59-12)$$

can be solved by some suitable method (LU decomposition, biconjugate gradient iterative solver, and so on). Note that in Eq. 59-12, the subscript n is associated with the expansion function in Eq. 59-11, while the subscript m is associated with the testing function. With these general comments in mind, it is instructive to look at two common antenna problems simulated using the MoM: wire and surface antennas.

Wire Antennas

Thin wire antennas represent the first major use of computational electromagnetics for antenna analysis and design, as well as one of the most prevalent uses even today. The widespread popularity of the Numerical Electromagnetics Code (NEC)—now in its fourth released version—is one of the reasons for widespread use. Although the basic NEC computer program is challenging to use, due to the fact that it was developed at a time when specification of an antenna using data cards was common, there are now commercial wrapper computer programs that offer a fully functional GUI and provide the input commands for NEC as its output. Examples of such front-end GUIs for NEC include: SuperNEC, MiniNEC, EZNEC, and NEC Basic, among others.

If one makes the assumption that the wire is very thin, i.e., the wire diameter is less than $\lambda_0/20$, then the following assumptions are reasonable: the surface current can be represented as a linear current and the current will only have an axial component (assume this is the z -component for convenience). This means that the thin-wire assumptions allows $\mathbf{J}(\mathbf{r}') \approx \hat{z}I(z')$. Under these conditions, the EFIE (Eq. 59-10) can be written as

$$jk_0 Z_0 \int_{-L/2}^{L/2} I(z') \left[1 + \frac{1}{k_0^2} \frac{\partial^2}{\partial^2 z} \right] G_w(z, z') dz' = E_z^{\text{inp}}(a, z) \quad (59-13)$$

where the thin-wire (a = radius) Green's function is given by

$$G_w(z - z') = \frac{e^{-jk_0 \sqrt{a^2 + (z - z')^2}}}{4\pi \sqrt{a^2 + (z - z')^2}} \quad (59-14)$$

Notice that the Green's function cannot become singular due to the approximations involved (this amounts to placing the testing points on the outer surface of the wire and the sources as filamentary currents along the axis of the wire). This particular integral equation is known as Pocklington's Integral Equation.

As an example of how a wire antenna simulation program can be used to design an antenna, a demonstration version of EZNEC (available at: www.eznec.com) was used to create the antenna pattern due to two monopoles, at approximately 300 MHz, shown in Figure 59-3. In Figure 59-3, the pattern is shown to be nearly a Cardioid pattern caused by choosing the excitation current phases and placement of the monopole radiators appropriately. The current is shown as a line with a vanishing value at the end of the monopole and a peak value at the feed (through the ground plane that is not shown but lies in the $z = 0$ plane) lying in the x - y plane as expected. In addition to currents and pattern, other engineering quantities such as the VSWR can be computed as shown for the same antenna in Figure 59-4.

Another NEC pre-processor and post-processor package is SuperNEC (<http://www.superneec.com>), which offers a 30-day demonstration copy for any user and a one-year free license for academic users. In both cases, models of up to 300 wire segments can be simulated. As an example, Figure 59-5 illustrates the currents for a Yagi-Uda antenna simulated at 300 MHz. As can be seen, the SuperNEC interface allows depiction of the current magnitude on the various wire elements. The co-polarized antenna pattern evaluated in the plane of the array (for example, the x - y plane) is shown in Figure 59-6.

Wires can also be used to simulate a surface by placing the wires sufficiently close to each other to make the wire mesh appear to be impenetrable in a manner reminiscent of a Faraday cage built using wire screens. This was a suitable and practical approach until the advent of a useful vector surface expansion function; the Rao-Wilton-Glisson (RWG) basis function was introduced in 1982.³

Surface Antennas

Many antenna structures can be represented using a surface integral equation formulation. Examples of these include: horn antennas, patch antennas, slot antennas, printed log-periodic antennas, printed spiral antennas, and Vivaldi slot antennas, among many others. Even wire antennas, especially thick wire antennas, can be modeled with a surface integral equation

FIGURE 59-3 Radiation pattern for a two-element monopole array along with current magnitude and geometry (Calculated using EZNEC, Roy Lewallen)

FIGURE 59-4 Standing wave ratio for the second element of a two element array (Calculated using EZNEC, Roy Lewallen)

formulation although it may be more efficient to utilize a wire formulation. Method of moments computer programs that utilize a surface integral equation differ in several ways; the most important are the Green's function used in the formulation and the basis functions used to represent the unknown quantity. For antennas in free space, the three-dimensional free space Green's function

$$G_0(\mathbf{r}, \mathbf{r}') = \frac{e^{-jk_0|\mathbf{r}-\mathbf{r}'|}}{4\pi|\mathbf{r}-\mathbf{r}'|} \quad (59-15)$$

FIGURE 59-5 Magnitude of the current on a Yagi-Uda antenna (Calculated using SuperNEC)

FIGURE 59-6 Co-polarized radiation pattern for a Yagi-Uda antenna (Calculated using SuperNEC)

is used. If the geometry includes a grounded material slab, then a Green's function that includes the ground plane and the material slab is generally used. In this case, the unknowns are restricted to the metallization on top of the material slab or embedded in the material slab. Hence, the order of the resulting linear system is relatively small; however, construction of the Green's function can be complex and computationally expensive unless series and/or integration acceleration techniques are used.

The RWG basis functions are probably the most widely used in the community. However, there are other surface functions that are used for particular reasons or applications. Typically a curved surface is approximated by a collection of flat facets (for example, RWG basis functions with support over flat triangles); however, in some applications, the curvature of the surface across an element is important. An example are surface elements with edge dimensions that are significant fractions of, or even larger than, a wavelength. Such elements are used to reduce the complexity of the meshing task by using higher-order expansion and surface geometry functions. Since the element dimensions are relatively large, it is important to explicitly include curvature in the element construction. This is usually accomplished by mapping a curved element to a flat element using a Jacobian.^{29–30} Note that with higher-order elements, the order of the resulting matrix is typically similar to the order of the matrix generated using low-order elements such as RWG; however, the definition of the surface can be simpler and more accurate with higher-order functions.

As an example of surface integral equation use, Makarov's book³¹ discusses the implementation of RWG basis functions and their use in solving surface antennas in free space (along with a treatment of dielectric loaded surface antennas such as patch antennas). The book comes with MATLAB scripts (these can also be found on-line at: <http://ece.wpi.edu/books/aemm/>). As an example of a complex antenna, consider the bow-tie antenna example in Chapter 8 of Makarov's book.³¹ Figure 59-7 illustrates the VSWR of that example and the current at 1 GHz. As can be seen, the antenna is relatively well matched across a wide bandwidth. The current plot indicates that the current density magnitude is greatest in the light shaded areas, for example, the antenna edges, while a dark shading indicates a region of lower current density.

FIGURE 59-7 VSWR for a bow-tie antenna simulated using MATLAB (inset: Current density at 1 GHz; light denotes a high current density.)

Other expansion elements used in practice are low-order vector basis functions that have support over a rectangular domain.²⁹ Although rectangular basis functions limit the geometrical complexity and flexibility that can be represented without approximation, under certain circumstances, an extremely efficient solver can be utilized that significantly reduces the computational cost (and thus the time to compute). For example, if the rectangular elements are identical across the computational domain, then the resulting matrix is Toeplitz. Such matrices can be solved extremely efficiently and the computational storage requirements are much less than the general case.

As an example, consider the simulation of a patch antenna using SonnetLite, the free version of Sonnet. This antenna is printed on 30 mil Rogers Duriod/5870 and is 40mm by 30mm in dimension. The antenna is fed using a probe feed (modeled in Sonnet using an autoground port) located 16.25 mm from the left side of the antenna and centered between the top and bottom of the antenna. The local field behavior of the antenna is given in Figure 59-8, including an inset figure illustrating the current supported by the patch metal near resonance. In this, a reasonably good match is achieved over a narrow bandwidth. Improved performance can no doubt be obtained with an iterative design procedure involving adjusting the feed location. For a two-element array comprised of identical patch antennas, the S-parameters are given in Figure 59-9 (the geometry is shown as an inset figure for reference).

Modeling three-dimensional antenna geometries with a surface formulation requires either a Green's function that represents the volumetric nature of the antenna or closed surfaces that enclose the antenna volume (for example, a dielectric resonator antenna). In the former case, the resulting formulation is limited in the types of antennas that can be efficiently simulated. For the latter case, the required number of unknowns can be very large, especially if there are a large number of material interfaces. In addition, in the latter case, very thin layers can lead to a numerically ill-conditioned problem since the surface currents on different interfaces are parallel and very close to each other. Because of this, it is sometimes useful to utilize a volume integral equation³² rather than a surface integral equation.

FIGURE 59-8 Performance of a single-patch antenna simulated using Sonnet (left: Smith chart, right: resistance and reactance spectrum, with inset figure illustrating resonant currents).

For example, the following integral equation³² can be used to represent dielectric materials with metallization

$$\begin{aligned} \mathbf{E}^i &= \mathbf{E} + [j\omega(\mathbf{A}_D + \mathbf{A}_M) + \nabla(\Phi_D + \Phi_M)] & \mathbf{r} \in V \\ \mathbf{E}_{\tan}^i &= [j\omega(\mathbf{A}_D + \mathbf{A}_M) + \nabla(\Phi_D + \Phi_M)]_{\tan} & \mathbf{r} \in S_M \end{aligned} \quad (59-16)$$

In Eq. 59-16, the volume of dielectric (V) and metal surface (S_M) are assumed to be in free space. The vector potentials (\mathbf{A}) and scalar potentials (Φ) are associated with the dielectric or metal and these are denoted by the subscript D or M , respectively. With this, the substrate need not be infinite in two dimensions and very thin dielectric layers can be simulated without unknown current surfaces that are too close. In addition, the substrate can be inhomogeneous. In contrast to most MoM implementations that utilize low-order expansion functions, higher-order functions are presented in the reference section.³³

FIGURE 59-9 S-parameters for a two-element array as computed using SonnetLite (the geometry is shown as an inset figure)

Higher-order functions can be used to more accurately represent a boundary and to reduce the meshing requirements. They do not always lead to fewer unknowns since there are more degrees-of-freedom per element associated with a higher-order function as compared to a low-order function.

Finite Element (FE) Method The finite element (FE) method provides one of the most powerful formulations for antenna modeling provided that the antenna has a dielectric load, particularly if the material load is inhomogeneous or anisotropic. The FE method can be used for antennas comprised of solely conducting material; however, in general the MoM is more efficient for such radiators. The finite element method is an approach for solving Maxwell's equation by solving the vector wave equation. For time-harmonic (also known as continuous wave or frequency domain) problems, Eq. 59-2 can be recast as

$$\begin{aligned}\nabla \times \mathbf{E} &= -j\omega\mu_r\mu_0\mathbf{H} \\ \nabla \times \mathbf{H} &= j\omega\epsilon_r\epsilon_0\mathbf{E} + \mathbf{J} \\ \nabla \cdot (\epsilon_r\mathbf{E}) &= \frac{\rho_e}{\epsilon_0} \\ \nabla \cdot (\mu_r\mathbf{H}) &= 0\end{aligned}\quad (59-17)$$

where the radial frequency $\omega = 2\pi f$ is related to the frequency (f) and the surrounding space may contain an anisotropic, inhomogeneous relative permittivity (ϵ_r) and/or an anisotropic, inhomogeneous relative permeability (μ_r). However, for simplicity, isotropic materials are assumed. In Eq. 59-17, the current density (\mathbf{J}) represents sources within the computational domain. This set of first-order partial differential equations (PDE) may be re-cast as a second-order PDE, known as the vector wave equation, by taking the curl of one or the other curl expressions in (59-17) and making use of the remaining expression for simplification. So, the vector wave equation is given by

$$\begin{aligned}\nabla \times \left[\frac{1}{\mu_r} \nabla \times \mathbf{E} \right] - k_0^2 \epsilon_r \mathbf{E} &= -jk_0 Z_0 \mathbf{J} \\ \nabla \times \left[\frac{1}{\epsilon_r} \nabla \times \mathbf{H} \right] - k_0^2 \mu_r \mathbf{H} &= \nabla \times \left[\frac{\mathbf{J}}{\epsilon_r} \right]\end{aligned}\quad (59-18)$$

where the upper equation is in terms of the total electric field while the lower equation is the case when the total magnetic field is needed. In Eq. 59-18, one of the equations or the other is used depending on which of the two fields, electric or magnetic, is being sought and which of the two is most amenable for enforcement of boundary conditions. Note that when solving Eq. 59-18 for the electric field, should the magnetic field be needed in post-processing, the appropriate equation from Eq. 59-17 may be used. It is impractical to enforce these equations at every point in space. This means that a so-called weak form of the vector wave equation is typically specified, either through minimization of a functional or by application of the Rayleigh-Ritz method. For the latter, one of the wave equations (in terms of the total electric field from now on, for convenience) is tested with a vector function. In this, the dot-product of the vector function is taken and the resulting scalar expression is integrated throughout the domain of the test function. As a result, Eq. 59-18 in the weak form is written after some manipulation (such as use of the First Vector Green's Theorem³⁴ to transfer a curl operator off of the unknown field onto the testing function, \mathbf{W}_i) as shown in

$$\int_V \left[\frac{\nabla \times \mathbf{W}_i \cdot \nabla \times \mathbf{E}}{\mu_r} - k_0^2 \epsilon_r \mathbf{W}_i \cdot \mathbf{E} \right] dV - jk_0 Z_0 \oint_S \mathbf{W}_i \cdot (\hat{n} \times \mathbf{H}) dS = -jk_0 Z_0 \int_V \mathbf{W}_i \cdot \mathbf{J} dV \quad (59-19)$$

where the subscript i refers to the testing function. Several observations can be made regarding this weak-form equation. In Eq. 59-19, the surface magnetic field will be provided either by a local condition or by an integral relation. In either case, the surface magnetic field is proportional to the surface electric field. It's a given for this expression that isotropic materials have been assumed, and the resulting matrix developed from Eq. 59-19 will be symmetric (since the electric field and testing functions may be interchanged without changing the form of the expression). In addition, the surface term in Eq. 59-19 allows the introduction of boundary conditions on $S = \partial V$. Through these boundary conditions, an external source may be included such as an impinging plane wave. A series of relatively easy-to-read papers for FEM beginners have been featured in the EM Programmer's Column of the IEEE Antennas and Propagation Magazine in recent years.³⁵⁻³⁶ The reader is encouraged to read such papers and their references for a greater understanding of the FE method.

Most implementations of the finite element method for electromagnetics primarily differ in the elements used to expand the unknown field (and usually the testing functions as well since these are similar) and the method to enforce the boundary conditions. The most popular elements for solution of the finite element equations are the brick, right prism, and tetrahedron. These are shown in Figure 59-10 with the brick on the left, the prism in the center, and the tetrahedron on the right.

By far the most popular, due to its flexibility, is the tetrahedron. Nevertheless, both the brick and right prism have their uses in that they are particularly easy to implement and, most importantly, rather easy to generate appropriate meshes for. Usually, the expansion functions are lowest mixed-order edge elements (for example, the field representation is constant for component of the field parallel to the edge and linear for the component of the field normal to the edge). However, higher-order expansion functions³⁷ and hierarchical functions³⁸ have been used by a number of researchers. The user will find that the major discriminator between finite element codes is not the element shape necessarily, nor even the order of the expansion; rather, it is the inclusion of a powerful mesh generator. It is not an understatement to say that a large portion, and sometimes the majority, of effort expended by antenna engineers in using a finite element code is in mesh generation rather than data collection.

The second major discriminator is the mesh termination condition. The following three methods are most popular:

- Absorbing boundary conditions³⁹
- Perfectly matched layers⁴⁰
- A boundary integral⁴¹

The first method, absorbing boundary conditions (ABCs), is widely used since it is particularly easy to implement without having to use user-defined parameters that

FIGURE 59-10 Typical finite element shapes: brick (left), right prism (center), and tetrahedron (right)

impact performance. The cost of using these ABCs is usually a larger computational domain since the mesh boundary must be maintained some distance from the structure being implemented. The distance required is dependent on the particular ABC and on the problem. In general, antenna simulations require a larger stand-off distance than scattering problems due to the need for accurate near-field quantities such as driving-point impedance. Perfectly matched layers (PMLs) are another local (or in other words, dependent only on field behavior in the vicinity of the PML) mesh truncation technique that generally requires less stand-off distance than ABCs. However, there are user-defined (or at least programmer-defined) parameters and typically, the condition number of the resulting matrix is poorer as compared to the ABC. The final method, a boundary integral (BI), is a global rather than local condition. It requires no stand-off distance; however, the resulting matrix is partially full due to the BI, and as a result, the demand for memory and solution time can be quite high. In addition, other aspects of the method formulation and implementation can impact solution performance. For example, the use of adaptive meshing⁴² is a common feature in commercial programs these days that largely reduces the need for specialized meshing expertise so that the essential field behavior is captured.

As an example of how the finite element method can be used for antenna analysis and design, consider a 40mm by 30mm cavity-backed antenna placed in a cavity that is 80 mm by 60 mm. The cavity is filled with 30 mil thick Rogers Duriod/5870. This particular antenna will be analyzed using the computer program provided on the author's web page (to obtain a copy of the source code, see the URL cited in the next section). This program utilizes right prism elements⁴³ and is written in MATLAB with a functional graphical user interface (GUI). The program is initiated in MATLAB by running the msGUI.m script. The cavity is divided into 32×24 cells that are then subdivided into triangles. The program then extrudes these triangles into right prism elements. Since the substrate is electrically thin, one layer of elements is sufficient to resolve the field behavior along the normal direction. The surface mesh, Smith Chart, and normalized electric field within the cavity are shown in Figure 59-11.

The fields shown are the normal component of the electric field. The patch antenna is excited using a probe-feed from the base of the cavity to the patch slightly left of the antenna center along the top-to-bottom centerline. This method of feeding excites the fundamental mode for this antenna. Notice that the normal fields are zero along the centerline of the antenna while those fields are a peak near the edges of the patch. This field distribution can be represented using a cosine function. The phase of the field distribution left of the centerline as compared to right of the centerline is 180 degrees out-of-phase resulting in radiation.

This particular example does not utilize the most significant feature of a finite element formulation: the ability to model inhomogeneous antenna loading materials. Simulation of grounded, homogeneous dielectrically-loaded antennas is most efficiently analyzed using an integral equation method (see the previous example using Sonnet). However, if the antenna has inhomogeneous (or anisotropic) materials in its construction, the finite element method is often the most efficient and accurate method to use for simulating resonant structures

FIGURE 59-11 Surface mesh (left), Smith chart (center), and normal field distribution (right) for a cavity-backed patch antenna simulated using the FE-BI method

(for example, the class of antennas that is best simulated using a frequency-domain solver). This is also true for the case of cavity-backed antennas, when the cavity is odd-shaped regardless of the cavity-fill material.

One comment is in order concerning simulation of realistic antennas in the MATLAB environment. Unless considerable effort is undertaken to vectorize (express the mathematical manipulations in terms of data vectors and matrices), parallelize, or compile as executable code, MATLAB is not an efficient platform for computing *large* problems. The definition of large is in the “eye of the beholder,” in the sense that for a given algorithm and the time a user is willing to wait for an answer, the computational size that constitutes a large problem varies. Nevertheless, for understanding the underlying concepts of various computational methods, it is an effective platform for discovery. It is particularly useful for students due to their general familiarity with MATLAB.

Other Frequency-Domain Methods

The method of moments and finite element methods are arguably the most prevalent frequency-domain CEM solvers in use today. Nevertheless, there are excellent alternative methods that have very specific advantages in certain circumstances and other methods that are growing in popularity and impact. One of the most effective means for computing the radiation by antennas in the presence of very large structures involves the use of high frequency (asymptotic) approximations such as the Uniform Theory of Diffraction (UTD). This method was extensively investigated by various research groups around the world during the 1970s and beyond, most notably by the group at The Ohio State University, along with their colleagues from around the world who spent time at the ElectroScience Laboratory as students, post-doctoral researchers, and as visiting scientists.^{44–45}

Another method of considerable note is the finite integration technique (FIT) mentioned earlier (in its time-domain incarnation). FIT is formulated using the integral form of Maxwell’s equations, either in the time- or frequency-domains. FIT can also be used in conjunction with a high frequency method such as UTD.⁴⁶ The method of lines is another method for simulating electromagnetic phenomena and it has been used to simulate conformal antennas.⁴⁷ A good reference for various conformal antenna formulations is provided by a recent text.⁴⁸

Another approximate technique for simulation of antennas installed in a large structure involves the use of reciprocity.⁴⁹ In this situation, the antenna radiating currents are computed and then integrated with the currents due to the structure resulting in the radiation pattern of the antenna in the presence of the structure. Although the paper is used for circular cylindrical structures, it can be used for more general shapes. These hybrid formulations are very powerful, and at the dawn of the 21st century, the only practical method for solving installed antenna design problems when the structure is electrically very large. It is probable that through advances in computer technology and in full-wave solution methods (for example, fast multipole methods among others) asymptotic methods will be needed less and less. Having said that, if history teaches us anything, design problems will become more complex and larger over time and thus, asymptotic and hybrid methods may be needed long into the future.

59.4 SUMMARY OF PUBLIC DOMAIN AND COMMERCIAL CODES: CAVEAT EMPTOR

Computational electromagnetics has undergone a typical evolution during the past half century: What was merely a research topic in the 1960s through the 1980s is now a thriving industry. Accordingly, many CEM tools are available for antenna design. Some of these

are in the public domain (some even provide the source code so that users can modify the program for their own needs), while others are commercial offerings. As the section title indicates, the user (or buyer) must beware in assuming a particular program will solve their problem, or even be correct, either in formation, assumption, or coding. In general, free programs have absolutely no guarantee as to their accuracy while commercial codes are generally easier to use and typically have technical professionals (such as application engineers) to help adopters generate solutions. One prevailing dictum of CEM users should be: “*Purgamentum init, exit purgamentum*”! Inexperienced users of any CEM computer program are cautioned to validate both the program and their use of the program by comparing their simulation with reference data. It is better to compare a user-generated case rather than running examples provided by the program developers since in that manner, the user will not only be testing the program, but their interpretation of how to give instructions to the program. By all means, initial users should explore the examples that are now standard for CEM codes; but at some point, users must try their own hand at developing a model before they try to solve the design challenge that originally prompted their need (or at least desire) for the CEM code. A brief listing of public domain and commercial codes is given next. In no manner does this constitute a comprehensive list and over the lifetime of this handbook, it can be expected that Internet links will be broken and that companies will no longer offer these codes. Hence, “Let the buyer beware!!!”

Disclaimer: *This section is not meant in any way to be an endorsement of any methods, computer programs, or company's offerings. It is merely meant to be an information source for antenna designers interested in using powerful CEM design tools. This is not a comprehensive list by any means and any omissions in the interest of brevity are regrettable, but not intentional.*

Public Domain Codes

Many computer programs are offered free-of-charge by the developers, in the interest of promoting the adoption of the technology or as a means of technology transfer. This was particularly true in the early days of CEM; it is less so in the 21st century as the intellectual property value of such codes is better understood. Nevertheless, very powerful computer programs may be downloaded, and in most cases, modified by the user since source code is available. Codes may be downloaded from

- **www.egr.msu.edu/~kempel/HandbookCodes** This is where you can find the MATLAB scripts used in this chapter. The FD-TD code is provided by Mr. Steven Cossmann and the FE-BI code by Mr. Lanwu Zhao (developed with partial support from the National Science Foundation under grant DUE-0231312).
- **<http://www.emclab.umn.edu/codes.html>** The University of Missouri at Rolla (UMR) maintains an excellent listing of public domain codes available on the Internet. The reader is encouraged to investigate this site when looking for a free program, especially the finite element code—EMAP—developed by the students and faculty at UMR.

Antenna Textbooks with Codes

Many antenna textbooks now come with accompanying computer programs to aid the student and engineer. Sometimes these codes come with a CD-ROM disk, while in some cases a related web site is provided for users to download code. This latter method has the distinct advantage in that program updates may be provided in a convenient manner.

Unfortunately, it has the disadvantage in that the site must be maintained and in practice, links to that web site may break over time. Nevertheless, the software provided with modern antenna textbooks is very useful for users, both to learn how antennas function and to provide validation data in the context of accurate CEM codes. Some texts have been discussed previously; however, for the convenience of the reader, they are repeated in the following list. Note that there are undoubtedly many more antenna textbooks with complementary computer programs; brevity necessitates an unfortunately incomplete list:

- David Davidson from the University of Stellenbosch in South Africa has written a textbook²⁵ describing various CEM techniques. A major application of that program is antenna design and performance analysis. Software for the text is provided via a resources web site maintained by Cambridge University Press (<http://www.cambridge.org>). Both MATLAB scripts and FEKO files are provided that support the material in the book. Note that Appendix F lists additional resources found on the Internet.
- Sergey Makarov of Worcester Polytechnic Institute wrote a textbook²⁶ that describes the modeling of various antenna geometries (such as patches, slots, inverted-F, and so on) using the method of moments. A new web site (<http://ece.wpi.edu/mom>) compared to the one cited earlier in the chapter provides MATLAB scripts and a user manual for using the scripts or for modifying them as needed for a different type of antenna. A companion paper illustrates some of the capability of this design tool.³² This package was developed with partial support from the National Science Foundation under grant DUE-0231312.
- John D. Kraus and Ron Marhefka from Ohio State University, in the third edition of their popular antenna textbook,²⁷ provided a web site for several antenna design computer programs (<http://www.antennas3.com>). These accurate and efficient programs are useful for understanding antenna function as well as providing a method for validation.
- Constantine Balanis from Arizona State University, in the third edition of his well-regarded antenna textbook,²⁸ provides various antenna modeling codes in both MATLAB and Fortran (from the second edition) via a CD-ROM. The scripts provided are especially useful for students and for antenna design engineers interested in validating a CEM tool.
- Atef Elsherbeni and Matthew Inman from the University of Mississippi have developed a textbook⁵⁰ that tightly integrates visualization of antenna properties (such as pattern impedance, and so on). Along with the book, the authors have developed software (www.adv-program.com) that implements standard formula for various wire-type antennas (such as dipoles, helices, and monopoles) in both single element and array configurations. The program has a GUI and can provide reference data for other programs that implement CEM techniques.

Commercial Codes

Commercial computer programs are not only powerful, but also designed to be easy-to-use. That last term is something that is in the “eye-of-the-beholder.” What software designers consider easy-to-use and dummy-proof often does not correspond to the expectations of the user. Nevertheless, commercial CEM codes are typically better designed from the user point-of-view than public domain codes. They typically have a Graphical User Interface (GUI) and application engineers that can (for a fee) help users obtain the best possible calculations for a given problem. During the 1990s and 2000s, the number and diversity of commercial CEM offerings have expanded greatly. The following list describes some of the most popular commercial CEM codes. No doubt during the lifetime of this edition, the offerings will change considerably:

- **www.ansoft.com** The Ansoft Corporation offers a variety of CEM solutions for antenna design, electromagnetic compatibility, and other applications. The computer codes offered by Ansoft utilize the finite element method, the method of moments, and circuit simulators. These computer programs are some of the most powerful in the industry and are widely used.
- **www.cst.com** Computer Simulation Technology offers widely used CEM tools based on the finite integration technique (FIT) and the method of moments. Both time-domain and frequency-domain solvers are available.
- **www.emssuusa.com** Electromagnetic Software and Systems offers a hybrid method of moments, finite element, and high frequency (uniform theory of diffraction) computer code (also known as FEKO). This tool is widely used for antenna design and for EMC analysis in the automobile industry.
- **www.remcom.com** Remcom offers a finite difference-time domain method computer program that can be used for antenna design, scattering analysis, and specific absorption rate (SAR) calculations, among other uses. It comes with a well-developed GUI and support for distributed parallel computers (for example, clusters).
- **www.sonnetusa.com** Sonnet Software offers a suite of full-wave electromagnetic design tools based on a frequency-domain method of moments for planar geometries. It provides a powerful GUI and allows for separation between the design workstation and the computational workstation. A free reduced-capability version is available for download.
- **www.wipl-d.com** WIPL-D is a powerful antenna design program capable of modeling antennas (and other structures) comprised of both metal and dielectric materials. WIPL-D is becoming increasingly popular amongst antenna engineers due to its flexibility and accurate solutions.
- **www.comsol.com** Comsol Software is based in Sweden with offices worldwide. Their main product is FEMLAB, a finite element-based simulation tool. Their claim to fame is the ability to include multiple physical and chemical models in the simulation. Thus, simultaneous simulation of both thermal and electromagnetic properties is facilitated by FEMLAB. It has a powerful mesh generator and various pre- and post-processing capabilities.
- **www.zealand.com** Zealand offers the popular integral equation-based solver, IE3D. This program is widely used for simulating planar, microstrip structures such as patch antennas with feed networks.

59.5 SOURCES FOR PARALLEL PROGRAMMING INFORMATION

Computer architectures have undergone considerable, and truly impressive, changes over the past 30 years. In the 1970s, computers for engineering design were primarily housed in centralized computing centers and used in a time-share manner (often with punch cards as the input method of choice). In the 1980s, with the advent of the personal computer, it became possible to put a computer on the desk of every engineer. This led to more detailed antenna designs, especially when the Numerical Electromagnetic Code (NEC) was released by Lawrence Livermore National Laboratory. In the 1990s, the widespread use of powerful engineering workstations led to increasing use of powerful computational electromagnetics tools in antenna design. During that decade, the workstation and personal computer merged (or more accurately, the personal computer became a workstation)

leading to even more widespread use of CEM codes. Simultaneously, during the latter 1980s and early 1990s, vector-based computing became available through CRAY Computers, leading to changes in computational algorithms that specifically made use of vector processors. Once the practical limit of vector processors have been reached (in terms of computations per second versus cost), the next major change in computation involved the use of many processing units simultaneously. These parallel processing computers offered the promise of nearly unlimited computational power as more and more “brains” were brought to bear on a problem. In reality, the community quickly learned that parallel programming is not trivial and that very real limits exist on the scalability of many CEM approaches. Nevertheless, for those fortunate souls with access to massively parallel computers, these new architectures offered unprecedented computing power.

Parallel computers traditionally are symmetric multiprocessing (SMP) or shared memory architectures. That means that each processor has access to all of the memory in the system. SMP machines are particularly easy to program since the processors and memory are tightly connected together. However, large SMP machines are highly-engineered and therefore rather expensive. Therefore, a popular parallel computer architecture available in the late 1990s and early 21st century is the so-called Beowulf cluster. These computers are made from a number (sometimes a large number) of commodity compute nodes connected together with some network fabric. The original network fabrics were 10 or 100 MHz Ethernet connections (identical to those used to form a local area network). Currently, the most commonly used network fabric is a Gigabit Ethernet fabric. It is becoming increasingly common to have higher speed (or lower latency) fabrics such as Myranet or Infiniband as the acquisition cost of these technologies is reduced. Clusters are distributed memory architectures that often have a lower acquisition cost as compared to a comparable number of processors in an SMP system. However, the programming requirements for a distributed cluster are often more significant than for an SMP system.

Recently, SMP machines are seeing a renaissance through the introduction of multiple core processors. Traditionally, each processor had a single compute core. Moore’s Law dictated a doubling of transistors every 18 months and as a result of this, it dictated an increase in computing power. However, it became evident as the industry entered into the 21st century that such an expectation could not be sustained indefinitely. One way to increase computing performance was to fabricate two (or dual) cores on each processor. This way every single processor computer became an SMP while traditional thin (minimal capability) nodes for a cluster went from having two processors (a so-called 2-way node) to four cores (a so-called 4-way node). Most laptop computers offered for sale in 2006 now have dual-cores and so are properly SMP computers. Realistically, with only two cores, efficient parallel programming is not practical due to overhead requirements. Nevertheless, the trend is clear. SMP computing is here to stay and will become ubiquitous. Indeed, processors with four cores (e.g., quad-core) were released at the end of 2006 to original equipment manufacturers (OEMs) and to the public. This means that computers will become 4-way SMP machines while thin cluster nodes will become 8-way SMP nodes.

It is therefore important for CEM code developers to become skilled at utilizing the dominant parallelization paradigms. It is also important for consumers of either public domain or commercial CEM codes to understand the difference between the two types of parallel architectures (SMP vs. distributed cluster) and the parallelization techniques used by those computer programs. The two dominant parallel programming models in use today are OpenMP and MPI. These two protocols are used to instruct the parallel computer on how to distribute the workload when more than one thread (akin to a core or processor) is being used simultaneously to solve a particular computational challenge. Each of these application programming interfaces (API) will be discussed, briefly, in turn. Finally, some brief comments on the use of the MATLAB distributed toolbox will be made along with the program environment, STAR-P.

OpenMP

OpenMP is perhaps the simplest way to parallelize a program for use on an SMP computer. Recall that an SMP computer has a number of threads within a single image (essentially, within a single node). The other major paradigm for parallelization of a program is Message Passing Interface (MPI). In MPI, the sending and receiving of data between nodes must be explicitly stated, as it is much more complex to implement than OpenMP. However, MPI can be used effectively on a cluster system while OpenMP cannot. With the emergence of quad-core processors, a four-processor computer has 16 cores and is in reality a 16-way system. This is could be the optimal computer for CEM codes utilizing a matrix solver.

There are a large number of OpenMP tutorials on the Internet⁵¹⁻⁵³ and textbooks including material on OpenMP.⁵⁴⁻⁵⁶ The examples in these texts are often in C (or C++); however, for those who still prefer Fortran, there are a large number of code examples in Fortran 77 and Fortran 90. These are the predominant languages used for scientific and engineering computing.

Parallelization of a program, at the most basic level, requires only a few commands describing how to partition the work amongst a number of threads for loop iteration. The beginning of a parallel region must be declared as does the end of that parallel region. Within the parallel region, loops that the programmer wishes to parallelize are identified individually along with some descriptions on how to parallelize the loop. Data within a parallel region is either “shared” or “private” with the assumed state varying between implementations of OpenMP. Shared data is available to all threads while private data is individual to a given thread. It is important to understand how the data is identified, especially when reduction of data strings occurs (for example, addition of data vectors from various threads into a single data vector in the master thread).

In general, users of OpenMP parallelized computer programs need to do little to nothing if the program is written in a user-friendly manner. One environment variable that may need to be set is the number of available threads. In OpenMP, the command varies a bit based on the operating system and, for either Unix or Linux, the shell being used. For example, in the Linux bash shell, the command `export OMP_NUM_THREADS=#` where “#” is the number of threads is used. Programs then utilize that environment variable information during execution. Typically this number should be set less than or equal to the number of available cores.

It is generally best to have a parallel region as large as possible to minimize overhead and to provide for the best synchronization of the program threads. This is due to the fact that there is an implied barrier as the end of parallel region is reached. What this means is that when an end of the parallel region is reached, all threads are synchronized. This means that the slowest thread to be executed defines when the program execution outside the parallel region can commence. Load balancing then becomes an important consideration for how well the program executes on a parallel machine. In a similar light, use of the parallel region construct will generally be favored over loop-level parallelization; however, it comes with the cost of greater programming complexity (to ensure that all the code in the parallel region is compatible with parallel execution).

MPI

Message Passing Interface (MPI) is the second predominant parallelization paradigm in use at the dawn of the 21st century. It has the distinct advantage (compared to OpenMP) of being useful on *distributed memory* computers, commonly referred to as clusters. MPI requires considerably more investment by the programmer in terms of effort, since with MPI the programmer must tell the program how to share information between nodes

(these details are hidden from the user with OpenMP). For example, if a matrix-vector product is to be parallelized using MPI, the data for a given worker must be sent by the master (including the type of data and number of entries) where the master identifies which worker will receive the data. Likewise, the worker must explicitly receive the data (knowing the format, data type, and so on), do the work needed, and then send the resulting data back to the master. In this case, the master must receive the data knowing which worker sent a particular set of data.

MPI is very powerful in that it can be used on both SMP and cluster computers. In general, the performance of a parallel program using MPI is greater than that of OpenMP, especially in terms of scalability. Loosely speaking, scalability indicates the number of threads that can be efficiently used. Many CEM algorithms by their nature do not scale beyond 8-16 threads except for some hardware implementations (for example, the differences in memory access methods, interconnects, and so on, will impact scalability). One reason for this is the large amount of memory required for the method as compared to the relatively narrow data pipes between the compute cores and the main memory. Note that FD-TD is the CEM method that is well-known to scale beyond 16 threads with even moderate levels of parallelization skill. There are many textbooks that discuss MPI programming.^{55,57-58}

For the user, the level of effort for running (rather than parallelizing) a program is not excessive; however, it is greater than what is needed for OpenMP. Minimally, the program must be compiled and linked with a particular implementation of the MPI libraries. These libraries are specific to the MPI implementation and to the interconnect fabric. Hence, a program linked to the MPI library for Myranet will not operate properly on a cluster that uses Infiniband. To run a program that has been parallelized with MPI, rather than running the executable code directly as one does with most Unix/Linux programs, the user must invoke the MPI execution wrapper. For example, to run the program foo, many MPI implementations require the following command for execution: `mpirun foo`. The user needs to consult the relevant documentation for both the cluster and the program in order to determine all the necessary environment variables and execution scripts.

MATLAB and STAR-P

In addition to traditional high-level languages, such as C, C++, and Fortran 90, a new type of parallel environment is being distributed and continuously improved. MATLAB, as stated previously in this chapter, is widely used in the engineering community. MATLAB offers a Distributed Computing Toolbox (see <http://www.mathworks.com>) that simplifies the implementation of MATLAB scripts for parallel execution on cluster computers. The user should be cautioned that placing this toolbox on a cluster system is not as straightforward as serial toolboxes since the distributed toolbox operation must be compatible with the scheduler and operating system implementation. Note that if the program is not compiled, execution of large problems will not usually be very efficient due to the interpretive nature of the MATLAB programming environment.

STAR-P is another recent product that simplifies the development and utilization of parallel programs on distributed computers. STAR-P is used in conjunction with interactive desktop tools, such as MATLAB. It acts as a bridge between MATLAB scripts and a cluster (or SMP) computer. So, its function is related to the Distributed Computing Toolbox offered by MathWorks. More information concerning STAR-P can be found at: <http://www.interactivsupercomputing.com>. The particular solution for any given application and user is dependent on the cluster system implementation. Nevertheless, it is prudent to test particular applications with the various options such as the Distributed Computing Toolbox, STAR-P, or other computing environments before promising results to customers!
